Institute for Solid State Physics, University of Tokyo

(Received October 3, 1958)

A variable energy 16″ Cyclotron was constructed to produce 1∼2 Mev deuterons and 2∼4 Mev α-particles by new designs in its magnet and oscillator system.

As far, deuterons in the energy range from 1.3 to 2 Mev and α-particles in the range from 3 to 4 Mev are used for (d, p), (α, p) reactions, coulomb excitations etc.

Although the variation of accelerating energy for a cyclotron is a considerably difficult problem, we found that it is possible, by some adjustments of the acceleration parameters of the cyclotron, to produce deuterons and α-particles over the sufficiently wide range of energy within a minute.

The cyclotron will be used for producing 2∼4 Mev protons by changing a part of the resonator.

§ 1. Introduction

The 16″ cyclotron of the Institute for the Solid State Physics, University of Tokyo, was designed to produce 1∼2 Mev deuterons and 2∼4 Mev α-particles, and to produce 2∼4 Mev protons by changing a part of the resonator.

The construction was begun in 1953 as a project of the Comittee for Nuclear Research of the Institute of Science and Technology, and the initial testing was done in June 1955. In summer 1956, when the construction of all the beam handling system was finished, analysed deuterons were obtained at the reaction chamber.

Since September 1956, deuterons in the energy range from 1.3 to 2 Mev and α-particles in the range from 3 to 4 Mev have been accelerated and used for (d, p)[1] (α, p) reactions, Coulomb excitations etc. 2∼3 Mev protons were detected with an inner probe, but not yet used for any nuclear research.

The key point of a variable energy cyclotron is in the designs of its magnet and variable frequency oscillator. The magnet of this cyclotron is so constructed that the magnetic field distribution does not change significantly by increasing the magnetic field strength.

The B-constant type of a magnet[2] was adopted to minimize the change of the magnetic field distribution, the cause of the change being believed to be in the local saturations of iron in the core.

The oscillator has a specially designed variable frequency resonator having a branch near the dee, to which a variable capacitor of coaxial type is connected in deuteron operation, and a coaxial tube with an adjustable shorting bar is connected in proton operation in order to change the frequency continuously.

The main part of the cyclotron is shown in Fig. 1.

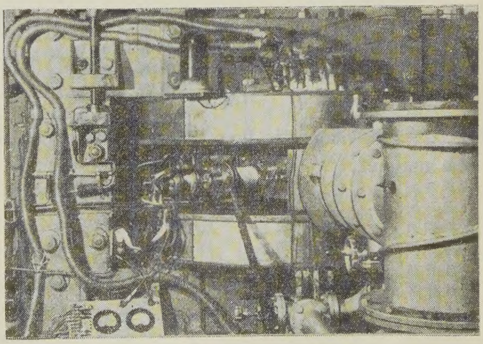

Fig. 1. Main part of the Cyclotron.

§ 2. Components of the Cyclotron

A. *Magnet*

For a variable energy cyclotron, the magnet should be designed to maintain the required field distributions for a wide range of the magnetic field strength. It is believed that the change of field distribution with the exciting current comes from local saturations of

---

* Now at Institute for Nuclear Study, University of Tokyo.

M 55'' 63/20 new

iron in the iron core, especially in the pole pieces. To maintain the constancy of the field distribution, it is desirable to minimize the local saturations. Ideally, if a magnet were so constructed that the density of magnetic flux is constant in all the core, the local saturation should not have any place until the magnetic field strength at the gap reaches to the saturation value of iron.

The magnet of this cyclotron is constructed of 7 tons of iron. The radius of the pole faces are 18.25 cm and the gap distance is 5 cm. Fig. 2 shows that, from the pole to the yoke, the cross section increases from 1 to 2.4 times of that of the pole face and the magnetic flux density is almost constant in all sections. The excitation curve of the magnetic field is shown in Fig. 3.

The radial and azimuthal variations of the magnetic field were measured by means of a coil mounted on an arm pivoted at the center of the magnet. The integrated electromotive force generated by the coil was plotted by a recording fluxmeter[3]. The radial magnetic field distributions at the excitation from 12,180 gauss to 20,050 gauss are shown in Fig. 4. Below 14,000 gauss, the effect of a Rose shim at the edge of the pole pieces becomes too large, then a lower limitation of acceleration energy with the present Rose shim will

be set at this point.

The azimuthal variations at the 18,000 gauss excitation are shown in Fig. 5. for some radii. The slight variation comes from the effect of six bolts connecting the pole pieces to the yoke. The amplitude of the variation is less than 0.02%.

The magnet current is controlled by a DC amplifier and an amplidyne generator, which supplies the exciting current of the main motor generator set. The current is stabilized within one part in 1,000.

B. *Oscillator*

This cyclotron has a remarkable design in the frequency variable resonator. The new design of the oscillator must allow for adjustment of the frequency continuously over the range from 10 to 14 Mc for the acceleration of 1～2 Mev deuterons, and from 20 to 28 Mc for 2～4 Mev protons. As illustrated in Fig. 6, this resonator has a branch near the dee, on which either a variable capacitor of coaxial type (See Fig. 7) or a coaxial tube with an adjustable shorting bar is connected according to the kind of accelerated particles.

The main part of the resonator consists of 4″ and 10″ copper tubes and the capacitor consists of five coaxially connected copper tubes, the maximum diameter of which is 8″. The coaxial tube with an adjustable

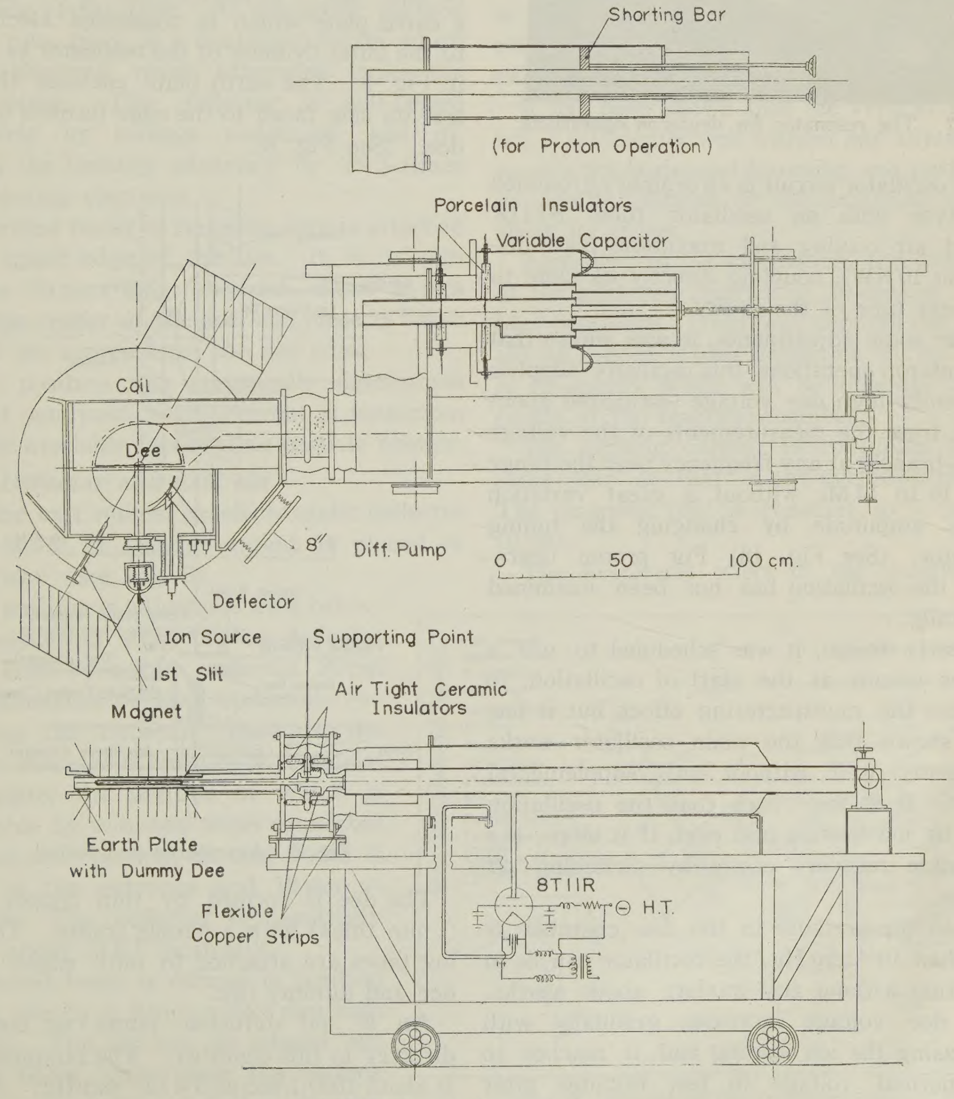

Fig. 6. Oscillator System

shorting bar consists of also 4″ and 10″ copper tubes.

Airtight ceramic insulators are used for supporting dee stem and for placing the main part of the resonator out of vacuum, hence adjustments of frequency and exchanges of resonator are very easily performed. Dee position is freely adjustable by moving the inner tube at the shorting point.

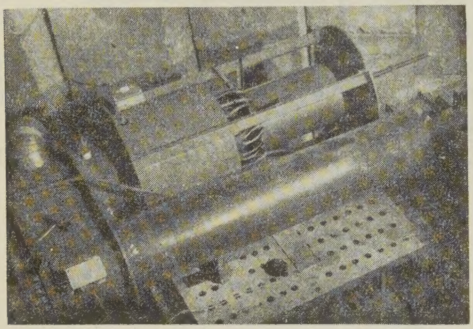

Fig. 7. The resonator for deuteron operations.

The oscillator circuit is an ordinary grounded grid type with an oscillator tube, 8T11R (forced air cooling and maximum plate dissipation 10 KW), coupling directly its plate to the inner tube of the cavity.

After some adjustments, it was shown that for deuteron operations, this oscillator supplies sufficiently high dee voltage (estimated about 20 KV from the measurements of the voltage at the branch) at any frequency over the range from 10 to 14 Mc without a great variation in its amplitude by changing the tuning capacitor. (See Fig. 18) For proton operations, the oscillation has not been examined in details.

In early design, it was scheduled to use a booster circuit at the start of oscillation, to suppress the multipactering effect but it has been shown that the main oscillator works sufficiently well without any supplemental circuit. It is very rare that the oscillation stops by ion loading and even if it stops, the oscillation recovers easily by switching off and on.

When the pressure in the dee chamber is less than 10^{-4} mm Hg, the oscillator can be in operation without any anxiety about sparks. The dee voltage increases gradually with decreasing the ion loading and it reaches to the normal voltage in few minutes after switching on.

Some troubles were encountered, in which a break down of the airtight ceramic insulator by over heating due to $R-F$ loss. A forced air cooling of the airtight ceramic insulators is adopted.

The input power of the oscillator is less than 10 KW at the maximum operation. And the oscillator plate voltage is supplied with a forced air cooled 3 phase selenium rectifiers delivering 10,000 volts at 1 ampere.

C. *Dee chamber and vacuum system*

The dee chamber is made of non magnetic stainless steel of 1.2 cm thick. The pole tips of the magnet take a role of a part of the chamber, and vacuum is held by ring gaskets between the pole pieces and the chamber. A half space of the chamber is occupied by a earth plate which is connected electrically to the outer cylinder of the resonator as shown in Fig. 6. The earth plate encloses the dee and its side faced to the edge forms a dummy dee. (See Fig. 8).

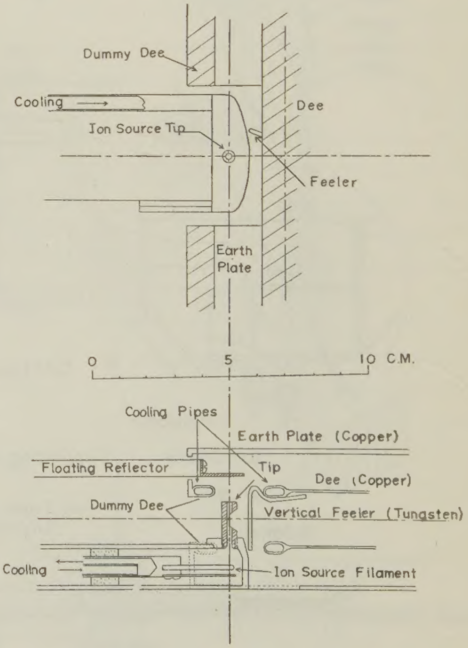

Fig. 8. Ion source and feeler.

The dee is formed by thin copper plates (1 mm thick) with a simple frame. The cooling pipes are attached to only edges of the dee and dummy dee.

An 8″ oil diffusion pump is connected directry to this chamber. The pumping speed is about 1000 l/sec at 5×10^{-6} mmHg. Another diffusion pump of 6″ is also connected at the beam duct as shown in Fig. 9. Because the vacuum system has a sufficiently large capacity in speed, it is possible to start the operation within an hour after switching on of the diffusion pumps, and about 20 minutes after repair of the ion source filament, for this procedure the air is let into the whole chamber.

D. *Ion source and feeler*

As illustrated in Fig. 8, the ion source is a standard type with a d.c. filament (1.5 mm dia. hair pin type)[4].

A conventional low voltage arc discharge takes place in a 5 mm outer dia., 2.2 mm inner dia. and 16 mm long tungsten-copper tube.

Ions are extracted through a 4 mm long cut open side of the tube. At the upper position of the tube there is a floating reflector which reflect electrons which otherwise strike the earth plate. This reflector is self-biased negatively by leakage resistance, and increases the ionising efficiency by 2∼3 times by reflecting electrons.

A vertical feeler of tungsten wire is attached to the upper edge of the dee. It is 1.5 mm dia. by 20 mm long, deviates about 10 mm from the center of the dee, and projects 5 mm toward ion source from the dee edge.

This position was empirically determined so that analysed beam current is maximum over the available accelerating particle energy.

E. *Deflector and exit slit*

At the exit radius, an electrostatic deflector which is 70° in angular extent is placed in clockwise. (See Fig. 5).

The position is adjustable by a below. The supporting stem of the deflector is insulated by a 7 cm outer dia. 20 cm long cylindrical ceramic insulator.

Facing the deflector, there is the septum made of 0.3 mm thick molybdenum plate, the position of which is adjustable by two steel wires connected with belows. Normal channel width is 3 mm at the entrance and 12 mm at the exit. The deflector is negatively biased about 30 KV normally.

Deflected beam is defined in position and in size by a 2 mm wide 3 mm high exit slit. The slit can be placed out of the beam path when the isotope productions or the radiation damage experiments are performed.

§ 3. Beam handling System

A. *Beam analyser*

The extracted beam from a cyclotron has, in general, an energy width of few percent. This width is too large to use the beam for nuclear research, and an energy selecting system should be added as a part of cyclotron.

The geometrical arrangement of the system is shown in Fig. 9. The analysing magnet is a double focussing type[5].

The particles extracted through the exit slit are deflected 45° by the analysing magnet placed at a distance of 1.5 m from the exit slit, and focussed at the center of the reaction chamber through a 5 mmϕ second slit which is placed at the entrance of the reaction chamber, at a distance of about 3 m from the exit of the analysing magnet.

It has been shown that the vertical focussing is sufficiently well without any adjustment, so only the horizontal focussing was performed by small rotations of the analysing magnet about its center.

According to the calculation, the dispersion of the analysing magnet is 20 kev/cm. for 2 Mev deuterons. Therefore through the second slit of 5 mmϕ, 2 Mev deuterons having 10 kev in its energy width will be obtained at the center of the reaction chamber.

The exciting current is controlled by the same way as that of the cyclotron magnet. The magnetic field is constant to 1 part in 10,000.

The hysteresis effect of the magnet was

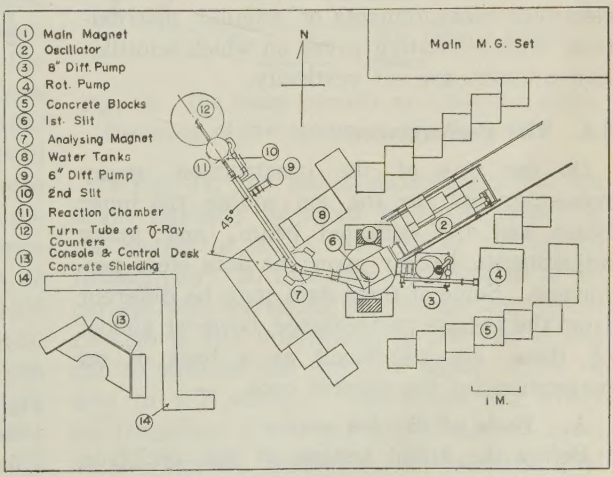

Fig. 9. Layout of the cyclotron room.

200 gauss when it was excited from 0 to 9,000 gauss, and decreased to 7,500 gauss, the normal field for 2 Mev deuterons. It corresponds to about 100 kev in energy. When the exciting currents are used for the estimation of the beam energy it must be cared about the hysteresis effect.

B. *Reaction chamber*

The reaction chamber was designed as simple and functional as possible.

The inner dia. of the chamber is 41 cm and it enables to contain a nuclear camera for measuring angular distribution with nuclear plates.

The windows at 0° and 90° are used to set scintillation counters which can be used for excitation measurements, or one of which as a monitor. When γ-rays are measured, the chamber has a role as only a part of the beam duct. (See Fig. 10) Slit system is attached at the entrance window, and can be changed its dia. from 20 mm to 3 mm.

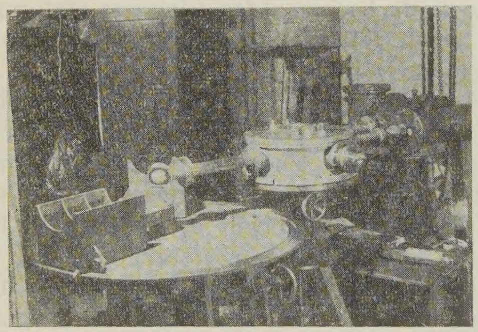

Fig. 10. The reaction chamber and the apparatus for measuring angular distribution of γ-rays.

The reaction chamber can be also used for electronic measurements of angular distributions with a rotating cover on which scintillation counters are set vertically.

§ 4. The Performance

On the way of the construction, many measurements for the ion source, the inner beam and the deflected beam, and many adjustments basing upon the data were performed. Some of these data may be different from the present performance, however almost of them are significant as a base of an estimation for the present ones.

A. *Tests of the ion source*

Before the initial testing of the cyclotron as a whole, the characteristics of the ion source have been measured.

At first, the most effective condition of discharge for deuteron is determined. The normal condition is at the arc voltage of 50∼100 volt and the gas flow of 0.7 cc/min. The ratios of the compositions D_1^+, D_2^+, and D_3^+ were roughly 50:40:10.

It was found that for obtaining high efficiency for D_1^+, it is desirable to decrease the filament current as far as discharge is maintained.

For α-particles, the normal condition is determined so as to adjust the arc voltage higher than 200 V, and the gas flow of 1.8 cc/min.

Both a horizontal feeler and a vertical one were tested to compare the extraction efficiency, and the vertical feeler was adopted because of its rather higher efficiency.

In the case of D_2 ions in excess of 50 mA are extracted from the ion source, at the normal condition.

The beam intensity depends remarkably on the shape of the tip of the ion source, especially on its inner diameter, and the shape was empirically determined as mentioned in § 3. D. (See Fig. 8)

B. *Measurements of the inner beam*

Since the initial testing in June 1955, many

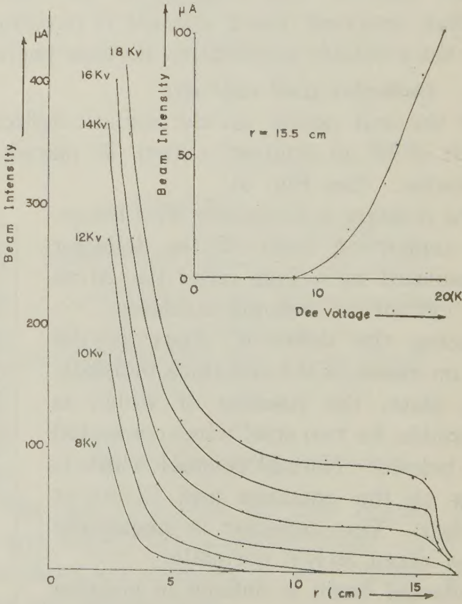

Fig. 11. Radial intensity distributions of inner beam for different dee voltages. The magnetic field is so adjusted that the intensity is maximum at r=15.5 cm.

adjustments had been performed, and after a month, the intensity of the inner beam increased up to 150μA of deuterons at the exit radius. To obtain the informations for the accelerating performance of the cyclotron, the measurements for the inner beam were performed from the various standpoints.

Using an inner probe, the radial distributions of the beam intensity were measured for the different dee voltages, where the magnetic field was so adjusted that the intensity is maximum at $r=15.5$ cm (See Fig. 11).

The beam intensity at the exit radius increases with increasing the dee voltage, and the dee voltage higher than 10 kV is necessary for ions to reach to the exit.

Out of the radius of about 10 cm, all the curves are almost constant showing that the magnetic focussing is sufficiently well. We observed also the radial distributions of the beam height using a piece of tungsten meshes, and found that the height is about 5 mm and almost constant out of the radius of 5 cm. It indicates that magnetic focussing effect is also sufficient out of the radius of 5 cm. The effectiveness of magnetic focussing action at the small radius is attributed to the constant magnetic field gradient (0.1 percent per centimeter) from the centre along the radius. Thus, it may be considered that the smooth decrease of intensity in the region from $r=$ 5 cm to 10 cm is due to the phase shifts with respect to the electric voltage[6)7)].

According to the calculation of Cohen[8)], the smooth decrease of intensity as mentioned above should not be observed under such a sufficient magnetic focusing action, because of the sharp bunching during initial few accelerations. However, in our cyclotron, the conditions for the initial few accelerations may be different with that of Cohen's calculation. That is; on account of relatively small geometry with respect to the dee voltage (dee gap, 2 cm, dee height, 1.6 cm, distance between ion source and Dee, about 1 cm, distance between ion source and feeler, about 1 cm as shown in Fig. 8, and dee voltage about 20 kV for 18,000 gauss) and of the effect of vertical feeler which forms weak field region between dee and itself along the ion path, ions get rather early into the field free region at the initial half rotation as illustrated in Fig. 12 and a sharp bunching may not occur. As will be seen by the following measurements, it is more plausible in our case to assume that ions have rather broad bunching in the initial few accelerations than to assume a sharp bunching.

Measuring the beam intensity as a function of the frequency of dee voltage, one can obtain the resonance curves of the cyclotron acceleration, where the magnetic field strength is constant. Fig. 13 shows the curves measured at $r=11,15$ and 16 cm. The difference of the frequencies of the peaks is due to the magnetic field decreasing toward the outside. It should be noted that the curve have asymmetric forms.

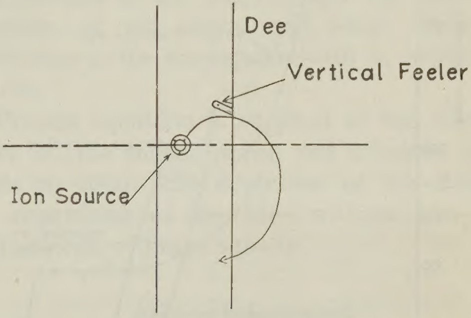

Fig. 12. Path of ion which is accelerated by the peak R.F. voltage, 20 kV. at $H=18,00^\circ$ gauss.

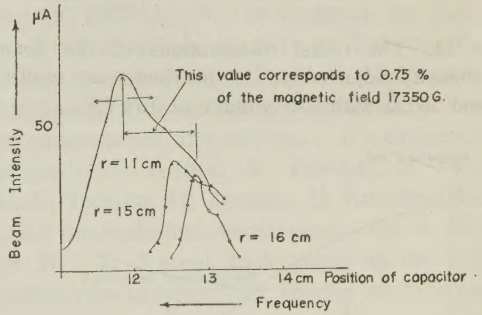

Fig. 13. The beam intensity as a function of the frequency of dee voltage at different radii.

In Fig. 14, the radial distributions of the beam intensity adjusted to be maximum at the radius of 8, 11, and 16 cm are shown respectively. In this case the decrease of ion current with increasing the radius from about $r=5$ cm is also interpreted by the loss of ions due to positive and negative phase shifts of ions to R-F voltage. The radius R_{res} where the frequency of the particle rotation is equal to the applied frequency, can be determiend as the radius where the curve becomes flat, because the loss due to the positive phase shifts ceases at the radius.

From Fig. 14, it can be seen that the radii, R_{res}, for curves I and II are those at $r \doteqdot 12$ cm and $r \doteqdot 7.5$ cm. The difference between the applied magnetic fields at $r \doteqdot 12$ cm and 7.5 cm is 0.75% as shown in Fig. 15 and this is consistent with the frequency difference between the peaks of resonance curves for $r=11$ cm and $r=16$ cm in Fig. 13.

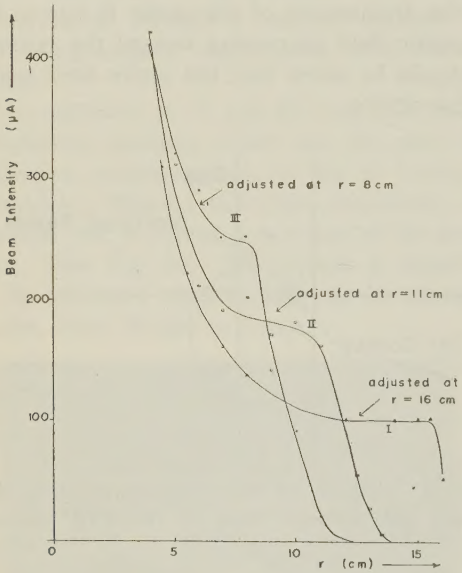

Fig. 14. The radial distributions of the beam intensity adjusted to be maximum at $r=8,11$ and 16 cm with R-F voltage of 15 kV.

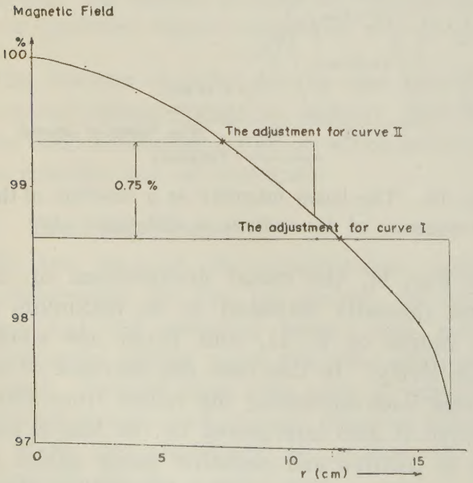

Fig. 15. The radial distribution of the applied magnetic field. The cross points represent the magnetic fields at the resonant radii: $R_{res}=7.5$ cm and $R_{res}=12$ cm.

Using Fig. 15, both the maximum phase shifts (positive and negative) are roughly estimated as about 80° for favorable ions for the adjustment at $r=16$ cm and at the dee voltage of 15 kV.

The curves II and III in Fig. 14 have considerably long tails. This shows that ions have not any sharp bunching actually.

We measured also the dependence of the beam intensity on vacuum. For H_2^+ molecular ions, the intensity decreases significantly with increasing the pressure, because of the dissociations of the molecules by the residual gases as shown in Fig. 16.

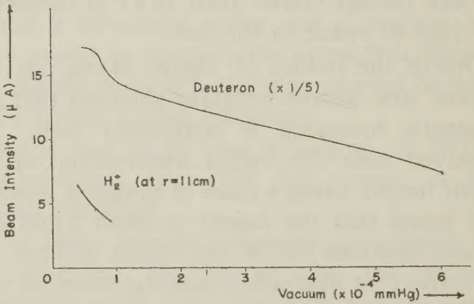

Fig. 16. The dependence of the beam intensity on vacuum.

C. *Performance of the deflector and the analysing system*

The ions extracted by the deflector amount to 30~50μA and its horizontal width is about 2 cm at the position of first slit.

Through the first slit, the beam of few μA is obtained at the entrance of the analysing magnet and its horizontal width is about 6 cm.

At the first setting, only the one-third of the entrance aperture of the analysing magnet allowed to pass the ions.

Moving the analysing magnet toward inside of the deflection, it has become possible that the ions can reach to the second slit passing through the almost whole aperture.

Deuteron beam obtained at the center of the reaction chamber is about 0.3μA, when the 5 mmφ slit is set at the entrance.

For determining the absolute energies corresponding to the current of the analysing magnet, a resonance of F^{19} $(p\,p'\gamma)$ at $E_p=$ 935 kev (resonance width 8 kev) was observed using H_2^+ ions.

The result is shown in Fig. 17 where a thin LiF target of few kev thick was used and the slit was 4 mm wide.

From the half width of the resonance peak, it can be estimated that the energy width of the beam is less than 14 kev for 935 kev protons.

This value is slightly large with compared to the calculation, and the small deviation is believed in the aberration of the analysing magnet.

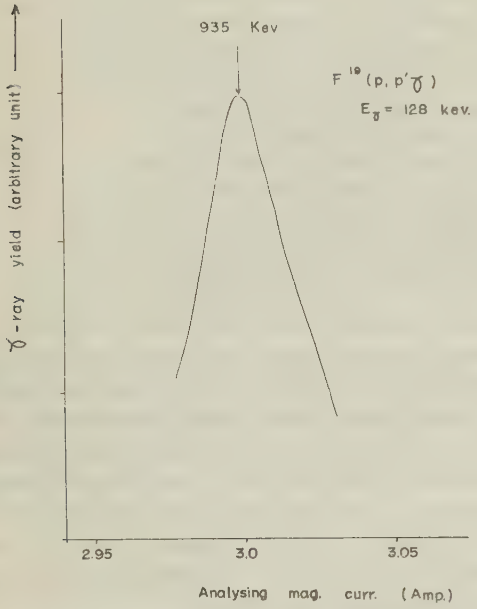

Fig. 17. Absolute measurement of the beam energy.

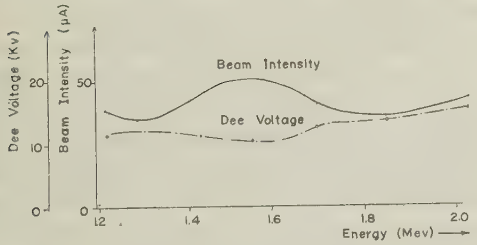

Fig. 18. Variation of the dee voltage and the beam intensity with the beam energy.

D. *Variation of energy*

At the early measurements, it has been shown that the inner beam intensity does not change significantly with variations of the beam energy, as shown in Fig. 18, and that the intensity of analysed beam does change since, for extracting the particles in good direction toward the analysing magnet, the path of the acceleration in cyclotron should be concerned.

For example, when the cyclotron is only adjusted at the higher energy so as to obtain a maximum intensity at the reaction chamber, the beam intensity of lower energy (1.3~1.4 Mev) decreases by one tenth of that of the higher.

Since the magnetic field distribution is not strictly constant, it is impossible to maintain the accelerating path always constant even if the Dee voltage is adjusted to be proportional to the acceleration energy.

It seems to us that the dee voltage higher than that proportional to E favours the acceleration at lower energy.

Readjustments of the direction of deflector, the position of ion source, and the relative position of ion source and feeler, become necessary as the accelerating path in cyclotron varies.

Present condition is adjusted at the higher part of the energy region and it makes possible to obtain the deuterons of 1.5~2 Mev or α-particles of 3~4 Mev without any readjustment within a minute.

Acknowledgements

The construction of the cyclotron was initially started as a project of the Comittee for Nuclear Research in the Institute for Science and Technology, University of Tokyo, whose leading members were Prof. T. Mutô and K. Murakawa. We are deeply grateful to their encouragements and advices. We express our thanks to H. Yoshiki, R. Yamada, S. Takeuchi, S. Tanaka, O. Tanaka, H. Kamitsubo and A. Itô for technical assistances. Dr. S. Suwa and Dr. T. Kamei took parts in the initial construction to whom our thanks are sincerely expressed.

Note on the Cluster Expansion Theory of Classical Fluids. Watermelon Approximation

By Ryuzo ABE

Department of Physics, Tokyo Institute of Technology, Oh-okayama, Meguro, Tokyo

(Received August 25, 1958)

The irreducible clusters appearing in the cluster expansion theory of fluids are classified according to the number of the branch points, to which three or more bonds are connected. All the terms arising from the irreducible clusters with two and only two branch points are summed up and the contribution of these terms to the free energy is obtained exactly in a simple closed form. This enables us to improve the results of calculation of the thermodynamic functions based on Montroll and Mayer's method, in which only clusters without branch point are taken into consideration. This kind of summation procedure seems to be necessary to avoid the divergence difficulty in the case of Coulomb interaction between particles in quantum mechanical systems as well as in classical systems.

§ 1. Introduction

Several attempts have been presented to deal with large clusters in the cluster expansion of the formulae for the free energy and the radial distribution function of dense gas and liquids. Montroll and Mayer[1] have proposed the ring approximation in which only the ring type of irreducible clusters is taken into account. Rushbrooke and Scoins[2] presented the netted chain approximation for the radial distribution function and Hiroike[3] applied it to the evaluation of the free energy. The nature of these approximations seems to be somewhat obscure, though the ring approximation is derived from an alternative view-point[4] which is physically more intuitive. Moreover summation procedure over infinite terms seems to be necessary to avoid divergence difficulty in a certain kind of problems of physical interest. For instance, for a system of particles with Coulomb forces, the usual cluster integrals are known to diverge to infinity owing to the long-range character of the interaction, except when the infinite terms of the clusters of ring type are all summed up. The situation is similar also in the case of quantum theory[5].

On the other hand, the calculation of the free energy without recourse to the cluster expansion has been discussed by different authors[6] with the aid of the collective coordinate description. In particular, Yukhnovsky[7] has investigated the special type of interactions between elementary excitations and obtained the expressions which can be applied to the system with weak interaction. Although this method provides a systematic way of calculating the free energy, the application to the singular potential such as the hard-sphere one is impossible since the existence of the Fourier component of potential is required in this method.

The purpose of this paper is to obtain an expression applicable to the singular potential and analogous to Yukhnovsky's one, from the standpoint of cluster expansion theory. In § 2 the irreducible cluster integrals are classified according to the number of junctions, where junctions are defined to be the points to which three or more bonds are connected. The summation over 0-junction clusters (simple rings) has been performed by Montroll and Mayer. It will be shown that the contributions of 2-junction clusters can be summed up into a closed form by means of the theory of Fourier transforms. The 2-junction cluster has the form of watermelon and therefore our approximation will be called *watermelon approximation*. In § 3 some discussions concerning the correlation energy of an electron gas will be given.

§ 2. Watermelon Approximation

Let us consider a uniform fluid of N identical particles in the volume V and at the temperature T. The potential energy is assumed to be the sum of potentials $\phi(r)$ due to pairs of particles.

The Helmholtz free energy A of the system is expanded in the virial series as[8)]

$$\frac{A}{NkT}=\ln\left(\frac{h^2}{2\pi mkT}\right)^{3/2}\frac{\rho}{e}-\sum_{n=1}^{\infty}\frac{1}{n+1}\beta_n\rho^n \qquad (1)$$

where $\rho=N/V$ is the number density and β_n is the irreducible integral defined by

$$\beta_n=\frac{1}{n!\,V}\iint\cdots\times\int dx_1dx_2\cdots dx_{n+1}\sum_{\substack{n+1\geq i>j\geq 1\\ \text{All products which are more}\\ \text{than singly connected.}}}\prod f_{ij}\,. \qquad (2)$$

Here f_{ij} is given by

$$f_{ij}=\exp\left[-\phi(r_{ij})/kT\right]-1\,. \qquad (3)$$

It is convenient here to express each term in the sum of integrand of (2) by a graph consisting of the numbered points, $1, 2, \cdots, n+1$, and of bonds connecting points i and j, representing the factor f_{ij} in the summand. Then the graphs drawn in this way will have the junctions, the points to which three or more bonds are connected. For example, in Fig. 1 the points 3, 4 and 6 are junctions.

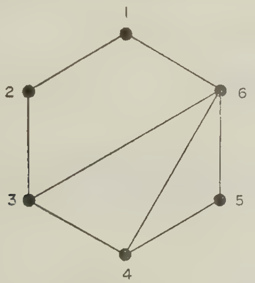

Fig. 1.

Then it is obvious that the various graphs contributing to β_n can be classified according to the number of junctions and β_n may be written as

$$\beta_n=\beta_n^{(0)}+\beta_n^{(2)}+\cdots+\beta_n^{(n+1)}\,, \qquad (4)$$

where $\beta_n^{(0)}$ means the contribution of 0-junction clusters, $\beta_n^{(2)}$ that of 2-junction clusters, etc., (the 1-junction cluster does not appear in the irreducible integral). If one retains only the first term in Eq. (4), one is led to Montroll and Mayer's approximation, i.e., the ring approximation corresponds to 0-junction approximation. If one further takes $\beta_n^{(2)}$, one is led to 2-junction approximation. This 2-junction cluster has the form represented in Fig. 2 which resembles the shape of a watermelon, and therefore we will call 2-junction approximation-watermelon approximation. It will be shown below that the cluster expansion for the free energy, Eq. (1), can be written in a closed form even if we consider 2-junction clusters besides 0-junction clusters.

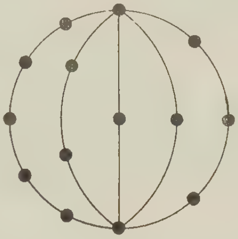

Fig. 2.

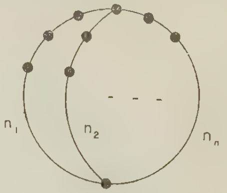

Fig. 3.

Let us consider $\beta_n^{(2)}$ for a given n ($\geqslant 3$) and assume that there are m lines between two junctions. We assume further that $n_1, n_2, \cdots, n_m$ particles lie on these lines respectively (see Fig. 3). Since only one of n_i's can be zero, the largest number of m is n, corresponding to the case where there are $n-1$ lines with only one particle and one line without particle. Furthermore it is evident that $m\geqslant 3$, since the case $m=2$ is not allowed for the 2-junction clusters. Therefore we have a relation

$$n\geqslant m\geqslant 3. \qquad (5)$$

We observe here the integral characterized by the set of numbers $(n_1, n_2, \cdots, n_m)$:

$$I(n_1, n_2, \cdots, n_m)=\frac{1}{V}\int^{(n_i)}\prod f_{ij}\,dx_1dx_2\cdots dx_{n+1}\,, \qquad (6)$$

where $\overset{(n_i)}{\prod} f_{ij}$ represents the product of f_{ij}'s corresponding to Fig. 3. In order to calculate this, it is convenient to introduce the Fourier transform of f_{ij} defined by

$$f_{ij}=\frac{1}{V}\sum_{k}F(k)e^{ik\cdot(x_i-x_j)}\,. \qquad (7)$$

If we substitute this into Eq. (6) (we set the coordinates of junctions to be x_1 and x_2) and integrate over the coordinates of particles on the connecting lines, we have

$$I=\frac{1}{V^{m+1}}\sum_{k_1,\cdots,k_m}\int F^{n_1+1}(k_1)e^{ik_1\cdot(x_1-x_2)}F^{n_2+1}(k_2)e^{ik_2\cdot(x_1-x_2)}\cdots\times F^{n_m+1}(k_m)e^{ik_m\cdot(x_1-x_2)}\,dx_1dx_2\,. \qquad (8)$$

If we further integrate over $\boldsymbol{x}_1$ and $\boldsymbol{x}_2$, we have

$$I=\frac{1}{V^{m-1}}\sum_{\boldsymbol{k}_1,\cdots,\boldsymbol{k}_{m-1}} F^{n_1+1}(\boldsymbol{k}_1)F^{n_2+1}(\boldsymbol{k}_2)\cdots F^{n_m+1}(-\boldsymbol{k}_1-\boldsymbol{k}_2-\cdots-\boldsymbol{k}_{m-1}) \,. \tag{9}$$

Therefore $I(n_1, n_2, \cdots, n_m)$ is written as

$$I(n_1, n_2, \cdots, n_m)=\int u_{n_1}(\boldsymbol{x})u_{n_2}(\boldsymbol{x})\cdots u_{n_m}(\boldsymbol{x})\,d\boldsymbol{x} \,, \tag{10}$$

where $u_n(\boldsymbol{x})$ is defined by

$$u_n(\boldsymbol{x})=\frac{1}{V}\sum_{\boldsymbol{k}} F^{n+1}(\boldsymbol{k})e^{i\boldsymbol{k}\cdot\boldsymbol{x}} \,. \tag{11}$$

We shall proceed to calculate the number of different ways in which the clusters characterized by the set $(n_1, n_2, \cdots, n_m)$ are constructed from the particles $1, 2, \cdots, n+1$. If we denote this by $C(n_1, n_2, \cdots, n_m)$, $\beta_n^{(2)}$ is evaluated by summing the product CI over possible set of n_i's and deviding by $n!$.

We may calculate $C(n_1, n_2, \cdots, n_m)$ in the following manner. First we select two particles as the junctions out of $n+1$ particles; the number of ways is $\binom{n+1}{2}$. Secondly n_1 particles are selected out of $n-1$ particles and arranged on the line; the number of ways is $\binom{n-1}{n_1}n_1!$. Thirdly n_2 particles are selected out of $n-n_1-1$ particles and arranged on the line; the number of ways is $\binom{n-1-n_1}{n_2}n_2!$, and so on. Using the equation $\sum_{i=1}^{m} n_i=n-1$, we may write the product of these numbers as

$$\binom{n+1}{2}\binom{n-1}{n_1}\binom{n-1-n_1}{n_2}\cdots\binom{n-1-n_1-n_2\cdots-n_{m-2}}{n_{m-1}}n_1!\,n_2!\cdots n_m!=(n+1)!/2 \,.$$

In calculating C we must note that if there are lines with the same number of particles, the interchange of these lines never leads to different clusters and therefore if we denote the number of lines with one particle by ε_1, that with two particles by ε_2, etc., we have

$$C(n_1, n_2, \cdots, n_m)=\frac{(n+1)!}{2}\,\frac{1}{\varepsilon_1!\,\varepsilon_2!\cdots} \,. \tag{12}$$

From Eqs. (10) and (12), we obtain the expression for the contribution of the clusters with a given value of m to the irreducible integral β_n in the following form:

$$\beta_{nm}^{(2)}=\frac{n+1}{2}\left[\sum_{\substack{(n_1,\cdots n_m)\\ n_i\geq 1}}\frac{1}{\Pi\varepsilon_i!}\int\prod_{i=1}^{m}u_{n_i}(\boldsymbol{x})\,d\boldsymbol{x}+\sum_{\substack{(n_1,\cdots n_{m-1})\\ n_i\geq 1}}\frac{1}{\Pi\varepsilon_i!}\int\prod_{i=1}^{m-1}u_{n_i}(\boldsymbol{x})f(\boldsymbol{x})\,d\boldsymbol{x}\right], \tag{13a}$$

where each term in the second sum stands for the contribution of a graph with single line on which no point lies. Furthermore $(n_1, n_2, \cdots, n_m)$ means the summation over the set of these n_i's. This summation is, however, easily transformed into multiple summations over n_i's as follows,

$$\beta_{nm}^{(2)}=\frac{n+1}{2}\left[\frac{1}{m!}\sum_{\substack{n_1,n_2,\cdots,n_m\\ n_i\geq 1}}\int\Pi\,u_{n_i}(\boldsymbol{x})\,d\boldsymbol{x}+\frac{1}{(m-1)!}\sum_{\substack{n_1,n_2,\cdots n_{m-1}\\ n_i\geq 1}}\int\Pi\,u_{n_i}(\boldsymbol{x})f(\boldsymbol{x})\,d\boldsymbol{x}\right]. \tag{13b}$$

For the number of ways in which the set $(n_1, n_2, \cdots, n_m)$ appears in the first sum of Eq. (13b) is $m!/\Pi\,\varepsilon_i!$ and therefore this is equal to the first sum of Eq. (13a). The situation is the same of the second sum.

Let us now consider the free energy arising from the clusters of watermelon type and define $(-A'/NkT)_W$ as

$$\left(-\frac{A'}{NkT}\right)_W=\sum_{n\geq 3}\frac{\beta_n^{(2)}}{n+1}\rho^n\,. \tag{14}$$

Then we obtain, from Eq. (13b),

$$\left(-\frac{A'}{NkT}\right)_W=\frac{1}{2}\sum_{\substack{n\geq 3\\ m\geq 3}}\left[\frac{1}{m!}\sum_{\substack{n_i\geq 1\\ \Sigma n_i=n-1}}\rho^n\int\Pi\, u_{n_i}(\boldsymbol{x})\,d\boldsymbol{x}+\frac{1}{(m-1)!}\sum_{\substack{n_1\geq 1,\cdots,n_{m-1}\geq 1\\ \Sigma n_i=n-1}}\rho^n\int\Pi\, u_{n_i}(\boldsymbol{x})f(\boldsymbol{x})\,d\boldsymbol{x}\right].$$

If we use the relation $n=1+\sum_i n_i$ and carry out the summations over n_i's, we have

$$\left(-\frac{A'}{NkT}\right)_W=\frac{\rho}{2}\int\sum_{m=3}^{\infty}\frac{h^m(\boldsymbol{x})}{m!}\,d\boldsymbol{x}+\frac{\rho}{2}\int\sum_{m=2}^{\infty}\frac{h^m(\boldsymbol{x})}{m!}f(\boldsymbol{x})\,d\boldsymbol{x}\,, \tag{15}$$

where $h(\boldsymbol{x})$ is given by

$$h(\boldsymbol{x})=\sum_{i=1}^{\infty}\rho^i u_i(\boldsymbol{x})\,. \tag{16}$$

If we perform the summation over m, we have

$$\left(-\frac{A'}{NkT}\right)_W=\frac{\rho}{2}\int\left\{e^{h(\boldsymbol{x})}-1-h(\boldsymbol{x})-\frac{h^2(\boldsymbol{x})}{2}\right\}d\boldsymbol{x}+\frac{\rho}{2}\int\left\{e^{h(\boldsymbol{x})}-1-h(\boldsymbol{x})\right\}f(\boldsymbol{x})\,d\boldsymbol{x}\,, \tag{17}$$

and, from Eqs. (11) and (16), it follows that

$$\begin{aligned}h(\boldsymbol{x})&=\frac{1}{V}\sum_{\boldsymbol{k}}\left[\rho F^2(\boldsymbol{k})+\rho^2F^3(\boldsymbol{k})+\cdots\right]e^{i\boldsymbol{k}\cdot\boldsymbol{x}}\\&=\frac{1}{V}\sum_{\boldsymbol{k}}\frac{\rho F^2(\boldsymbol{k})}{1-\rho F(\boldsymbol{k})}e^{i\boldsymbol{k}\cdot\boldsymbol{x}}\,.\end{aligned} \tag{18}$$

On the other hand, the free energy term arising from 0-junction clusters has been calculated by Montroll and Mayer[1] and takes the form:

$$\left(-\frac{A'}{NkT}\right)_R=\frac{\rho}{2}F(0)-\frac{1}{2V\rho}\sum_{\boldsymbol{k}}\left[\ln\{1-\rho F(\boldsymbol{k})\}+\rho F(\boldsymbol{k})+\frac{\rho^2F^2(\boldsymbol{k})}{2}\right]. \tag{19}$$

In this way the summation over 2-junction clusters together with 0-junction clusters has been reduced to a simple quadrature. By means of Eqs. (1), (17), (18) and (19) the free energy under the ring and watermelon approximations is evaluated. It should be noted here that the first term of Eq. (17) has a form similar to that obtained by Yukhnovsky[7]. The essential difference is, however, that his expression cannot be applied to the singular potentials while ours can be applied to such cases.

§ 3. Discussions

In this paper it is shown that the summation over 2-junction clusters is reduced to a single integral in the coordinate space. In general the summation over n-junction clusters may be reduced to $(n-1)$-fold integral after the integration over the coordinates of particles on the lines connecting various junctions. This suggests that the cluster expansion may be summed up in a series of which each term represents the contribution of clusters characterized by the number of junctions. In fact the theory of classical fluids along this line will be developed by Morita[9] in his forthcoming papers.

An interesting problem which can be treated by the present method is an evaluation of the free energy of the system with Coulomb forces. In this case the function $h(\boldsymbol{x})$ defined by Eq. (18) is the screened potential such as $A\exp(-\kappa r)/r$. If one retains here only the clusters with $m=3$ as shown in Fig. 4, the free energy term contains an integral:

$$\frac{\rho}{2}\int_0^\infty \frac{1}{3!}\frac{A^3 \exp(-3\kappa r)}{r^3} r^2\, dr\,, \qquad (20)$$

if the term $m=3$ is retained in Eq. (15). This integral is of logarithmic divergence at $r=0$. However if one sums the terms with $m \geqslant 3$, the result is no longer divergent as is seen in Eq. (17).

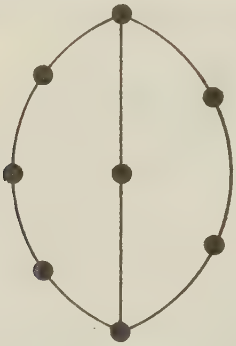

Fig. 4.

The same situation may exist in quantum theory, since at high temperatures the quantum statistics reduces to classical one. In fact Montroll and Ward[5] have shown that the correlation energy of an electron gas[10] can be obtained by summing the graphs which are of ring type (by replacing the particles in classical theory by torons). The corresponding summation in turn leads to the Debye-Hückel equation in classical theory. Therefore it may follow that the summation of the clusters shown in Fig. 4 will lead to the divergence in quantum theory as well as in classical one. However this difficulty will be avoided if the clusters $m \geqslant 3$ are summed up. It seems that the summation of this type will be important if one wishes to improve on the approximation employed in calculating the correlation energy of an electron gas at high densities.

In conclusion the author wishes to express his sincere thanks to Prof. H. Ichimura and Mr. K. Hiroike for helpful discussions and also to Mr. T. Morita for giving him a number of kind suggestions and informing the result about the generalization of the present method before publication.

High Electric Field Effects in Germanium *p*−*n* Junction

By Jiro Yamaguchi and Yoshihiro Hamakawa
Faculty of Engineering, Osaka University, Osaka

(Received November 25, 1957)

When the squarewave pulses of 5∼160 μs duration with the repetition rate of 1,000 pulses per sec. are impressed across the germanium $p-n$ junction of grown type in the reverse direction, the critical voltage of the avalanche beginning rises up with the temperature of the specimen.

On the other hand, the onset voltage of negative resistance decreases with the increasing ambient temperature of specimens and duration of pulse impressed across the $p-n$ junction. Furthermore, even if the ambient temperature of specimens is widely changed, the barrier temperature, which is estimated from the saturation current in reverse direction, is almost constant. Therefore, the temperature rise in barrier layer is also necessary for the onset of negative resistance, though the avalanche ionization is essential.

At the negative resistance region, the property of jumping or oscillation occurs. Which of the two prevails, depends on the circuit resistance and other experimental conditions. These properties seems to have relation with the barrier temperature.

§ 1. Introduction

When a pulse voltage is applied to the germanium $p-n$ junction in reverse direction, the volt-ampere characteristics of the junction may be divided into the following regions, i.e., saturation current, excess current, avalanche, negative resistance and ohmic property. They appear successively with the increasing voltage of pulse source. These regions are shown as OA, AB, BC, CDE in Fig. 1 and FG in Fig. 9.

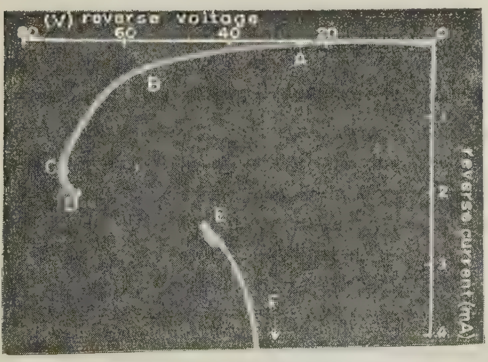

Fig. 1. Volt-ampere characteristic of reverse direction.

On the problem of the high electric field effects in germanium $p-n$ junction, many experimental and theoretical studies have been made in recent years. McKay[1)] has discussed the avalanche process in silicon step junction and Miller[2)] has reported that the charge multiplication takes place in the step junction of germanium at prebreakdown voltage. The negative resistance properties have been experimentally studied for point contact diodes[3-5)] and the critical temperature of pulse breakdown, which has been measured at different ambient temperatures of specimens and calculated by postulating a simple model with considerations of the power dissipation at the contact, is estimated at the barrier to (95∼147)°C[4)] or 90°C[5)]. At the same time the jumping or oscillation characteristics have been shown also with germanium point contact diodes. Recently, the experimental results of negative resistance property have been shown in grown or alloyed junctions of germanium[6)] and silicon[7-8)]. Gunn has theoretically demonstrated the negative resistance property by the concept of avalanche injection and obtained the relation of $V_a \propto J^{-1/2}$, where V_a and J are the voltage across the avalanche and current density, respectively. However, their experimental results show that the above relation can not be observed, but only a sudden decrease of voltage as the current is increased.

In this report, we discuss the relative distinction between the avalanche multiplication and the onset of negative resistance and that between jumping and oscillation property in the negative resistance region, taking into consideration the open-circuit voltage of the $p-n$ junction and the barrier temperature, which is estimated from the saturation current of the junction as described below.

The applied voltage used in this investigation is the squarewave pulses, which enables the electric behavior of junction to be clear. The $p-n$ junction in this study is of the base and collector of $n-p-n$ grown type transistors, which are made in our country and hermetically sealed in capsules. The resistivities of p-region and n-regions are 0.1 and 1 Ω cm respectively, therefore the impurity concentrations are estimated to be 2.4×10^{16} and 2.0×10^{15} cm^{-3}. The distribution of net impurity concentration in the junction is of linear gradient.

§ 2. Experimental Procedures

Fig. 2 shows the electric circuit for measuring the property of $p-n$ junction. As a power source we used squarewave pulses having a duration of 5∼160 μs with the repetition rate of 1,000 pulses per sec.. C.R.O-1 and 2 are respectively used for showing the volt-ampere characteristic as in Fig. 1, the wave form of the voltage and that of the current in the junction.

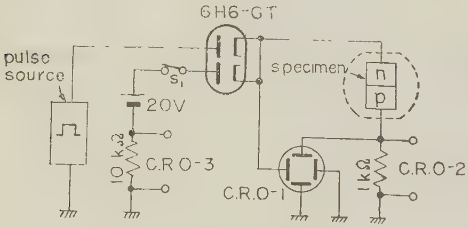

Fig. 2. Connection diagram for measurement.

Fig. 3 (a), shows the characteristic of the saturation current at different temperatures of the specimen, expressing that the current is nearly constant for a wide range of applied voltage as well known and Fig. 3 (b) indicates a plot of saturation current (i_s) measured at 20 V versus ambient temperature of (−23∼87)°C of the specimen. By this relation, we can estimate the barrier temperature. The relation of these two quantities can be expressed by

$$i_s \simeq i_0 \exp\left(-\frac{0.62\,\text{eV}}{kT}\right),$$

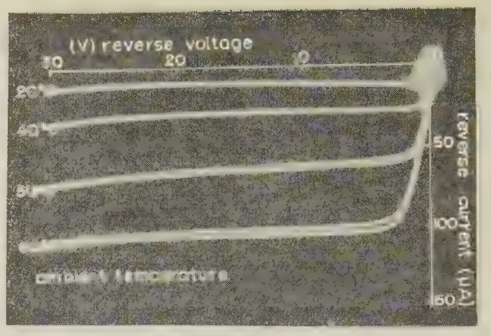

Fig. 3 (a). Saturation current at different temperatures.

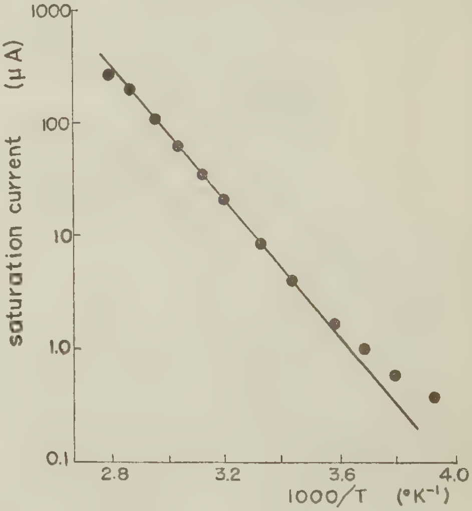

Fig. 3 (b). Relation between saturation current and temperature of specimen.

where k, T and i_0 are Boltzmann's constant, absolute temperature and a certain constant respectively.

§ 3. Experimental Results and Discussions

(a) *Avalanche multiplication*

When the applied voltage is raised over the value represented at the point B in Fig. 1, the di/dv increases rapidly with the voltage. From the experimental results, the critical voltage of the current increase, i.e., the voltage indicated at the point B does not depend on the duration of pulses (5∼160)μs, but grows with the ambient temperature of specimen as shown in Fig. 4. The relative temperature coefficient of critical voltage at room temperature can be obtained from Fig. 4 and is estimated to be 8×10^{-4} (°C^{-1}), which is of the same order as the temperature coefficient for multiplication characteristics of silicon step junction[1]. Furthermore, approximate calculations show that, as the width constant of the specimens used is 8.6×10^{-5} cm²⁾, the maximum field intensity in the junction at the critical voltage is 265 kVcm⁻¹. Miller reported that the maximum field in the junction at the prebreakdown is 237 kV cm⁻¹ for germanium step junctions. Consequently, the critical voltage described above would correspond to the onset voltage of avalanche multiplication.

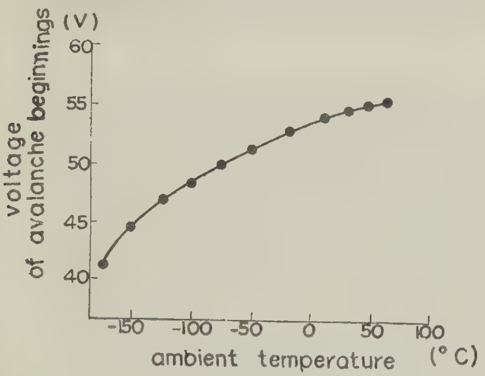

Fig. 4. Critical voltage of avalanche beginning versus ambient temperature.

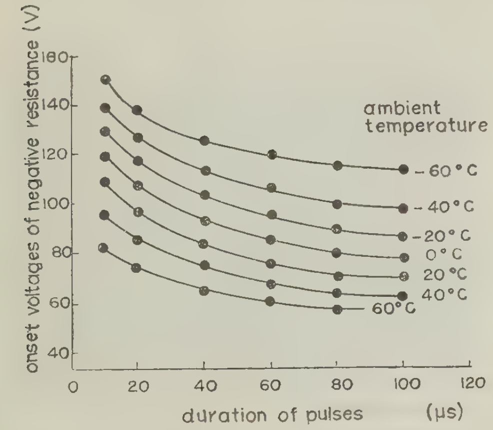

Fig. 5. Onset voltage of negative resistance versus pulse duration at different ambient temperatures.

(b) *Onset of negative resistance*

When the impressed voltage is raised from the avalanche region and attains the value corresponding to the point C in Fig. 1, the current increases extremely rapid, di/dv becomes infinite and the negative resistance property occurs. Fig. 5 shows the relation of the onset voltage of negative resistance versus pulse duration, ambient temperature being taken as a parameter. From this result, the onset voltage of negative resistance seem to depend on the temperature of the junction.

(c) *Barrier temperature*

The barrier temperature in the avalanche and breakdown regions is estimated by the relation of Fig. 3 (b).

When the squarewave pulses, their duration being 10 μs with the repetition rate of 1,000 p/s, are applied to the specimen, the wave form of saturation current can be observed at the pulse interval by C.R.O-3 in Fig. 6. We can observe from Fig. 6 (a) that the saturation current of the reverse direction is comparatively small in the regions of saturation current and excess current but increases slightly in the avalanche region. When the junction operates at the negative resistance region, the saturation current rapidly increases and has simultaneously a decay component (i_e), on which we will discuss below. It is noticeable that the i_e component does not appear at the onset of negative re-

sistance region, i.e. the point C, but predominates at DE in Fig. 1.

From these experimental results, the temperature rise in the junction barrier, which can be estimated from i_s, is negligibly small in the saturation current region and large in the negative resistance region.

Table I. Barrier temperature (°C).

Region / Ambient temperature	Avalanche ionization	Negative resistance	Ohmic property
−70	−10∼28	40*∼ 52	52∼ 70
−30	18∼38	42*∼ 58	58∼ 80
0	30∼43	46*∼ 65	65∼ 90
30	40∼58	62*∼ 87	87∼ 95
60	84∼90	90*∼100	100∼110

(Duration of pulses is 20 μs, and numerical values marked with * are obtained at the onset of negative resistance region.)

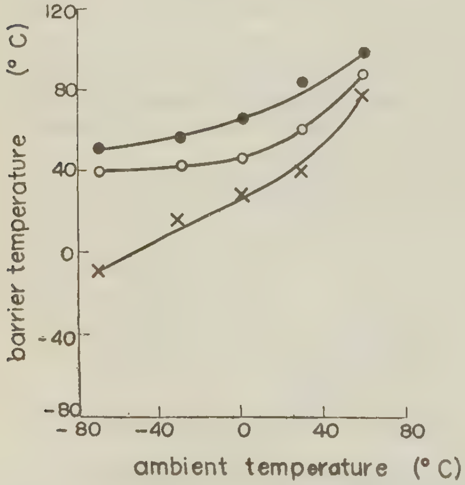

Fig. 7. Barrier temperature versus ambient temperature, the dots express ohmic property, the circles onset of negative resistance and the crosses onset of avalanche multiplication.

Table I and Fig. 7 show the relation between the barrier temperature at different operating regions and the ambient temperature of specimen. From Fig. 7, it is concluded that even if the ambient temperature of the specimen is (−70∼20)°C, the barrier temperature at the onset point of negative resistance is approximately constant at (40∼54)°C. It is remarkable that the onset of negative resistance property in $p-n$ junction neccesiates not only the avalanche ionization but the temperature rise in the barrier. On the other hand, the barrier temperature at the critical voltage of avalanche multiplication increases with the ambient temperature.

As shown in Fig. 6 (a) and (b) the decay component (i_e) of the saturation current does not appear in the saturation and avalanche regions, but appears in the negative resistance region of jumping or oscillation and grows with the increasing pulse duration.

Microplasmas have been observed at the breakdown in silicon $p-n$ junction8),9), hence, if similar phenomenon is applied to our case of germanium $p-n$ junction, it may be suggested that in the negative resistance region the barrier is electrically punched through in some spots by the pulse voltage, microplasmas may arise and i_e may be the current through hot patches in junction which would be caused by plasmas. Just after the pulse termination, the junction recovers with the time constant of several μs, which corresponds to the decay time of i_e. On the contrary, the barrier still exists in the avalanche region, because i_e could not be observed.

(d) *Negative resistance and ohmic property*

When the voltage of pulse source is raised still more, the volt-ampere characteristic indicated at the point D in Fig. 1 jumps to that of the point E, or the electrical oscillation occurs at the frequency of 200 kc∼1 Mc between the point D and E. The wave forms of voltage and current are shown in Fig. 8. It is significant that the line $\overline{CDE}$ in Fig. 1 is considered to be the resistance line of the external circuit. As the pulse voltage of electric source is further raised, the volt-ampere relation is expressed as a straight line as shown in Fig. 9. In this range the $p-n$ junction has merely the ohmic property. As explained above, the characteristic of $p-n$ junction may be in brief expressed as the lines OC and EF in Fig. 10, which correspond to the property before and after the breakdown. Hence, when the voltage of pulse source and the resistance line of external circuit are assumed to be OG and GH, the operating point of the junction will be given at the point C or E. Therefore, it is expected that whether the electric jumping

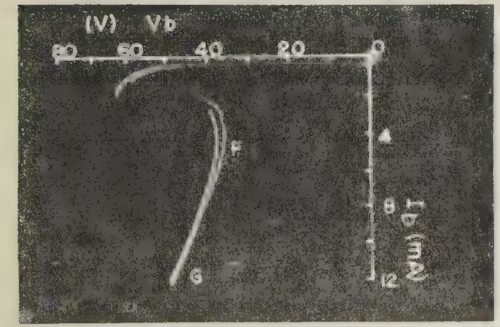

Fig. 9. Volt-ampere characteristic at ohmic region. (Taken with half-wave rectified voltage of single phase 60 c/s instead of pulse source in Fig. 2).

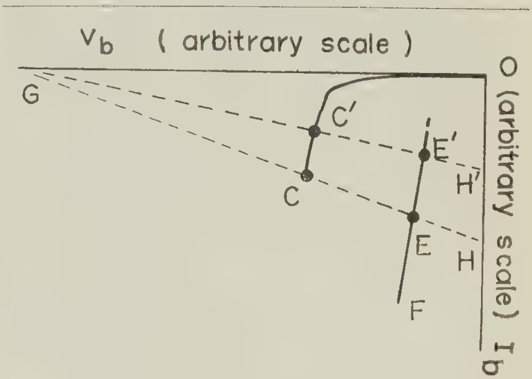

Fig. 10. Simplified characteristics of *p-n* junction, before and after the breakdown.

or oscillation prevails in negative resistance region, depends on the difference of the barrier temperature at the point E and that of C. Namely, the electrical oscillation occurs when the barrier temperature at the point C is higher than the one at E and the electrical jumping occurs in the opposite case.

This argument is ascertained by the experiment, in which several resistances are inserted in the external circuit and the operating point of $p-n$ junction is changed in the volt-ampere characteristic as shown in the points (C, E) or (C′, E′) of Fig. 10. The experimental results are indicated in Fig. 11. In this figure, the hyperbolas express the equi-power line, and (D_1, E_1)(D_2, E_2)(D_3, E_3) (D_4, E_4) and D_5 represent respectively the operating point of $p-n$ junction with the external resistances shown in Table II. The five D_s' and the four E_s' correspond to D and E in Fig. 1 in their property. Hence we can observed that the $p-n$ junction operates in the jumping, oscillation or avalanche region with the change of external resistance. In the above discussion, the points C and D in the volt-ampere characteristic are considered to be in the same position, because the region of CD is short in Fig. 1 and the temperature dependence of the bulk resistance of specimen is not taken into consideration.

Table II. Explanation of Fig. 11.

Externally inserted resistance ($k\Omega$)	Operating point	Electrical property
4	D_1, E_1	jumping
about 4.5	D_2, E_2	Boundary of jumping and oscillation
7~8	D_3, E_3	oscillation
about 8.5	D_4, E_4	Boundary of oscillation and avalanche
9	D_5	Avalanche ionization

Fig. 12 shows the domains of avalanche, oscillation and jumping property at different external resistances and pulse durations.

Gunn has suggested from the concept of avalanche injection that the relation of $V_a J^{1/2} \simeq$ constant holds in the negative resistance region, but $V_a J$ is constant in the equi-power dissipation. Hence it would be impossible to observe stably the negative resistance region on the volt-ampere characteristic. Moreover, Rose has discussed the fluctuating frequency in the negative resistance region and his conclusion is that the oscillation of current is explained by statistical problems of chance fluctuation of microplasmas.

In our standpoint of view, the oscillation frequency would depend on

i. The time required from the onset of negative resistance to the growth of microplasmas.

ii. The time of extinguish of the current through punched spots in junction.

iii. The time required from the state of avalanche ionization, which is partly determined by the voltage of electric source and external resistance, to the onset of negative resistance.

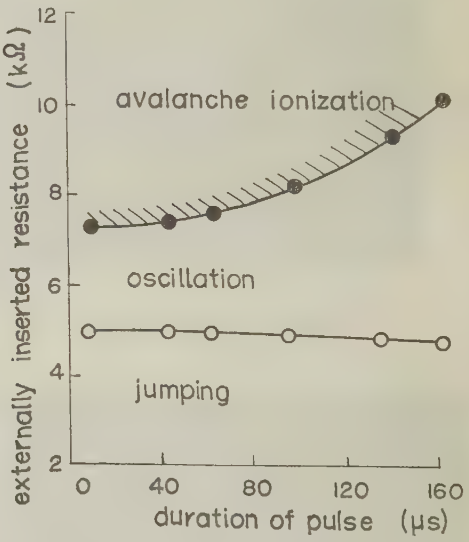

Fig. 12. Domains of negative resistance and avalanche region.

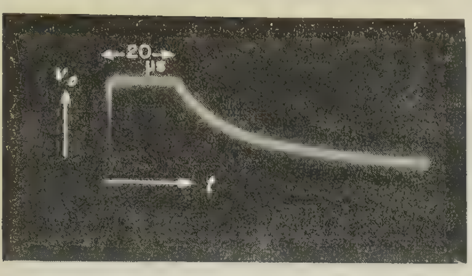
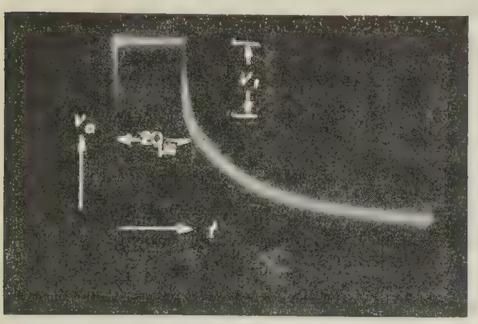
(e) *Open-circuit voltage*

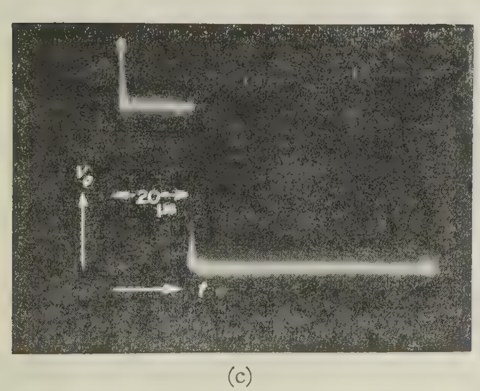
The wave forms of the terminal voltage across the $p-n$ junction, which are observed in C.R.O-1 of Fig. 1, are shown in Fig. 13. The pulse duration in this case is 20 μs. As shown in Fig. 13 (a) and (b) the terminal voltage in the saturation current and avalanche regions has the decay component with the time constant of about 20 μs at the interception of pulses. As is well known, the decay component is caused by the diffusion of stored charge carriers in the $p-n$ junction. On the other hand, in the negative resistance region, the decay component can not be observed as shown in Fig. 13 (c). Therefore in the former, the barrier still exsists, but in the latter, the barrier is extinguished and the $p-n$ junction becomes only a resistance. Besides, v_1 in Fig. 13 (b) is the



(a)
Saturation and excess current region.



(b)
Avalanche region.



(c)
Negative resistance region.

Fig. 13. Wave forms of open-circuit voltage.

voltage drop in the bulk resistance of the specimen.

§ 4. Conclusion

In the avalanche region, the critical voltage of avalanche beginning rises with the ambient temperature of specimen which is somewhat lower than the barrier temperature.

In the onset of negative resistance region, the barrier temperature is (40∼54)°C at the ambient temperature of (−70∼20)°C, i.e., the former is nearly constant while the latter changes widely.

In the negative resistance region, the characteristic of the $p-n$ junction shows the electrical jumping or oscillation. Which of the two prevails, is caused by the temperature rise in the barrier and can be controlled by the resistance inserted in the external circuit.

Acknowledgments

The authors are indebted to Sony Corp. and Kobe Kogyo Corp., for the supply of the $p-n$ junctions. They are also grateful to the staff members of 2nd lectureship of our school for valuable discussions and to Mr. H. Matsushiro, Mr. S. Horiuchi and Mr. K. Sugimoto for the experimental helps.

Interaction of Conduction Electrons with Acoustic Phonons

By Nobuo MIKOSHIBA

Electrotechnical Laboratory, Nagatacho, Tokyo

(Received July 26, 1958)

The interaction of conduction electrons with acoustic phonons is studied from the general point of view. Parmenter's theory of acousto-electric effect in the high frequency range is criticized for several reasons. It is shown that Weinreich's relation between acousto-electric effect and the absorption coefficient of acoustic waves holds only in the high frequency range, and the limitation to its application is also discussed. New magneto-acoustic resonance suggested by the present author is examined qualitatively.

§ 1. Introduction

As is well-known[1)], there are three different types of the interaction of conduction electrons with acoustic waves corresponding to three frequency ranges of waves:

(1) the low frequency range ($\omega\tau \ll 1$, $ql < 1$),

(2) the intermediate frequency range ($\omega\tau < 1$, $ql > 1$) and

(3) the high frequency range ($\omega\tau > 1$, $ql \gg 1$).

Here ω and q are the angular frequency and the wave number of acoustic waves, τ and l are the relaxation time and the mean free path of conduction electrons. The presence of the intermediate frequency range results from the difference between the average velocity (or Fermi velocity) of conduction electrons v_0 and the sound velocity s. From the relations $\omega = sq$ and $l = \tau v_0$, we get

$$\omega\tau = \left(\frac{s}{v_0}\right) ql \,. \qquad (1.1)$$

Then if $s/v_0 < 1$, the intermediate frequency range occurs.

In the low frequency range we may treat acoustic waves *classically as potential waves* for conduction electrons. On the other hand, in the high frequency range we treat them *as an acoustic phonon beam* which scatters conduction electrons. There are two approaches in treating acoustic waves in the intermediate frequency range. One is the approach from the low frequency range as treated in Pippard's theories of the absorption of acoustic waves[1)] and of magneto-acoustic resonance[2)]. The other is the approach from the high frequency range as in Paranjape's[3)] and Kittel's[4)] theories of the absorption of waves. There are three phenomena relating to the interaction of conduction electrons with acoustic waves:

(1) acousto-electric effect,

(2) the absorption of acoustic waves and

(3) magneto-acoustic resonance.

In this paper we restrict ourselves to discuss only the phenomena in the high (and the intermediate) frequency range and to treat the interaction of conduction electrons with *acoustic phonon beam* (*longitudinal waves*). First we examine the critical frequencies between three frequency ranges at liquid helium temperature, taking Cu as an example for metals and n-Ge for semiconductors. The results are listed in Table I.

Table I. The critical frequency between three frequency ranges.

	Cu	n-Ge
τ (sec)	10^{-10}*	10^{-10}
l (cm)	1.6×10^{-2}	4×10^{-4}**
v_0 (cm/sec)	1.6×10^{8}	4×10^{6}
s (cm/sec)	4.5×10^{5}	5×10^{5}
ω_1 (rad/sec)***	2.8×10^{7}	1.3×10^{9}
ν_1 (cyc/sec)	4.5×10^{6}	2.1×10^{8}
ω_2 (rad/sec)****	10^{10}	10^{10}
ν_2 (cyc/sec)	1.6×10^{9}	1.6×10^{9}

* We take the specimen of the highest purity.

** $v_0 = (8\kappa T/\pi m^*)^{1/2}$, $m^*/m = 0.1$, where m^* is the effective mass of conduction electrons.

*** $\omega_1 = (1/\tau)(s/v_0)$ and $\nu_1 = \omega_1/2\pi$

**** $\omega_2 = 1/\tau$ and $\nu_2 = \omega_2/2\pi$

Since the maximum available frequency of acoustic waves at the present time may be $\nu \sim 5\times10^{8}$ cyc/sec, it is difficult to realize the condition for the high frequency range. However, it may be possible in future, to realize such conditions by developments in techniques of producing high frequency acoustic waves together with that of purification of materials which reduces the critical frequency ν_2. As mentioned above, the approach of treating acoustic waves as phonon beams is approximately applicable to the intermediate frequency range, so that the theoretical results presented in § 2 and § 3 can be applied to Cu for $\nu > 4.5$ Mc/sec and to n-Ge for $\nu > 210$ Mc/sec.

In § 2 we calculate acousto-electric effect by the low temperature approximation according to Van Den Beukel's method[5] who has used the high temperature approximation inadequate for the physical situations. In this connection Parmenter's theory[6] of electron-trapping by acoustic waves is criticized. In § 3 the absorption coefficient of acoustic waves by conduction electrons is calculated for metals and semiconductors. For metals Paranjape and Kittle have already calculated the coefficient which agreed very well with experiments[7]. Weinreich's relation[8] between the acousto-electric effect and the absorption coefficient is satisfied in our case, too. A limit of applicability of his relation is also discussed. In the last section § 4, new magneto-acoustic resonance phenomenon in the high frequency range is discussed in detail, which has been suggested by the present author in the previous paper[1].

§ 2. Acousto-Electric Effect in the High Frequency Range

We assume acoustic waves travelling in x-direction. Conduction electrons are scattered on the average to x-direction by acoustic phonons which constitute acoustic waves. On the other hand, thermal phonons or impurities scatter on the average conduction electrons to the opposite direction. Then the stationary current flows along x-direction. Under the open circuit condition, the stationary current is cancelled by the electromotive force which is called acousto-electromotive force. In general, we call this phenomena acousto-electric effect. Now we shall calculate the order of magnitude of acousto-electric effect at liquid helium temperature.

For simplicity we take the following four assumptions[5].

(I) *Free electron model.* The energy of an electron is given by

$$\mathrm{E}(\boldsymbol{k})=\frac{\hbar^2k^2}{2m^*}\,, \tag{2.1}$$

where $\boldsymbol{k}$ is the wave number vector of a conduction electron and m^* is its effective mass.

(II) *The presence of the relaxation time* τ. The distribution function of conduction electrons is expressed as

$$f(\boldsymbol{k})=f_0(\boldsymbol{k})-\frac{\partial f_0(\boldsymbol{k})}{\partial \mathrm{E}}\boldsymbol{k}_x\mathrm{C}(\mathrm{E})\,. \tag{2.2}$$

Here $f_0(\boldsymbol{k})$ is Fermi function. The change of the distribution function per unit time due to thermal phonons or impurities is written as follows:

$$\left(\frac{\partial f}{\partial t}\right)_{ti}=-\frac{f-f_0}{\tau}=\frac{1}{\tau}\frac{\partial f_0}{\partial \mathrm{E}}\boldsymbol{k}_x\mathrm{C}(\mathrm{E})\,. \tag{2.3}$$

We assume for simplicity

$$\frac{1}{\tau}=\mathrm{QE}^{\alpha}\,, \tag{2.4}$$

where Q is the numerical factor depending on the scattering processes of conduction electrons. In the case of the scattering by thermal phonons at low temperatures, the expression (2.3) is not valid. But for the other scattering processes the assumption (2.3) may be valid in general. The values of α are as follows:

For metals,

(a) $\alpha=-3/2$ for $\mathrm{T}>\Theta$ and

(b) $\alpha=1/2$ for $\mathrm{T}\ll\Theta$ (impurity scattering),

where Θ is Debye temperature.

For semiconductors,

(a) $\alpha=1/2$ for lattice scattering,

(b) $\alpha\cong-3/2$ for ionized impurity scattering and

(c) $\alpha=0$ for neutral impurity scattering.

(III) *The expansion of the distribution function.* We shall expand the distribution function as

$$f(\boldsymbol{k}\pm\boldsymbol{q})\cong f(\boldsymbol{k})\pm\frac{\partial f(\boldsymbol{k})}{\partial k_x}q\,. \tag{2.5}$$

To make this assumption, it is necessary to compare k_0 with q. If we take as $\nu=5\times10^8$ cyc/sec, $q=7\times10^3\,\mathrm{cm}^{-1}$ for Cu or $q=6.5\times10^3\,\mathrm{cm}^{-1}$ for n-Ge. On the other hand $k_0=m^*v_0/\hbar=1.4\times10^8\,\mathrm{cm}^{-1}$ for Cu or $k_0=3.5\times10^5\,\mathrm{cm}^{-1}$ for n-Ge. Then we can assume $|\boldsymbol{k}|\gg|\boldsymbol{q}|$ and (2.5) for metals and semiconductors at liquid helium temperature.

(IV) *The occupation number of acoustic* *phonons is larger than 1.* Then we can put

$$\mathrm{N}(\boldsymbol{q})\pm 1 \simeq \mathrm{N}(\boldsymbol{q}) \equiv \mathrm{N}\,. \tag{2.6}$$

With the use of above assumptions we shall calculate the change of the distribution function of conduction electrons due to acoustic phonons. Taking the volume of the system as unity,

$$\left(\frac{\partial f}{\partial t}\right)_{ac} = \frac{\mathrm{C}^2 q^2 \mathrm{N}}{\rho h \nu}\{[f_{\boldsymbol{k}+\boldsymbol{q}}(1-f_{\boldsymbol{k}})-f_{\boldsymbol{k}}(1-f_{\boldsymbol{k}+\boldsymbol{q}})]\Omega^{+} + [f_{\boldsymbol{k}-\boldsymbol{q}}(1-f_{\boldsymbol{k}})-f_{\boldsymbol{k}}(1-f_{\boldsymbol{k}-\boldsymbol{q}})]\Omega^{-}\}\,, \tag{2.7}$$

where C is the well-known coupling constant of conduction electrons with phonons and ρ the density of materials.
And

$$\left.\begin{aligned} &\Omega^{\pm} = \Omega(\mathrm{E}_{\boldsymbol{k}} - \mathrm{E}_{\boldsymbol{k}\pm\boldsymbol{q}} \pm h\nu) \\ &\Omega(x) = \frac{\sin(xt/\hbar)}{x/\hbar}\,. \end{aligned}\right\} \tag{2.8}$$

Using (2.5), (2.7) becomes

$$\left(\frac{\partial f}{\partial t}\right)_{ac} \cong \frac{\mathrm{C}^2 h q^3 \mathrm{N}}{4\pi^2 \rho m^* \nu} k_x \frac{\partial f_0}{\partial \mathrm{E}} (\Omega^{+} - \Omega^{-})\,. \tag{2.9}$$

Next, the change of the distribution function due to acousto-electromotive force F is given by

$$\left(\frac{\partial f}{\partial t}\right)_{el} = \frac{e\mathrm{F}}{\hbar}\cdot\frac{\partial f_0}{\partial k_x} = \frac{e\mathrm{F}\hbar}{m^*}k_x\frac{\partial f_0}{\partial \mathrm{E}}\,, \tag{2.10}$$

where e is the charge of a conduction electron.

Now we can derive the expression for C(E) with the use of Boltzmann equation

$$\left(\frac{\partial f}{\partial t}\right)_{ac} + \left(\frac{\partial f}{\partial t}\right)_{el} + \left(\frac{\partial f}{\partial t}\right)_{ti} = 0\,; \tag{2.11}$$

i.e.

$$\mathrm{C(E)} = -\frac{he}{2\pi \mathrm{Q}\mathrm{E}^{\alpha} m^*}\left[\mathrm{F} + \frac{\mathrm{C}^2 q^3 \mathrm{N}}{2\pi\rho\nu e}(\Omega^{+} - \Omega^{-})\right]. \tag{2.12}$$

From the condition that there is no electric current,

$$\int f_{\boldsymbol{k}} k_x d\boldsymbol{k} = 0\,. \tag{2.13}$$

Substituting (2.2) and (2.12) into (2.13) and solving it for F,

$$\mathrm{F} = \frac{\mathrm{C}^2 q^3 \mathrm{N}}{2\pi\rho\nu e}\cdot\frac{(\mathrm{K}^{-} - \mathrm{K}^{+})}{\mathrm{K}^0}\,, \tag{2.14}$$

where

$$\mathrm{K}^0 = \int \mathrm{E}^{-\alpha}\frac{\partial f_0}{\partial \mathrm{E}}\cdot k_x^2 d\boldsymbol{k} \quad \text{and} \quad \mathrm{K}^{\pm} = \int \mathrm{E}^{-\alpha}\frac{\partial f_0}{\partial \mathrm{E}}\cdot \boldsymbol{k}_x^2 \Omega^{\pm} d\boldsymbol{k}\,. \tag{2.15}$$

Now, we shall calculate K⁰, K± for metals and semiconductors. The calculation of K⁰ is carried out very easily and gives

$$\mathrm{K}^0 = \begin{cases} -\dfrac{2\pi(2m^*)^{5/2}}{3\hbar^5}\cdot \mathrm{E}_0^{(3/2)-\alpha} & \text{for metals and} \\ -\dfrac{2\pi(2m^*)^{5/2}}{3\hbar^5}\cdot \Gamma\left(\dfrac{5}{2}-\alpha\right)\cdot(\kappa T)^{(3/2)-\alpha}\cdot \exp(\mathrm{E}_0/\kappa T) & \text{for semiconductors}\,, \end{cases} \tag{2.16}$$

where E_0 is Fermi energy and $\Gamma(n)$ is gamma function of the n-th order:

$$\Gamma(n) = \int_0^{\infty} x^{n-1} e^{-x} dx\,. \tag{2.17}$$

The calculation of K± is as follows: let us introduce the polar coordinate (k, θ, φ) in $\boldsymbol{k}$-space and take the polar axis parallel to $\boldsymbol{q}$ (i.e. $\boldsymbol{k}_x$). Then

$$\mathrm{K}^{\pm} = \int \mathrm{E}^{-\alpha}\frac{\partial f_0}{\partial \mathrm{E}} k^4 \cos^2\theta\cdot\Omega^{\pm}\left(\mp\frac{\hbar^2 kq}{m^*}\cos\theta - \frac{\hbar^2 q^2}{2m^*} \pm h\nu\right) dk \sin\theta d\theta d\varphi\,. \tag{2.18}$$

Since $\Omega^{\pm}$ has the properties similar to δ-function, it will be allowed to put

$$\cos^2\theta = \left[\frac{4\pi m^*\nu \mp \hbar q^2}{2\hbar kq}\right]^2, \tag{2.19}$$

When the relations[9),

$$\frac{ks}{\pi} > \nu \qquad \text{or} \qquad \frac{2m^*s^2}{h}\,, \tag{2.20}$$

are satisfied,

$$\int_0^\pi \Omega^\pm \sin\theta d\theta = \frac{\pi m^*}{\hbar kq}\,. \tag{2.21}$$

With the use of (2.19) and (2.21) we get

$$\mathrm{K}^\pm = -\frac{\pi^2 m^{*2}(4\pi m^*\nu \mp \hbar q^2)^2}{2\hbar^5 q^3}\mathrm{E}_0^{-\alpha} \tag{2.22}$$

for metals and

$$\mathrm{K}^\pm = -\frac{\pi^2 m^{*2}(4\pi m^*\nu \mp \hbar q^2)^2 \Gamma(1-\alpha)}{2\hbar^5 q^3}(\kappa T)^{-\alpha}\cdot \exp\left(E_0/\kappa T\right) \tag{2.23}$$

for semiconductors. That the relations (2.20) can be satisfied is shown by the following estimations:

$$\begin{cases} \dfrac{k_0 s}{\pi} = 2\times 10^{13} \quad \text{for Cu}\,, \quad 5.6\times 10^{10} \quad \text{for } n\text{-Ge}\,, \\ \nu = 5\times 10^8 \quad \text{and} \\ \dfrac{2m^*s^2}{h} = 5\times 10^{10} \quad \text{for Cu}\,, \quad 6\times 10^9 \quad \text{for } n\text{-Ge}\,. \end{cases}$$

After all, from (2.14), (2.16), (2.22) and (2.23)

$$\mathrm{F} = \begin{cases} \dfrac{3\pi^2 \mathrm{C}^2 m^{*1/2}\nu}{\sqrt{2}\,\rho e s^3 \mathrm{E}_0^{3/2}}\gamma & \text{for metals} \\ \dfrac{3\pi^2 \mathrm{C}^2 m^{*1/2}\nu}{\sqrt{2}\,\rho e s^3 (\kappa T)^{3/2}} \cdot \dfrac{\Gamma(1-\alpha)}{\Gamma(\frac{5}{2}-\alpha)}\cdot\gamma & \text{for semiconductors}\,, \end{cases} \tag{2.24}$$

where

$$\gamma = \mathrm{N}h\nu s \tag{2.25}$$

is the acoustic flow intensity. It is interesting to note that for metals F is temperature-independent and agrees with the values obtained by the high temperature approximation. For semiconductors F differs from Van Den Beukel's value[5)] only by the factor of $\Gamma(1-\alpha)/\Gamma(\frac{5}{2}-\alpha)$ (See Table II).

Table II. The numerical values of $\Gamma(1-\alpha)/\Gamma(\frac{5}{2}-\alpha)$.

	α	$\Gamma(1-\alpha)/\Gamma(\frac{5}{2}-\alpha)$
lattice scattering	1/2	$\sqrt{\pi}$
ionized impurity scattering	−3/2	$\sqrt{\pi}/8$
neutral impurity scattering	0	$4/3\sqrt{\pi}$

Now let us estimate the order of magnitude of acousto-electromotive force, taking the unit of F and γ as volts/cm and watts/cm² respectively. When $\nu = 5\times 10^8$ cyc/sec,

$$\mathrm{F} = \begin{cases} 6.5\times 10^{-9}\gamma & \text{for Cu} \\ 1.1\times 10^{-4}\gamma & \text{for } n\text{-Ge} \end{cases} \tag{2.26}$$

where it was assumed that C=6.2 ev for Cu and C=1.7 ev, $\alpha = -3/2$ for n-Ge. Even at the present time, it may be possible to detect the effect for n-Ge.

Finally we criticize Parmenter's theory[6] of electrons trapped by acoustic waves in the high frequency range. His theory leads to

$$F=10^{-6}\gamma^{3/4} \qquad \text{for Cu} \tag{2.27}$$

under the same conditions with (2.26). But we may conclude that Parmenter's theory cannot be applied to real systems for two reasons.

(1) Parmenter neglected *the scattering processes of trapped electrons by thermal phonons or impurities* which are present even at very low temperatures.

(2) Parmenter's mechanism producing the relatively larger value of F, (2.27), may contribute to the absorption of acoustic waves. On the contrary, the experimental value[7] of the absorption coefficient is in agreement with the theoretical value due to the electron-phonon interaction and has *no contribution from his mechanism.* Our results (2.24) or (2.26) satisfies Weinreich's phenomenological relation between acousto-electric effect and the absorption coefficient (see the next section), and so (2.24) is verified *indirectly* by the experiment of the absorption.

§ 3. Absorption of Acoustic Phonon Beam by Conduction Electrons

With the use of the approximations of § 2, we shall calculate the change of the occupation number N of acoustic phonons by conduction electrons. Similar arguments leading to (2.7) give

$$\left(\frac{\partial N}{\partial t}\right)_{el}=\frac{C^2q^2N}{\rho h\nu}\sum_k\{[f_{k+q}(1-f_k)-f_k(1-f_{k+q})]\Omega^+ + [f_k(1-f_{k-q})-f_{k-q}(1-f_k)]\Omega^-\}\ . \tag{3.1}$$

From (2.5) and $\sum_k \to 2\int dk \Big/ (2\pi)^3$,

$$\left(\frac{\partial N}{\partial t}\right)_{el}=\frac{\hbar C^2q^3N}{8\pi^4m^*\rho\nu}(K^+ + K^-) \tag{3.2}$$

where

$$K^{\pm}=\int\frac{\partial f}{\partial E}k_x\Omega^{\pm}dk\ . \tag{3.3}$$

In the same method as § 2, we get

$$K^{\pm}=\begin{cases} -\dfrac{\pi^2m^{*2}(4\pi m^*\nu\mp\hbar q^2)}{\hbar^4q^2} & \text{for metals ,} \\ -\dfrac{\pi^2m^{*2}(4\pi m^*\nu\mp\hbar q^2)}{\hbar^4q^2}\exp(E_0/\kappa T) & \text{for semiconductors .}\end{cases} \tag{3.4}$$

Substituting (3.4) into (3.2)

$$\left(\frac{\partial N}{\partial t}\right)_{el}=-\frac{2m^{*2}C^2\nu}{\rho\hbar^3s}N \quad \text{and} \quad -\frac{2m^{*2}C^2\nu}{\rho\hbar^3s}N\exp(E_0/\kappa T)\ . \tag{3.5}$$

As is well known the absorption coefficient of acoustic waves Λ is defined by

$$\frac{\partial U}{\partial t}=-\Lambda\gamma\ , \tag{3.6}$$

where

$$U=Nh\nu \tag{3.7}$$

is the acoustic energy density. Making the comparison of (3.5) with (3.6) we get the absorption coefficient by conduction electrons,

$$\Lambda=\begin{cases}\dfrac{2m^{*2}C^2\nu}{\rho\hbar^3s^2} & \text{for metals ,}\\[2ex] \dfrac{2m^{*2}C^2\nu}{\rho\hbar^3s^2}\exp(E_0/\kappa T) & \text{for semiconductors .}\end{cases}\tag{3.8}$$

The estimation of (3.8) under the same conditions as (2.26) gives

$$\Lambda=\begin{cases}20\ \text{nepers/cm} & \text{for Cu}\\ 0.02\times\exp(E_0/\kappa T)\ \text{nepers/cm} & \text{for } n\text{-Ge .}\end{cases}\tag{3.9}$$

It has been shown that the theoretical value of Λ in metals is in good agreement with the experiments at low temperatures in the intermediate frequency range. However, it will be difficult in semiconductors to detect the absorption by conduction electrons owing to the small factor of $\exp(E_0/\kappa T)$.

Recently, Weinreich[8)] has proposed a general relationship between the absorption coefficient of acoustic waves and acousto-electromotive force:

$$\Lambda=\delta\frac{nes}{\gamma}F\tag{3.10}$$

where n is the number density of conduction electrons and δ is the numerical factor depending on the scattering processes of conduction electrons. The relation (3.10) can be obtained easily by the following considerations. The momentum transfers of acoustic waves to conduction electrons occur with the energy losses. Then

$$\frac{dU}{dt}=s\frac{dp_{ac}}{dt}=-ns\frac{dp_{el}}{dt}\ .\tag{3.11}$$

where p_{ac} and p_{el} are the momentum of waves and an electron respectively and the momentum conservation was assumed.

From the acceleration equation, $dp_{el}/dt=eF$,

$$\frac{dU}{dt}=-nesF\ .\tag{3.12}$$

Comparing (3.12) with (3.6) we can get Weinreich's relation.

It is proved in our case that Weinreich's relation is satisfied if we put[11)]

$$n=\begin{cases}\dfrac{2^{3/2}}{3\pi^2}\left(\dfrac{m^*E_0}{\hbar^2}\right)^{3/2} & \text{for metals ,}\\[2ex] \dfrac{1}{2^{1/2}\pi^{3/2}}\left(\dfrac{m^*kT}{\hbar^2}\right)^{3/2}\exp(E_0/\kappa T) & \text{for semiconductors}\end{cases}\tag{3.13}$$

and choose δ as

$$\delta=\begin{cases}1 & \text{for metals ,}\\[1ex] \dfrac{4}{3\sqrt{\pi}}\cdot\dfrac{\Gamma(\frac{5}{2}-\alpha)}{\Gamma(1-\alpha)} & \text{for semiconductors .}\end{cases}\tag{3·14}$$

On the other hand, the other relationship may be present which connect Λ with F. This relationship combines with the process of Ohmic losses of the energy of conduction electrons by thermal phonons or impurities. Then instead of (3.12) we obtain

$$\frac{dU}{dt}=-\sigma F^2\ .\tag{3.15}$$

Here we denote σ as the electrical conductivity. Again making the comparison of (3.15) with (3.6), the relation

$$\Lambda=\delta\frac{\sigma}{\gamma}F^2=\delta\frac{nev_d}{\gamma}F\tag{3.16}$$

is obtained where v_d is the drift velocity of conduction electrons given rise by acoustic waves. Ohmic relation (3.16) was used essentially by Pippard in his theory[1)] of the absorption of acoustic waves in the low frequency range; however, F is *the oscillating field* contrary to the d.c. field in the high frequency range.

Why Weinreich's and Ohmic relations are separately satisfied in the high and the low frequency ranges can be understood as follows. First, it is necessary to point out the following facts. Since in the low frequency range the mean-free path of conduction electrons l

is smaller than the wave length of acoustic waves λ, conduction electrons suffer *the oscillating forces*. Then the electronic current relative to the ionic motion or acousto-electric field cancelling the current oscillate like acoustic waves, i.e.

$$\mathrm{F}=\mathrm{F}_{0s}+\mathrm{F}_{DC}\,,\quad \mathrm{F}_{0s}\gg\mathrm{F}_{DC}\,. \tag{3.17}$$

In the other case, since $l\gg\lambda$ and *the width of the wave packets of monochromatic waves must be larger than* λ[6], conduction electrons suffer the *d.c. forces*: i.e.

$$\mathrm{F}=\mathrm{F}_{0s}+\mathrm{F}_{DC}\,,\quad \mathrm{F}_{0s}\ll\mathrm{F}_{DC}\,. \tag{3.18}$$

In fact, the treatment of acoustic waves as acoustic phonon beam is the approximation neglecting F_{0s}.

From the above discussions, the absorption coefficient Λ connect mainly with F_{0s} and F_{DC} in the low and high frequency ranges respectively. In general, the losses of energy (or momentum) of acoustic waves take place in two processes shown in Fig. 1.

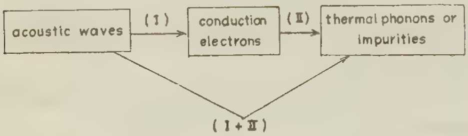

Fig. 1. The processes of the energy loss of acoustic waves.

Undoubtedly Weinreich's relation concerns only with process (I) and Ohmic relation with process (I+II). In the high frequency range Λ is determined by process (I) because $\mathrm{F}\cong\mathrm{F}_{DC}$. In fact, since $\mathrm{F}\ll 1$ volt/cm, $v_d\ll s$. Then for the same F (3.16) gives smaller value of Λ than (3.10). The temperature of the system of conduction electrons may rise during acoustic waves are passing through materials.

The circumstances are very different in the low frequency range. Since F is oscillating like acoustic waves, in process (I) the energy is *going and coming* between acoustic waves and conduction electrons. Then the net losses of energy is determined by process (I+II) i.e. Ohmic relation.

§ 4. Magneto-Acoustic Resonance in the High Frequency Range

Recently Pippard[2] has proposed a concept of magneto-acoustic resonance to interpret the experiments of Bömmel[11] who detected the resonance-like behavior of the absorption coefficient in a magnetic field. Morse *et. al.*[12], however, analyzed their experiments with some different concepts. But as was pointed out by the present author[1], Pippard's and Morse *et. al.*'s concepts are applicable only to the intermediate frequency range and new magneto-acoustic resonance may be expected in the high frequency range. In this section we shall discuss qualitatively new magneto-acoustic resonance of the latter type.

When a magnetic field is applied in z-direction, the wave function and the energy eigenvalue of a conduction electron are given by[13]

$$\psi(n,\ x_0,\ k_z)=\varphi_n(x-x_0)\exp\left(-\frac{m\omega_c}{\hbar}x_0y\right)\exp(-ik_z\cdot z) \tag{4.1}$$

$$\mathrm{E}(n,\ x_0,\ k_z)=\hbar\omega_c\left(n+\frac{1}{2}\right)+\frac{\hbar^2k_z^2}{2m}\,, \tag{4.2}$$

if we choose the vector potential as $\mathrm{A}_x=\mathrm{A}_z=0$, $\mathrm{A}_y=\mathrm{H}x$. Here

$$x_0=-\frac{\hbar k_y}{m\omega_c}\,,\qquad \omega_c=\frac{e\mathrm{H}}{mc} \tag{4.3}$$

and $\varphi_n(x-x_0)$ represents the n-th order wave function of a harmonic oscillator centered at x_0. The change of the occupation number of acoustic phonons by conduction electrons is given, similar to (3.1), by

$$\begin{aligned}\left(\frac{\partial\mathrm{N}}{\partial t}\right)_{el}=&\frac{\mathrm{C}^2q^2\mathrm{N}}{\rho h\nu}\sum_{n,x_0,k_z}W_{n,n'}\\&\times\left\{\left[f\left(n',\,x_0-\frac{\hbar q_y}{m\omega_c},\,k_z+q_z\right)(1-f(n,\,x_0,\,k_z))-f(n,\,x_0,\,k_z)\left(1-f\left(n',\,x_0-\frac{\hbar q_y}{m\omega_c},\,k_z+q_z\right)\right)\right]\Omega^+\right.\\&\left.+\left[f(n,\,x_0,\,k_z)\left(1-f\left(n',\,x_0+\frac{\hbar q_y}{m\omega_c},\,k_z-q_z\right)\right)-f\left(n',\,x_0+\frac{\hbar q_y}{m\omega_c},\,k_z-q_z\right)(1-f(n,\,x_0,\,k_z))\right]\Omega^-\right\}\end{aligned} \tag{4.4}$$

where

$$\left.\begin{aligned} \Omega^{+}&=\Omega\left\{\mathrm{E}(n,\ x_0,\ k_z)-\mathrm{E}\left(n',\ x_0-\frac{\hbar q_y}{m\omega_c},\ k_z+q_z\right)+h\nu\right\}, \\ \Omega^{-}&=\Omega\left\{\mathrm{E}(n,\ x_0,\ k_z)-\mathrm{E}\left(n',\ x_0+\frac{\hbar q_y}{m\omega_c},\ k_z-q_z\right)-h\nu\right\} \end{aligned}\right\} \tag{4.5}$$

and

$$\left.\begin{aligned} W_{nn'}&=|J_{nn'}|^2, \\ J_{nn'}&=\int_{-\infty}^{\infty}\exp(iq_x x)\cdot\varphi_n(x-x_0)\cdot\varphi_{n'}\left(x-x_0\pm\frac{\hbar q_y}{m\omega_c}\right)dx \end{aligned}\right\} \tag{4.6}$$

Though it is very difficult to compute (4.4) exactly, the following qualitative conclusions can be obtained. When acoustic phonon beam is travelling in the direction perpendicular to the magnetic field, $q_z \doteqdot 0$, y-component of phonon beam changes the center x_0 of conduction electrons and x-component produce the transition between oscillator states of electrons. Asymmetry of the role of x- and y-component of phonon beam results from the asymmetrical choice of the vector potential. Therefore, in general, the transverse component of phonon beam gives rise the change in both x_0 and n. From (4.5) the integral must be finite only when

$$\mathrm{E}(n,\ x_0,\ k_z)-\mathrm{E}\left(n',\ x_0\mp\frac{\hbar q_y}{m\omega_c},\ k_z\right)\pm h\nu=0\ . \tag{4.7}$$

Substituting (4.2) into (4.7), we get the condition of magneto-acoustic resonance in the high frequency range:

$$|n-n'|\hbar\omega_c=\hbar\omega\ , \tag{4.8}$$

which is different from the resonance in the intermediate frequency range by a factor[1] of $(\pi/2)(s/v_0)$. It is interesting to note that cyclotron resonance[14] in semiconductors corresponds rather to magneto-acoustic resonance in the high frequency range.

When acoustic phonon beam is travelling in z-direction, the transition between oscillator states does not occur. The resonance-like behavior cannot be expected in this case.

It will be important to point out that magneto-acoustic resonance occurs not only in the absorption of waves but in acousto-electric effect. Physical considerations give a picture that under the resonance condition the component of electronic momentum parallel to $\boldsymbol{q}$ will rapidly increase receiving the acoustic momentum, then the current or acousto-electromotive force will have *the resonance-like behaviors.*

§ 5. Concluding Remarks

As was mentioned in § 1, the high frequency range has not been achieved up to the present. It is, however, expected to make the experimental proof of our theory in future.

From the experimental point of view, it is easier for metals to detect (1) the absorption coefficient by conduction electrons, (2) magneto-acoustic resonance in the absorption of waves. On the contrary, however, it is easier

Table III. The main results obtained in this paper.

On the Dielectric Losses in Impure Ionic Crystals

By Tosiyuki NINOMIYA*

Department of Applied Physics, Faculty of Engineering, University of Tokyo, Tokyo

(Received August 28, 1958)

Mechanisms of the dielectric loss due to vacancy-impurity complexes are re-examined by considering effects of polarization of both impurity- and lattice ions. We find that these effects cause some amounts of dielectric loss and a loss curve is well represented by a Debye type one. We point out that these effects may remove the quantitative discrepancy between the previous theory and experiments.

§ 1. Introduction

Ionic crystals containing divalent impurity cations show dielectric loss peaks at low temperature in low frequency range. These loss peaks are nearly of Debye type and considered to be those due to impurity-vacancy complexes.

The relation between the number of complexes and the magnitude of a loss peak has been given as[1)]

$$\tan\delta=\frac{8\pi e^2a^2}{3\varepsilon kT}N_c\frac{\omega\tau}{1+\omega^2\tau^2}\,, \tag{1.1}$$

where a is the anion-cation distance in the solvent crystal, N_c the number of complexes per unit volume, ε the dielectric constant and τ the relaxation time.

Teltow and Wilke[2)] used this equation to analyse their result of measurements on the dielectric loss in silver bromide crystals containing small amounts of cadmium bromide and found that the calculated number of complexes is about two and a half times smaller than the total number of impurity ions, although their experimental result suggested that practically all of the impurity ions were associated with the vacancies. Similar results have been obtained in sodium chloride crystals by Haven[3].

---

* Present Address: the Institute for Solid State Physics, University of Tokyo, Tokyo, Japan.

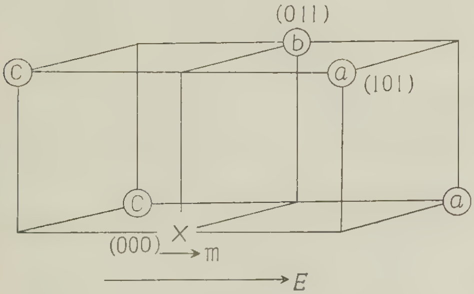
This discrepancy is considered to be partly due to the over-simplification of the model used in deriving Eq. (1.1). Lidiard has explored the possibility of explanation of this, but the reason still remains uncertain. The purpose of this paper is to present another possibility.

§ 2. Polarization of Complexes

When a pure crystal is polarized, we may imagine that the positive ions remain in their original positions, while the negatives are displaced. The displacement of the ions may be considered to have the effect of introducing a point dipole at each negative lattice point. In a crystal containing foreign cations a displacement of an impurity ion relative to the negative ions is different from that of the cations of the host crystal because of its different amount of charge or ionic radius. This different displacement introduces a dipole m at the site of impurity ion. In this section this effect will be taken into account. In Fig. 1 a part of the twelve nearest neighbouring positions of an impurity ion in a lattice of NaCl type is shown. The potential energies at various points due to the dipole, the moment of which is parallel to the external field, are as follows:

$$\left.\begin{aligned} &\varphi(101)=0.354m/a^2\,, \\ &\varphi\left(\frac{1}{2}\,\frac{1}{2}\,\frac{3}{2}\right)=0.110m/a^2\,, \\ &\varphi(011)=0\,, \qquad \text{etc.}\,. \end{aligned}\right\} \tag{2.1}$$

Therefore, this dipole restricts a change of orientation of the complex, part of which the impurity ion is.



× : impurity ion
C : nearest neighbour

Fig. 1. A part of the twelve nearest cation neighbours to an impurity ion in a lattice of NaCl type. If the impurity ion is part of a complex, one of these twelve sites will be vacant.

Secondly the effect is considered which arises from a change of dipole moment of the complexes. An impurity ion which is associated with a cation vacancy is attracted towards the vacancy electrostatically. The polarization of the impurity ion due to the vacancy differs from that of a nearest neighbour cation to the vacancy and this also introduces a dipole $-\sqrt{2}\,\beta ea$, the moment of which is parallel to that of the complex, at the impurity ion site.

When a cation moves from the (101) site to the (011) via the $\left(\frac{1}{2}\,\frac{1}{2}\,\frac{3}{2}\right)^*$, it must surmount a potential barrier, the height of which is

$$U+\frac{1}{2}eaE-(0.354-0.110)em/a^2 -\frac{1}{2}\left(E+\frac{4\pi}{3}P\right)\beta ea\,, \tag{2.2}$$

where U is the height of the barrier in the absence of an external field and P is the polarization of the crystal. The third term of the formula (2.2) is that which results from the presence of the potential of constraint given by Eq. (2.1) and the fourth term is the work done by the external field when the dipole $\sqrt{2}\,\beta ea$ follows the motion of the vacancy to change its orientation.** Approximately

$$E+\frac{4\pi}{3}P=\frac{\varepsilon+2}{3}E\,, \tag{2.3}$$

where ε is the dielectric constant of the pure solvent crystal. m is proportional to the strength of the external field,

$$m=\alpha E\,. \tag{2.4}$$

---

* Haven suggested that a positive ion passes near the tetrahedral hole on its way from one site to another. Even if an ion migrates via any other point, the equation (2.15) which gives the polarization of the complexes does not change.

** Note that the Lorentz internal field acts on an ion to make polarize but does no work when an ion jumps from one lattice site to another[4]. Strictly speaking E is replaced by $E+\frac{4\pi}{3}(P_i+P_c)$ in the second term of the formula (2.2). But, in the case of usual concentration of impurity, $\frac{4\pi}{3}(P_i+P_c)$ is far smaller than E and can be neglected.

Inserting this into the formula (2.2), we have

$$U+\frac{1}{2}(1+p)eaE \tag{2.5}$$

as the height of barrier, where

$$p=-0.488\alpha/a^3-\frac{\varepsilon+2}{3}\beta\ .$$

The height of the potential barrier to surmount on the way to the (101) site from the (011) is

$$U=\frac{1}{2}(1+q)eaE\ , \tag{2.6}$$

where

$$q=-0.220\alpha/a^3-\frac{\varepsilon+2}{3}\beta\ .$$

Those for other processes of vacancy migration are treated similarly.

Next the exchange of positions between the impurity ion and its attached vacancy is considered. When the vacancy is at the (101) site, the electrostatic interaction energy of the dipole m with the vacancy is $-0.354me/a^2$, since the cation vacancy has the charge $-e$ effectively. The height of the barrier which the impurity ion must surmount in the exchange process is

$$\begin{aligned} U'-eaE+\varphi+0.354me/a^2+\frac{\varepsilon+2}{3}\beta eaE \\ =U'-(1+p')eaE\ , \end{aligned} \tag{2.7}$$

where

$$p'=-\left(0.354\alpha/a^3+\varphi/eaE+\frac{\varepsilon+2}{3}\beta\right)$$

and φ is the potential energy of the dipole m at the peak of the barrier. The activation energy for the inverse process is

$$\begin{aligned} U'+eaE+\varphi-0.354me/a^2-\frac{\varepsilon+2}{3}\beta eaE \\ =U'+(1+q')eaE\ , \end{aligned} \tag{2.8}$$

where

$$q'=-\left(0.354\alpha/a^3-\varphi/eaE+\frac{\varepsilon+2}{3}\beta\right).$$

Because φ is proportional to m and, therefore, to E, p' and q' are independent of E.

The equations giving the numbers n_a, n_b, n_c of dipoles with (a), (b), (c) orientations are

$$\begin{aligned} \frac{dn_a}{dt}=&-2n_aw_1\left\{1+\frac{ea}{2kT}(1+q)E\right\}+2n_bw_1\left\{1-\frac{ea}{2kT}(1+p)E\right\} \\ &-n_aw_2\left\{1+\frac{ea}{kT}(1+p')E\right\}+n_cw_2\left\{1-\frac{ea}{kT}(1+q')E\right\}, \end{aligned} \tag{2.9}$$

$$\frac{dn_b}{dt}=2n_aw_1\left\{1+\frac{ea}{2kT}(1+q)E\right\}-4n_bw_1+2n_cw_1\left\{1-\frac{ea}{2kT}(1+q)E\right\}, \tag{2.10}$$

$$\begin{aligned} \frac{dn_c}{dt}=&2n_bw_1\left\{1+\frac{ea}{2kT}(1+p)E\right\}-2n_cw_1\left\{1-\frac{ea}{2kT}(1+q)E\right\} \\ &+n_aw_2\left\{1+\frac{ea}{kT}(1+p')E\right\}-n_cw_2\left\{1-\frac{ea}{kT}(1+q')E\right\}, \end{aligned} \tag{2.11}$$

where w_1 is the jump frequency with which a vacancy will jump from one attached position to another particular attached position in the absence of the external field and w_2 is that with which an impurity ion and its attached vacancy will exchange their positions. When E varies harmonically with time,

$$E=E_0\exp(i\omega t)\ ,$$

the steady state solutions of (2.9) to (2.11) to the first order in E are

$$n_a=\frac{1}{3}N_c-E_0\exp(i\omega t)\frac{2eaN_c}{3kT}\left\{\left(1+\frac{p+q}{2}\right)w_1+\left(1+\frac{p'+q'}{2}\right)w_2\right\}\Big/2(w_1+w_2)+i\omega\ , \tag{2.12}$$

$$n_b=\frac{1}{3}N_c\ , \tag{2.13}$$

$$n_c=\frac{1}{3}N_c+E_0\exp(i\omega t)\frac{2eaN_c}{3kT}\left\{\left(1+\frac{p+q}{2}\right)w_1+\left(1+\frac{p'+q'}{2}\right)w_2\right\}\Big/2(w_1+w_2)+i\omega\ , \tag{2.14}$$

where N_c is the total number of the complexes per unit volume and

$$p+q=p'+q'=-\left[0.708\alpha/a^3+\frac{2(\varepsilon+2)}{3}\beta\right].$$

The polarization of the complexes is then

$$\begin{aligned}P_c&=ea(n_c-n_a)\\&=\frac{2e^2a^2N_c}{3kT}E_0\exp(i\omega t)\left(1+\frac{p+q}{2}\right)\Big/1+\frac{i\omega}{2(w_1+w_2)}\,.\end{aligned}\tag{2.15}$$

§ 3. Polarization of the Lattice Ions of the Host Crystal and of Impurity Ions

The total polarization of a crystal is the sum of three parts; the polarization of the complexes, of the lattice ions of the host crystal and of the impurity ions. The first has been obtained in Sec. 2. In this section the last two are considered.

The field which acts on the lattice ions to make polarize is

$$F_l=E+\frac{4\pi}{3}(P_l+P_i)\,,\tag{3.1}$$

where P_l is the polarization of the host crystal lattice ions and P_i is that of the impurity ions. Then we obtain

$$P_l=\frac{\varepsilon-1}{4\pi}E+\frac{\varepsilon-1}{3}P_i\,.\tag{3.2}$$

When we let α_i be the polarizability of an impurity ion,

$$\begin{aligned}P_i&=N_i\alpha_i\left[E+\frac{4\pi}{3}(P_l+P_i+P_c)\right]-\beta P_c\\&\approx N_i\alpha_i\left(E+\frac{4\pi}{3}P_l\right)-\beta P_c\,,\end{aligned}\tag{3.3}$$

where N_i is the number of the impurity ions per unit volume.

The total polarization is

$$\begin{aligned}P&=P_c+P_l+P_i\\&=\frac{\varepsilon-1}{4\pi}E+\frac{\varepsilon+2}{3}N_i\alpha_i\left(E+\frac{4\pi}{3}P_l\right)\\&\quad+\left(1-\frac{\varepsilon+2}{3}\right)P_c\end{aligned}\tag{3.4}$$

and the dielectric loss due to the complexes is given as

$$\begin{aligned}&\tan\delta\\&=\left(1-\frac{\varepsilon+2}{3}\beta\right)\left(1+\frac{p+q}{2}\right)\frac{8\pi e^2a^2}{3\varepsilon kT}N_c\frac{\tau\omega}{1+\tau^2\omega^2}\,,\end{aligned}\tag{3.5}$$

where $\tau=1/2(w_1+w_2)$. This expression gives the value which is $\left(1-\frac{\varepsilon+2}{3}\beta\right)\left(1+\frac{p+q}{2}\right)$ times larger than that used usually.

§ 4. Discussions

It is difficult to make an accurate evaluation of $\left(1-\frac{\varepsilon+2}{3}\beta\right)\left(1+\frac{p+q}{2}\right)$, unless the calculation is made on the basis of the Born-Mayer model. In this situation we shall make a rather rough estimation of it for silver bromide and compare it with the results of measurements of Teltow and Wilke. It is obtained from the continuum model that a nearest cation neighbour to a vacancy is displaced by $\frac{1}{8\pi}\left(1-\frac{\varepsilon_0}{\varepsilon}\right)$ towards the vacancy. If a displacement of an impurity ion, which is part of a complex, is same to this, β is obtained to be about 0.02. However, the displacement of the ion can be expected to be a little larger, when we calculate it on the basis of the discrete model, and the impurity ion is attracted more strongly to the vacancy than the silver ion because of its double charge. Therefore, it seems reasonable to estimate that β becomes about 0.03.

On the other hand, when an external field is applied, the displacement of the positive ions relative to the negatives is given as $\frac{a^3}{2\pi e}(\varepsilon-\varepsilon_0)E$. Since the electrostatic force which acts on an impurity ion to make polarize is twice times that for a silver ion, the displacement of an impurity cadmium ion may be larger than that of silver ions. But the six nearest anion neighbours to the impurity ion are displaced inwards, and there may exist a larger repulsive interaction between the anions and the foreign ion. Therefore, the displacement of the impurity ion due to an external field may not be able to be twice times that of a silver ion. When the ratio of a displacement of an impurity ion to that of a silver ion is 1.5 and 1.25, $0.708\alpha/2a^3$ has the value of about 0.48 and 0.24 respectively. Using that $\beta\sim 0.03$, the value of

$$\left(1-\frac{\varepsilon+2}{3}\beta\right)\cdot\left(1+\frac{p+q}{2}\right)$$

is shown in Table I. In the above estimation of m and β, the contribution from the differring electronic polarizability is neglected, since this is considered to be small.

Table I. Values of the correction factor.

The ratio of amount of displacement	$\left(1-\frac{\varepsilon+2}{3}\beta\right)\left(1+\frac{p+q}{2}\right)$
1.5	0.31
1.25	0.52

The correction factor is required to be about 0.4 from the result of measurements of Teltow and Wilke, if all the vacancies are associated with the impurity ions under the conditions of their experiments. Therefore, if the amount of displacement of a cadmium ion is 1.25 to 1.5 times larger than that of a silver ion under an external field, the experimental result can be explained, and this amount seems not unreasonable.

If the observed loss curve is wider than a simple Debye curve as in the case of alkali halide crystals[5)], although this is not sure in the data of Teltow and Wilke, the number calculated from the peak height is ought to be smaller than the number of complexes actually present. Then the correction factor required is larger than 0.4 and a smaller displacement of an impurity ion is enough to explain the discrepancy.

§5. Conclusion

In the calculation of the magnitude of dielectric loss due to impurity-vacancy complexes, the effect of polarization of both impurity and lattice ions is investigated. This leads to a change of the magnitude of the loss, without shift of its peak frequency in the isothermals of loss plotted against the frequency. It may be possible to explain Teltow and Wilke's work by considering the effects mentioned above, although an accurate value of the correction factor can not be obtained, unless we perform a detailed computation on the basis of Born-Mayer model. The result of such a calculation on alkali halide crystals will be published later.

Acknowledgement

I would like to express my sincere thanks to Professor Y. Suge and Professor T. Inui for their guidance and encouragement. I am also much indebted to Dr. A. B. Lidiard and Dr. S. Sonoike for many valuable discussions.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 14, No. 1, JANUARY, 1959

On the Theory of the Thermoelectricity in Two-Band Semiconductors

By Eijirō HAGA

Department of Physics, Faculty of Science, Niigata University, Niigata

(Received September 3, 1958)

In many literatures the thermoelectromotive force of a circuit composed of two different conductors is expressed by an integral of the field $\oint\vec{E}\cdot\vec{dl}$ along the circuit with two junctions of different temperature. This definition is not free from ambiguity when we deal with the thermoelectricity of two-band semiconductors. In the present paper a theory of the thermoelectricity of two-band semiconductors is developed with consideration of temperature dependence of the gap energy. The Thomson relations are proved to be satisfied.

§ 1. Introduction

Let us imagine a circuit which is composed of two kinds of conductors *I* and *II*. They are connected with two junctions (x_1 and x_2, respectively), whose temperature is kept constant (T_1 and T_2, respectively; $T_2>T_1$). In many literatures on the theory of thermoelectricity the thermoelectromotive force of such a circuit is identified with the electric field integrated along the circuit

$$\Theta_{I,II}(T_1,\ T_2)=-\int_{x_0}^{x_3}E_x\,dx \qquad (1)$$

under the subsidiary condition that the current is zero.

First we consider n-type semiconductors or single-band metals with an assumption that the position of the band edge of the conduction band does not vary with temperature. Then, the electric field is given by

$$-eE_x=T\frac{d}{dx}\frac{\mu}{T}+\frac{K_2}{TK_1}\frac{dT}{dx}\,, \qquad (2)$$

where μ is the Fermi level *measured from the bottom of the conduction band* and

$$K_n=-\frac{1}{4\pi^3}\int\tau v_x{}^2\mathcal{E}^{n-1}\frac{\partial f_0}{\partial\mathcal{E}}\,d\Omega\,. \qquad (3)$$

Here f_0 is the Fermi distribution function, $d\Omega$ the volume element in the reduced wave vector space and other notations are as ordinary. Integrating Eq. (2) along the circuit, we have by partial integration

$$-e\int_{x_0}^{x_3}E_x dx=[\mu]_{x_0}^{x_3}+\int_{x_0}^{x_3}\frac{1}{T}\left(\frac{K_2}{K_1}-\mu\right)\frac{dT}{dx}dx\,. \qquad (4)$$

In many literatures the first term in the above is tacitly assumed to be zero. This, however, is not true as far as the integration is carried out along the interior of the conductors excluding junctions. Instead we have

$$[\mu]_{x_0}^{x_3}=\{\mu_{II}(x_2)-\mu_I(x_2)\}-\{\mu_{II}(x_1)-\mu_I(x_1)\} \qquad (5)$$

which does not vanish in general. To find the thermoelectromotive force of the circuit we must add to the right-hand side of Eq. (4) the integration *across* the junctions. The latter is seen to be equal to the algebraic sum of the jumps of the bottom level, $\mathcal{E}_c$, of the conduction band at the junction:

$$-\{\mathcal{E}_{cII}(x_1)-\mathcal{E}_{cI}(x_1)\}+\{\mathcal{E}_{cII}(x_2)-\mathcal{E}_{cI}(x_2)\}, \qquad (6)$$

since eE is nothing other than gradient of the bottom level of the conduction band:

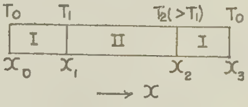

Fig. 1.

$$eE_x=\frac{d\mathcal{E}_c}{dx}\,. \qquad (7)$$

And we see that expressions (5) and (6) cancel each other as the Fermi level

$$\zeta=\mathcal{E}_c+\mu \qquad (8)$$

(not μ) is continuous at the junctions. Hence we are allowed to identify the second term of Eq. (4) with the thermoelectromotive force of the circuit multiplied by elementary charge as usually done in literatures.

The above situation will more easily be

seen if we trace throughout the circuit the Fermi level instead of the bottom level of the conduction band. In this respect Eq. (2) may be rewritten as (see Eq. (7) and (8))

$$-\frac{d\zeta}{dx}=\frac{1}{T}\left(\frac{K_2}{K_1}-\mu\right)\frac{dT}{dx}\,. \tag{9}$$

Now, the experimentally measurable thermoelectromotive force is the difference of the Fermi levels at x_0 and x_3, $\zeta(x_0)-\zeta(x_3)$, the temperatures at x_0 and x_3 being assumed to be equal to each other (say, equal to T_0°K). Hence, after integrating Eq. (9) along the circuit we have

$$e\Theta_{I,II}(T_1,\ T_2)\equiv\zeta(x_0)-\zeta(x_3)$$
$$=\int_{T_1}^{T_2}\frac{1}{T}\left(\frac{K_2}{K_1}-\mu\right)_{II}dT-\int_{T_1}^{T_2}\frac{1}{T}\left(\frac{K_2}{K_1}-\mu\right)_{I}dT\,. \tag{10}$$

It will be reasonable to define the absolute thermoelectromotive force, Θ, of a conductor to be the height of the Fermi level at the hot end relative to that at the cold end:

$$\Theta(T_1,\ T_2)=\frac{1}{e}\{\zeta(T_2)-\zeta(T_1)\} \tag{11}$$

which is equal to

$$\Theta(T_1,\ T_2)=-\frac{1}{e}\int_{T_1}^{T_2}\frac{1}{T}\left(\frac{K_2}{K_1}-\mu\right)dT \tag{12}$$

according to Eq. (9). Then the thermoelectromotive force of the circuit is given as

$$\Theta_{I,II}=\Theta_I-\Theta_{II}\,. \tag{13}$$

Differentiating Eq. (12) with respect to T and putting $T_2=T$, we have for the absolute thermoelectric power $Q=d\Theta/dT$

$$Q(T)=-\frac{1}{eT}\left(\frac{K_2}{K_1}-\mu\right). \tag{14}$$

Hitherto we have assumed that bottom level of the conduction band does not vary with temperature. As is well known this is not true in general. Nevertheless we can assert that the above consideration is valid even when the bottom level depends on temperature, because the force acting on an electron is equal to $-d\mathcal{E}_c/dx$, irrespective of whether the bottom level varies with temperature or not.

The situation is more complicated if we deal with two-band semiconductors. The gap energy between the bottom level, $\mathcal{E}_c$, of the conduction band and the top level, $\mathcal{E}_v$, of the valence band

$$\mathcal{E}_g=\mathcal{E}_c-\mathcal{E}_v \tag{15}$$

depends on temperature ($d\mathcal{E}_g/dT\sim10^{-4}$ ev/degree, being of the same order of magnitude as the very thermoelectric power of semiconductors), so that the "electric field" acting on electrons and that on holes, which should be identified with $e^{-1}d\mathcal{E}_c/dx$ and $e^{-1}d\mathcal{E}_v/dx$, respectively, are in general different to each other at the presence of temperature gradient. Therefore the integrated "electric field" (the left hand of Eq. (4)) loses the definite meaning in thermally inhomogeneous two-band semiconductors, and hence it will be more convenient to work with the gradient of the Fermi level from the outset.

§ 2. Thermoelectricity in Two-Band Semiconductors

In two-band semiconductors, the electric current density at the presence of temperature gradient is given by

$$j_x=j_x^{(1)}+j_x^{(2)} \tag{16}$$

with

$$\frac{j_x^{(1)}}{e}=\left(eE_x^{(1)}+T\frac{d}{dx}\frac{\mu}{T}\right)K_1^{(1)}+\frac{1}{T}K_2^{(1)}\frac{dT}{dx}\,,$$
$$\frac{j_x^{(2)}}{e}=\left(eE_x^{(2)}+T\frac{d}{dx}\frac{\mathcal{E}_g+\mu}{T}\right)K_1^{(2)}-\frac{1}{T}K_2^{(2)}\frac{dT}{dx}\,, \tag{17}$$

where affices (1) and (2) refer to electrons and holes, respectively. In Eq. (17) $E_x^{(1)}$ and $E_x^{(2)}$ denote the "electric fields" acting on electrons and holes, respectively:

$$eE_x^{(1)}=\frac{d\mathcal{E}_c}{dx}\,,\quad eE_x^{(2)}=\frac{d\mathcal{E}_v}{dx}\,. \tag{18}$$

These are not equal to each other at the presence of temperature gradient as mentioned in the previous section. Instead, we have, from Eqs. (15) and (18),

$$eE_x^{(2)}+\frac{d\mathcal{E}_g}{dx}=eE_x^{(1)}\,. \tag{19}$$

Taking this into consideration we have from Eqs. (16) and (17)

$$\frac{d\zeta}{dx}=eE_x^{(1)}+\frac{d\mu}{dx}=\frac{1}{K_1^{(1)}+K_1^{(2)}}\frac{j_x}{e}-\frac{1}{K_1^{(1)}+K_1^{(2)}}[(K_2^{(1)}-\mu K_1^{(1)})-(K_2^{(2)}+(\mathcal{E}_g+\mu)K_1^{(2)})]\frac{1}{T}\frac{dT}{dx}\,. \tag{20}$$

The expression for the absolute thermoelectric power in two-band semiconductors may easily be formed from Eq. (20) with $j_x=0$ (see § 1). We have

$$Q=\frac{1}{eT}\frac{1}{K_1^{(1)}+K_1^{(2)}}[(K_2^{(2)}+(\mathcal{E}_g+\mu)K_1^{(2)})-(K_2^{(1)}-\mu K_1^{(1)})] \,. \tag{21}$$

This may be written in the form

$$Q=\frac{1}{\sigma^{(1)}+\sigma^{(2)}}(\sigma^{(1)}Q^{(1)}+\sigma^{(2)}Q^{(2)}) \tag{22}$$

with

$$\sigma^{(1)}=e^2K_1^{(1)} \,, \qquad \sigma^{(2)}=e^2K_1^{(2)} \tag{23}$$

and

$$Q_1=-\frac{1}{eT}\left(\frac{K_2^{(1)}}{K_1^{(1)}}-\mu\right), \qquad Q_2=\frac{1}{eT}\left(\frac{K_2^{(2)}}{K_1^{(2)}}+\mathcal{E}_g+\mu\right). \tag{24}$$

In the above $\sigma^{(1)}(\sigma^{(2)})$ is the electronic (hole) conductivity and $Q^{(1)}(Q^{(2)})$ is the absolute thermoelectric power when only electrons (holes) would contribute to the conduction in the absence of holes (electrons). Eq. (20) may be rewritten in terms of Q as

$$\frac{d\zeta}{dx}=\frac{e}{\sigma}j_x+eQ\frac{dT}{dx} \,, \tag{25}$$

where $\sigma=\sigma^{(1)}+\sigma^{(2)}$ is the total conductivity. The physical meaning of this equation is obvious. The first term is the ohmic potential drop and the second is of thermoelectric origin.

The *energy flow* carried by charge carriers is given by

$$C_x=-(K_2^{(1)}-K_2^{(2)})\frac{d\zeta}{dx}-\frac{1}{T}[K_3^{(1)}-\mu K_2^{(1)}+K_3^{(2)}+(\mathcal{E}_g+\mu)K_2^{(2)}]\frac{dT}{dx}-\mathcal{E}_c\frac{j_x}{e}+\mathcal{E}_g\frac{j_x^{(2)}}{e} \,. \tag{26}$$

Here also we have used the relation Eq. (19). Inserting Eq. (17) for $j_x^{(2)}$ and substituting Eq. (20) for $d\zeta/dx$, we may express the energy flow in terms of j_x and dT/dx. We have

$$C_x=(eTQ-\zeta)\frac{j_x}{e}-\kappa_e\frac{dT}{dx} \,. \tag{27}$$

Here

$$\kappa_e=\frac{1}{T}\left[\left(K_3^{(1)}-\frac{K_2^{(1)2}}{K_1^{(1)}}\right)+\left(K_3^{(2)}-\frac{K_2^{(2)2}}{K_1^{(2)}}\right)\right]+\frac{1}{T}\frac{(K_1^{(1)}K_2^{(2)}+K_2^{(1)}K_1^{(2)}+\mathcal{E}_gK_1^{(1)}K_1^{(2)})^2}{(K_1^{(1)}+K_1^{(2)})K_1^{(1)}K_1^{(2)}} \tag{28}$$

is the electronic thermal conductivity. The first term of Eq. (27) means the energy flow accompanied by the current and states that the energy carried by unit current is equal to

$$TQ-\frac{\zeta}{e} \,. \tag{29}$$

Hence we see that the absolute Peltier heat, π, defined as the energy relative to the Fermi level carried by unit current is

$$\pi=TQ \,. \tag{30}$$

The rate of heat production in unit volume, H, is given as

$$H=-\frac{dC_x}{dx} \,. \tag{31}$$

Inserting Eq. (27) into Eq. (31) and using Eq. (25) (note that $d\mathcal{E}_c/dx=eE_x^{(1)}$) we have

$$H=\frac{j_x^2}{\sigma}-T\frac{dQ}{dT}j_x\frac{dT}{dx}+\frac{d}{dx}\left(\kappa_e\frac{dT}{dx}\right). \tag{32}$$

The second term of Eq. (32) is the Thomson heat and we have for the Thomson coefficient

$$\sigma_T=T\frac{dQ}{dT} \,. \tag{33}$$

Eqs. (30) and (33) are the so called Thomson relations,

§ 3. Discussion

The transport theory of the thermoelectricity for two-band semiconductors was first developed by Johnson and Lark-Horovitz⁽¹⁾. They first derived the expression for Thomson coefficient by calculating the rate of heat production and then integrated the Thomson relation (Eq. (33)) to find the expression for thermoelectric power. In calculating the rate of heat production they overlooked the heat released (or absorbed) by recombinations (or creations) of electron-hole pairs. If the variation of the gap energy with temperature is neglected as done by them the recombination heat may be expressed in our notations as

$$\varepsilon_g \frac{1}{e} \frac{dj_x^{(1)}}{dx} = -\varepsilon_g \frac{1}{e} \frac{dj_x^{(2)}}{dx} \tag{34}$$

which does not vanish in general at the presence of temperature gradient. We can easily ascertain that the recombination heat is automatically included in our calculation (see Eq. (26) for the rate of energy flow).

Tauc²⁾ followed the traditional way of identifying electric field integrated along whole circuit with its thermoelectromotive force tacitly assuming the gap energy to be independent of temperature. His results are legitimate as far as the assumptions made are granted. As pointed out in § 1, however, the temperature derivative of the gap energy is of the same order of magnitude as the thermoelectromotive force itself, so that we must emphasize that the temperature dependence of the gap energy must be taken into consideration in the transport theory of thermoelectricity of two-band semiconductors.

The writer wishes to express his cordial thanks to Mr. I. Yokota and Mr. S. Miyatani for their useful discussions and kind advices, and also to Professor A. Okazaki for his interests and encouragements for this work.

The present work was supported by the Scientific Research Fund of the Ministry of Educations.

Photo-voltaic Effect in Se-photocells having Artificial Intermediate Layers of CdSe, CdTe, ZnSe and ZnTe

By Hirosi TUBOTA and Hiromichi SUZUKI

General Education Department, Kyusyu University

(Received September 15, 1958)

Measurements of the photovoltages generated in the Se-photocells which have each an artificial intermediate layer such as CdSe, CdTe, ZnSe and ZnTe have been made. From the results obtained, the double barrier effect on both side contacts of selenide or telluride layer was concluded.

§ 1. Introduction

It is believed that in selenium rectifiers the rectifying barrier lies at the contact between Se (*p*-type) and CdSe (*n*-type) formed by the reaction of Se and a counter electrode alloy¹⁾. There should be also a rectifying barrier at the contact between the counter electrode metal and CdSe layer. But it is generally admitted that the effect of the former barrier should be predominant to the latter and that, in practice, the effect at the contact between CdSe and the counter electrode metal may be negligible in the rectification.

We considered more closely the problem whether any individual information about the effects at both side contacts of CdSe layer could be obtained. In connection with this problem, we studied photo-voltaic effects in selenium photocells having artificial intermediate layers of selenides and tellurides of Cd and Zn. To interpret the results obtained, it seems to be useful to consider the effects at both side contacts of selenide or telluride layers.

§ 2. Experiments

Selenium barrier layer photocells used in this study were prepared in our laboratory, depositing thin films of CdSe (n-type), CdTe (p-type), ZnSe (p-type) and ZnTe (p-type) respectively by vacuum evaporation on an ordinary commercial selenium rectifier disk which has not any counter electrode. Then, on these films, metals such as Au, Cd, Zn and In were, respectively, evaporated as a transparent counter electrode. The thickness of an evaporated film was estimated by the weighing method.

Measurements of open circuit photovoltages (V_p) generated in these photocells were made by a conventional method at room temperature. At first we obtained V_p also from the voltage current characteristics under illumination[2]. But, as we ascertained that the agreement of the values obtained by the above two methods was fairly good, we used the open circuit method for simplicity thereafter. The sample was set so as to receive only the direct beams from a light source. The light source (100 watt tungsten lamp) was placed at a fixed distance (25 cm) from the sample throughout this study. As a filter to cut off the infrared radiation effective for the temperature rise of samples, we used a copper sulfate saturated solution. All measurements were made at the stationary state reached after the exposure to light.

In the first series, we measured the photovoltages (V_p) for the samples with CdSe layers of various thicknesses. As the counter electrodes, evaporated Au-layers with the same thickness were used in this series. The actual preparations of these samples were as follows: on a Se rectifier disk, four CdSe layers (diameter: 1 cm) with different thickness were separately deposited, and then Au-layers with the same thickness were deposited on each CdSe layer. Table I shows the typical values of V_p obtained at the three periods after the preparation of the samples. It is seen from the table that as the thickness of CdSe layer varies from 0.4μ to 1.5μ, there is a maximum value of V_p, and each value of V_p for different thickness of CdSe layer is nearly constant, at least, during two weeks after the preparation of the sample.

Table I. V_p of photocells with CdSe layers (Counter electrode: Au, about 0.1μ thickness).

Thickness of CdSe layer (in μ)	V_p (in Volt)		
	Immediately	After 1 day	After 14 days
0.4	0.036	0.038	0.037
0.7	0.044	0.044	0.045
1.0	0.080	0.081	0.081
1.5	0.043	0.045	0.044

In the second series, the measurements for the counter electrodes of different kinds of metals mentioned above in the case of CdSe layer of the same thickness were made. The samples were prepared such as in the first series of experiments, namely, a set of samples with CdSe layers of the same thickness and the counter electrodes of different kinds was formed on one Se rectifier disk. The results for two kinds of thickness of CdSe layer are shown in Table II.

Table II. V_p of photocells with CdSe layer for the electrodes of different kinds of metals (in volt).
(Thickness of counter electrodes: about 0.1μ).

Thickness of CdSe layer (in μ)	Electrode metal			
	Au	Cd	Zn	In
0.7	0.09	0.11	0.16	0.05
1.0	0.10	0.14	0.18	0.07

In the third series, we observed the dependence of the magnitude of V_p upon the thickness of metal electrodes in the case of CdSe layer of a fixed thickness. The results showed that V_p merely decreases as the thickness of the electrode increases from about 0.1μ to 1μ in the case of Au electrode.

In all measurements for the case of CdSe layer, we observed that the sense of V_p agrees with that of commercial selenium photocells, that is, it is negative at the counter electrode. In comparison with our samples, we measured V_p of the commercial selenium photocells and

Table III. V_p of photocells with CdTe, ZnSe and ZnTe layers for the electrodes of different kinds of metals (in volt).
(Thickness of counter electrodes: about 0.1μ).

Electrode metal		Au	Cd	Zn	In
Material	Thickness				
ZnSe	0.3μ	0.0001	0.0007	−0.003	−0.003
ZnTe	1.0μ	0.0001	0.0001	0.0001	−0.0001
CdTe	0.5μ	0.0000	0.05	0.001	0.0003

obtained the value of about 0.1 volt in our experimental procedure. But in the cases of CdTe, ZnSe and ZnTe, we found that the values of V_p for nearly all samples were small compared with that of the case of CdSe and also there was the reverse sign of V_p for Zn and In electrodes, as seen in Table III.

§ 3. Discussion

To explain the behaviors observed in the study mentioned above, it seems to be reasonable to consider the double barrier layers appeared on contacts of counter electrode metal-intermediate layer (*n* or *p*)-selenium (*p*) such as shown in Figs. 1 and 2. It may be considered that V_p should be attributed to two effects at the two barriers, one from the metal-intermediate layer contact and the other from the intermediate layer-selenium contact. In the dependence of V_p upon the thickness of an intermediate layer, there is the maximum value of V_p as shown in Table I. This may be explained as follows: As the thickness of the layer increases, the barrier is gradually formed, therefore V_p increases with the thickness at first due to electron-hole generation by light. As the thickness increases further, the light is more absorbed in the bulk of the intermediate layer and can hardly reach the intermediate layer-selenium contact. Then there should be a maximum value of V_p.

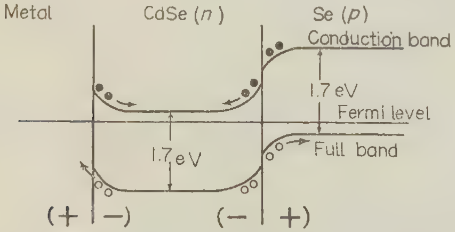

Fig. 1. Energy level scheme in the case of CdSe intermediate layer.

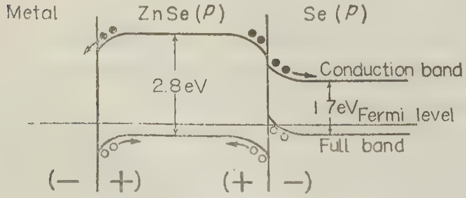

Fig. 2. Energy level scheme in the case of ZnSe intermediate layer.

In the case of CdSe, the fact that the sense of V_p is in agreement with that of commercial selenium photocells suggests that the effect at the contact of CdSe-Se is predominant to that at the contact of metal-CdSe. On the other hand, in the cases of ZnSe and ZnTe, the appearance of the reverse sign of V_p suggests that, for example, the contact of ZnSe-Se is more effective than that of In-ZnSe. At the contact of ZnSe-Se, there may be some other types of energy level schemes different from that shown in Fig. 2. But, considering the predominant effect at this contact, we assume the type as shown in the figure. It is difficult to make further discussions without a sufficient knowledge of band structure and optical properties of these materials.

The authors wish to express their sincere thanks to Prof. A. Okazaki for his continual advice and encouragement, and also to Shindengen-Kōgyō Company for offer of selenium rectifier disks. The present investigation was supported partly by the Scientific Research Expenditure of the Ministry of Education.

Lattice Scattering Mobility of Electrons in Cadmium Sulphide

By Hisao MIYAZAWA, Hajime MAEDA and Hiroshi TOMISHIMA

Matsuda Research Laboratory,
Tokyo-Shibaura Electric Co., Kawasaki

(Received October 1, 1958)

The Hall mobility of electrons has been measured between 90~400°K with many dark-conducting CdS/Ga, CdS/Cl and CdS/Cd single crystals. Among these results several typical data taken with crystals having non-degenerate carrier concentrations were chosen for analysing temperature dependence of the mobility. Assuming the observed mobility at lower temperatures is slightly influenced by the impurity scattering and Conwell Weisskopf formula is available here, it has been found that the plausible lattice scattering mobility after correction is well given by the following polar scattering form

$$\mu_L = A\{\exp(\Theta/T) - 1\}$$

with $A = 92.5 \pm 15$ cm²/volt sec and $\Theta = 370 \pm 30$°K.

In order to reach this result it is necessary to suppose there are about $10^{17} \sim 10^{18}$ uncontrollable deep-lying centers per unit volume in the present crystals, which permanently capture the conduction electrons and act as scatterers. The value of the characteristic temperature seems to be reasonable as compared with the one ($\Theta = 250 \sim 300$°K) previously obtained by Philips group in view of the infrared absorption band ($\Theta' = 335$°K) and the fine structure data in the edge emission ($\Theta = 460$°K).

§ 1. Introduction

After the development of Frerich's vapor method for growing artificial crystals, there exists an extensive literature on both electrical and optical properties of cadmium sulphide single crystals because of their striking photoconductive nature. Two dominant factors which determine the photoconductive sensitivity are the mean lifetime and the mobility of excited carriers, though they are usually inseparable in the observation of photocurrent. It has been said that the large photoconductivity of cadmium sulphide is mainly attributed to long mean lifetime of photoelectrons¹⁾, while electron mobility which is rather small is relatively ineffective. However, the lifetime is extremely structure-sensitive and depends upon capture cross section of many kinds of crystal imperfections or impurity centers of which atomic picture is not yet disclosed. On the other hand, the electron mobility is not so structure-sensitive that it is comparatively easy to get the intrinsic value. In any case, it is always desirable to know each individual parameter by all means.

As for the electron mobility of cadmium sulphide, the most detailed and precise study up to the present may be the one carried out by Kröger et al at Philips Laboratories²⁾. They observed the Hall effect and the resistivity on many single crystal specimens in the wide temperature ranges and obtained the Hall mobility of electrons. Their final results conclude that the temperature variation of Hall mobility as limited by lattice scattering between 200 and 700°K is accounted for with a characteristic temperature of longitudinal optical modes $\Theta = 250 \sim 300$°K, and a scattering at acoustical modes $aT^{-3/2}$ with $a = 3 \sim 8 \times 10^6$ cm² deg$^{3/2}$/volt sec, using the reasonable effective electron mass $0.2m_0 \sim 0.3m_0$ deduced from thermoelectric power data together with Hall coefficient.

However, their conclusion is based on the data that, between 75 and 300°K, Hall mobility of photoconducting specimens containing fairly large amount of ionized centers under illumination and, above 300°K, Hall mobility of the heavily doped dark-conducting specimens, respectively, may be regarded as lattice scattering mobility without any correction, since there appears no appreciable effect of impurity scattering. There will be little problem at higher temperatures where lattice scattering predominates, but at lower temperatures it will be questionable whether the observed mobility is influenced only by lattice scattering. Apparently, there is considerable discrepancy below 200°K between their calculated curve and observed one, which they also have thought of but have given up how to deal with. Therefore, in order to increase our understanding it will be worthwhile to reconsider the temperature dependence of Hall mobility by subtracting the impurity scattering effect.

As in our laboratories similar experimental work was carried out on cadmium sulphide single crystals having non-degenerate and suitable dark-conducting carriers still at lower temperatures, an attempt was made to estimate plausible lattice scattering mobility, assuming the observed data are combination of lattice and impurity effects. Though our correction method will be inaccurate to a certain extent because of the controversial assumptions, the procedures and the results which lead to a little higher characteristic temperature than that obtained by Philips group will be described in this paper.

§ 2. Experimental Results

Fairly dark-conducting single crystals, containing Cl or Ga respectively, were prepared by the ordinary vapor method, letting HCl or Ga vapor in the silica reaction tube during the growing of crystals. Crystals containing excess Cd, which were conductive too, were obtained by the heat treatment of pure crystals in H_2 atmosphere. Among these single crystals a number of favorable flakes, whose dimensions were about $10 \times 2 \times 0.1\,\mathrm{mm}^3$, were picked up for the present purpose. The specimens were electroded with indium metal and furnished with tungsten whisker probes.

The resistivity and the isothermal Hall coefficient have been measured for a number of these specimens between 90 and 400°K, from which several typical data have been chosen and are shown in Fig. 1 and Fig. 2. It is noticed that the carrier concentrations of these specimens are non-degenerate and in accordance with difference of the resistivity from one specimen to another there comes out a systematic correlation in the Hall coefficients.

The observed value of Hall mobility μ is given by the relation

$$\mu = R/\rho \,, \tag{1}$$

where R is the Hall coefficient and ρ is the resistivity. The values of μ are plotted in Fig. 3 as a function of temperature. A

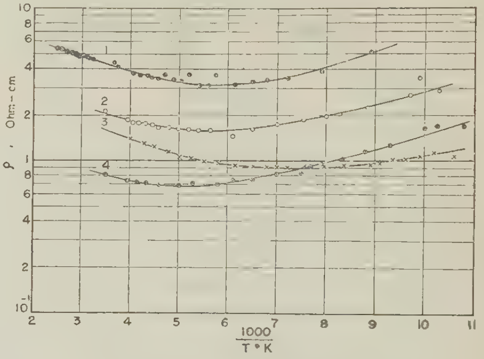

Fig. 1. Resistivity as a function of temperature.
1. CdS/Ga #1–17 2. CdS/Ga #1–5
3. CdS/Cd #3–5 4. CdS/Ga #1–15

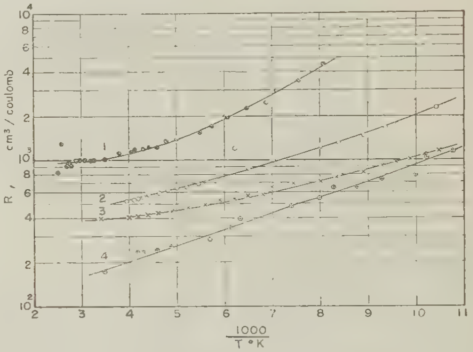

Fig. 2. Hall coefficient as a function of temperature.

3. CdS/Cd #3–5 4. CdS/Ga #1–15

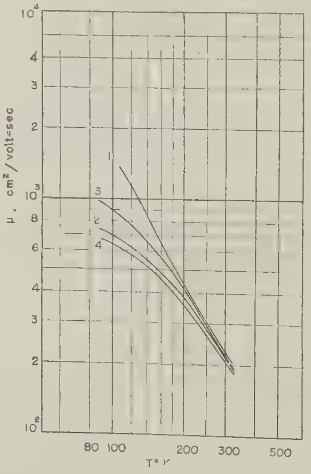

Fig. 3. Hall mobility vs temperature characteristics calculated from the data of Fig. 1 and Fig. 2.
1. CdS/Ga #1–17 2. CdS/Ga #1–5
3. CdS/Cd #3–5 4. CdS/Ga #1–15

general tendency is again noticed that the slope of the mobility curve at lower temperatures is steeper in the specimen of higher resistivity or higher Hall coefficient.

There are many other data in which the Hall coefficients are too small or too large. The former group, indicating small Hall coefficients, is unfavorable for the present purpose, because the carrier concentrations are degenerate and the Hall mobilities at lower temperatures are too flat to be correctly analysed. For the latter group of low carrier concentrations, on the other hand, it is difficult to observe isothermal Hall voltage accurately at lower temperatures because of high resistance between probes. Hence, all these data are omitted here.

§ 3. Assumptions

To obtain the lattice scattering mobility from the observed Hall mobility, several assumptions were made for the convenience of subsequent calculations as follows:

(1) The mechanisms of the lattice scattering and the impurity scattering are independent of each other, and the total scattering probability $1/\tau$, where τ is the relaxation time, can be written as

$$1/\tau=1/\tau_L+1/\tau_I \, . \qquad (2)$$

Here τ_L and τ_I are the relaxation times as determined by lattice scattering and impurity scattering respectively.

(2) As for the impurity scattering mobility, it is assumed that the modified Conwell-Weisskopf's formula is valid for these crystals, since the carrier concentrations are non degenerate and the scattering center concentrations are expected not so high in the present case.

(3) It is also assumed that whole scattering centers are singly charged, since their is no explicit evidence that the centers have double or more charges. Here, as shown in Fig. 4, the concentration of monovalent scattering centers N_I can be expressed as

$$N_I(T)=N_0+n(T) \, , \qquad (3)$$

where $n(T)$ is the conduction electron density slightly depending upon temperature and N_0 is the temperature-independent term which unfortunately is a priori unknown and should be properly adjusted. It is considered N_0 equals twice the density of deep-lying acceptor centers which may permanently trap some of the conduction electrons.

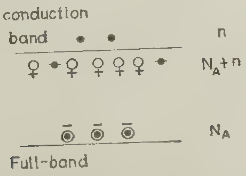

Fig. 4. Model for impurity scattering centers. The total density $N_I=N_O+n$, where $N_O=2N_A$.

(4) The mobility ratio μ/μ_d, where μ_d is the drift mobility, is taken as unity, i.e.

$$\mu=\mu_d \, . \qquad (4)$$

The carrier density is computed without significant reason from the relation

$$n=(3\pi/8)(1/Re) \, . \qquad (5)$$

Strictly speaking, these are incorrect because the relations are influenced by scattering mechanisms, but the effect on the final results may not be so serious that the computation can be carried out along this line.

§ 4. Analysis

According to the preceding assumptions the lattice mobility *vs* the temperature characteristics will be obtained in the following way.

In the first place, in order to eliminate the impurity mobility from the observed mobility, combination law between the lattice mobility and the impurity mobility must be investigated. Let us consider there are two scattering mechanisms A and B independent of each other, of which relaxation times are τ_A and τ_B respectively, and then τ_A and τ_B are power functions of the kinetic energy E of conduction carriers expressed as

$$\left.\begin{aligned}\tau_A&=a(T)E^{p/2} \, ,\\ \tau_B&=b(T)E^{q/2} \, ,\end{aligned}\right\} \qquad (6)$$

where $a(T)$ and $b(T)$ are temperature-dependent coefficients, p and q are the scattering indices of the two mechanisms respectively. Then the total scattering probability $1/\tau$ is given as $1/\tau=1/\tau_A+1/\tau_B$, and the drift mobility μ can be obtained, performing the average over the Boltzmann distribution at a temperature T:

$$\begin{aligned}\mu&=\frac{e}{m^*}\cdot\frac{4}{3\sqrt{\pi}}(kT)^{-5/2}\\ &\quad\times\int_0^\infty E^{3/2}\tau\exp(-E/kT)\cdot dE\\ &=\frac{e}{m^*}\cdot\frac{4}{3\sqrt{\pi}}a(T)\cdot(kT)^{p/2}\\ &\quad\times\int_0^\infty\frac{x^{(q+3)/2}\exp(-x)}{(a/b)(kT)^{(p-q)/2}+x^{(q-p)/2}}\,dx \, , \qquad (7)\end{aligned}$$

where m^* is effective mass of the electrons, k is Boltzmann's constant and x is defined as E/kT. Transformation of (7) into a convenient form gives

$$\frac{\mu}{\mu_A}=\frac{1}{\Gamma\left(\frac{5+p}{2}\right)}\times\int_0^\infty\frac{x^{(q+3)/2}\exp(-x)}{\left\{\Gamma\left(\frac{5+q}{2}\right)\Big/\Gamma\left(\frac{5+p}{2}\right)\right\}\cdot\left[\frac{\mu_A}{\mu_B}\right]+x^{(q-p)/2}}\,dx\,, \tag{8}$$

where $\Gamma(x)$'s are gamma functions. Here, μ_i is the mobility when the mechanism i is predominant. The (μ/μ_A) *vs* (μ/μ_B) curves are shown in Fig. 5 by numerical calculation for several cases. For the case $p=1$, $q=3$ and $p=-1$, $q=3$, one can use the numerical table calculated by Dingle et al in "Semiconductor Integrals".[3)]

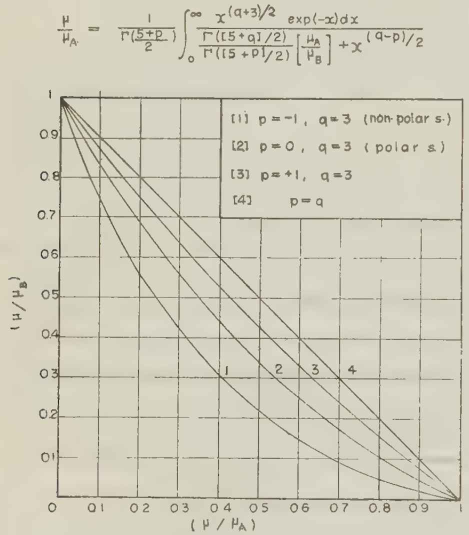

Fig. 5. Combination law between mobilities μ_L, μ_I and μ.

For the present case, the scattering index of impurity scattering, say q, is 3. On the other hand, the scattering index of the lattice scattering p has to be determined suitably. When the non-polar scattering by acoustical modes is dominant, $p=-1$. If this is the case, logarithmic plot of the corrected lattice mobility against the temperature T should form a straight line probably with the slope of $-3/2$. At first, such an analysis was tried on several data, which resulted in $\mu_L \propto T^{-2.1}$, indicating steeper slope than the expected one. In addition, there are a few specimens, whose mobility curves plotted against the temperature in logarithmic scales possess upwards concave part with reasonable accuracy, even if no correction is made. Two examples are curve 1 and curve 2 in Fig. 3. In the meantime, it was reported by Yoshinaga et al[4)] that there was a sharp and strong optical absorption band at 43μ owing to the lattice vibration in the hexagonal cadmium sulphide.

Taking into account these facts, the analysis with $p=-1$ was abolished and the predominance of the polar scattering by optical modes was presumed. The relaxation time of the polar scattering by optical modes τ_L is calculated by Callen and others[5)]. In this case, the result is somewhat complicated and the scattering index p can not be uniquely determined. However, the approximate results may be given by

$$\left.\begin{aligned}\tau_L &\propto E^0 \qquad 0<E<\hbar\omega_0=k\Theta\,,\\ &\propto E^{1/2} \quad \hbar\omega_0<E<10\hbar\omega_0\,,\end{aligned}\right\} \tag{9}$$

where ω_0 is the angular frequency of the longitudinal optical modes, and Θ is its characteristic temperature. For cadmium sulphide $\Theta\sim 400°\text{K}$ as discussed later, while τ and τ_L should be averaged over the Boltzmann distribution. Since the present aim is principally to correct the data below 200°K, no serious error is expected even though it is supposed $\tau \propto E^0$

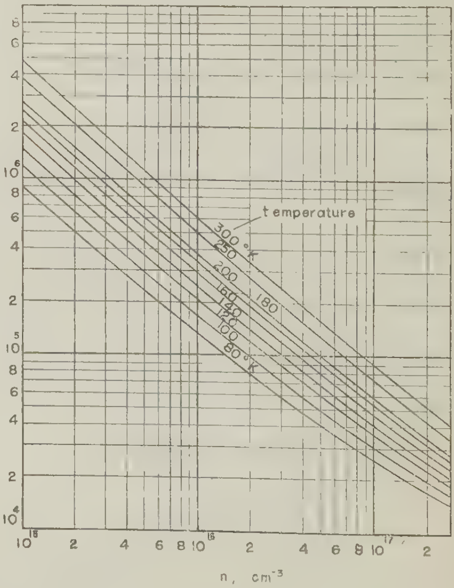

Fig. 6. Impurity scattering mobility μ_I *vs* carrier density n characteristics for several temperatures, calculated from modified Conwell-Weisskopf's formula with $m^*=0.3\,m$ and $\kappa=12$.

or $p=0$ for all electrons. If p were unity, on the other hand, slightly smaller μ_L would result. This is easily understandable in Fig. 5, where the combination law curve 3 instead of curve 2 has to be used in the latter case.

In the second place, it is necessary to evaluate the impurity mobility μ_I. According to the modified Conwell-Weisskopf's formula[6)]

$$\left.\begin{aligned} \mu_I &= \frac{2^{7/2}}{\pi^{3/2}}\cdot\frac{\kappa^2 k^{3/2}}{m^{*1/2}e^3}\cdot\frac{T^{3/2}}{N_I}\left[\ln(1+b)-\frac{b}{1+b}\right]^{-1}, \\ b &= \frac{6}{\pi}\cdot\frac{\kappa m^* k^2}{\hbar^2 e^2}\cdot\frac{T^2}{n}, \end{aligned}\right\} \tag{10}$$

where κ is the static dielectric constant. n and N_I have been defined in Eq. (3). Substitution of the numerical values of the constants with $m^*=0.3\,m_0$ and $\kappa=12$ measured by Kröger et al gives

$$\left.\begin{aligned} \mu_I &= \left(\frac{n}{N_I}\right)\times 8.7\times10^{18} \\ &\quad\times\left(\frac{T^{3/2}}{n}\right)\left[\ln(1+b)-\frac{b}{1+b}\right]^{-1}, \\ b &= 4.7\times10^{14}\times\left(\frac{T^2}{n}\right). \end{aligned}\right\} \tag{11}$$

Fig. 6 shows $(N_I/n)\mu_I$ *vs* n for several temperatures. Since $n=(3\pi/8)(1/Re)$ and $N_I=N_0+n$, the impurity mobility $\mu_I(T, N_0)$ can be evaluated from (11) or Fig. 6, if the value of N_0 is expediently given for each specimen. With thus evaluated $\mu_I(T, N_0)$ and the observed $\mu(T)$, the lattice mobility $\mu_L(T)$ can be straightway settled by means of the combination law curve 2 in Fig. 5.

In the last place, therefore, it must be mentioned how to determine the value of N_0. The determination of N_0 for each specimen was performed in the following way.

(1) Let the upper limit of N_0 be $N_0^{\max}$, then $N_0^{\max}$ is defined now by putting $\mu=\mu_I$ at the lowest temperature of the present observation, say 90°K. Since always $\mu\leqq\mu_I$, this gives $N_0^{\max}$ from (11), where the substitution of the observed n(90°K) and μ(90°K) gives $N_I^{\max}$, in turn $N_0^{\max}$.

(2) Let the lower limit of N_0 be $N_0^{\min}$. The method obtaining $N_0^{\min}$ is based upon the hypothesis that the resultant $\mu_L(T)$ *vs* T curve must not be upwards convex but be at least a straight line, provided the plot is made in both logarithmic scales. This was performed by the trial and error method which, in practice, was rather easy.

These values are listed in Table I together with other observed quantities.

From $N_0^{\max}$ and $N_0^{\min}$ a set of $\mu_L^{\max}(T, N_0^{\max})$ and $\mu_L^{\min}(T, N_0^{\min})$ will follow for each specimen, whose results are shown in Fig. 7. As for the most plausible lattice scattering mo-

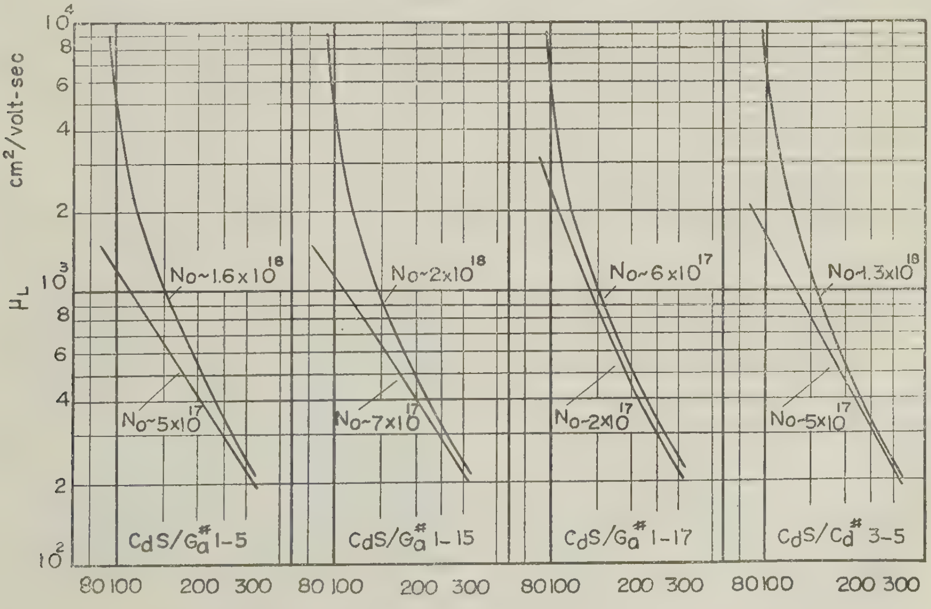

Fig. 7. Upper and lower limits of $\mu_L(T)$ for each specimen.

Table I.

Sample	μ_{RT} (cm^2/volt sec)	n_{RT} (cm^{-3})	$N_0^{\max}$ (cm^{-3})	$N_0^{\min}$ (cm^{-3})
CdS/Ga #1–17	220	0.7×10^{16}	0.6×10^{18}	0.2×10^{18}
CdS/Cd #3– 5	218	1.8	1.3	0.5
CdS/Ga #1– 5	210	1.6	1.6	0.5
CdS/Ga #1–15	205	4.3	2.0	0.7

bility $\mu_L(T)$ it would be appropriate to extract the common part of the regions limited by these curves. Solid bars at each temperature in Fig. 8 indicate the final regions obtained in this way.

In the present case, μ_L will be given by

$$\mu_L(T)=A\{\exp(\Theta/T)-1\}\ . \tag{12}$$

Then, to fit (12) with the above results two constants A and Θ must lie between the two sets of values listed in Table II. The $\mu_L(T)$ *vs* T curves calculated by substituting these values into (12) are given in Fig. 8.

In conclusion, the final and the best empirical formula for $\mu_L(T)$ is given by

$$\mu_L(T)=(92.5\pm15)\{\exp(370\pm30/T)-1\}\ \text{cm}^2/\text{volt sec}\ , \tag{13}$$

which passes through the mid region limited by the two curves in Fig. 8.

Table II.

	A (cm^2/volt sec)	Θ (°K)
Upper limit	80.6	400
Lower limit	107	340

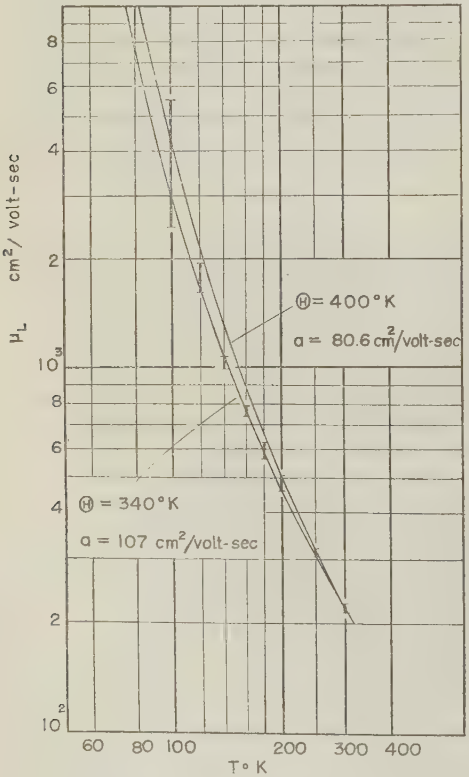

Fig. 8. Regions of the most plausible $\mu_L(T)$ (solid bars and theoretical curves calculated from $\mu_L=A\{\exp(\Theta/T)-1\}$ with the values given in the figure.

§ 5. Discussion

Despite a number of controversial assumptions, it is believed the resultant characteristic temperature Θ, say 370°K, is a reasonable one in view of the infrared absorption band observed by Yoshinaga et al. Since the absorption band has its peak at 43μ, it follows that the characteristic frequency ν_t of the transverse wave and the corresponding temperature $\Theta'(=h\nu_t/k)$ equal 6.98×10^{12} sec^{-1} and 335°K respectively. Meanwhile, the characteristic frequency ν_l of the longitudinal wave, which is responsible for the scattering of electrons in NaCl type polar lattices, is given by

$$\nu_l=\nu_t\left(\frac{\kappa}{\kappa_0}\right)^{1/2} \tag{14}$$

where κ_0 is the optical dielectric constant[7]. Since κ_0 is about 6 in the present materials, (14) gives $\nu_l \doteqdot 1.4\nu_t$. Though the structure of cadmium sulphide single crystal is not cubic but hexagonal, the corresponding characteristic temperature Θ of the longitudinal wave should be nearly equal to or slightly higher than 335°K of Θ'. Another evidence of Θ is a characteristic vibrational fine structure of the edge emission at low temperature[8]. The results obtained by Kröger and Meyer suggest $\Theta=460$°K. At least it cannot be emphasized that the values of Θ lower than 300°K are preferable.

It is also plausible that the concentrations $N_0/2$ of deep-lying centers for the present specimens are of the order 10^{17} cm^{-3}, because carrier compensations in some degree are inevitable at the present stage of crude crystal growing techniques. Probably these centers may be responsible for the trapping of positive holes and always make them immobile when photoconduction is induced in insulating crystals under illumination.

All of these results are suggestive that the intrinsic electron mobility of cadmium sulphide possesses remarkable polar nature and rather larger value at lower temperatures, but there exists a considerable effect of the impurity scattering which is depressing the mobility and cannot be neglected.

The authors are indebted to professor Y. Uemura and Mr. K. Maeda for many helpful discussions.

Relaxation Time Anisotropy in Cadmium Sulphide Studied with Electrical Resistivity and Magneto-Resistance Effect

By Taizō MASUMI

Department of Applied Physics, University of Tokyo, Tokyo, Japan

(Received October 3, 1958)

Anisotropic temperature dependences of electrical resistivity and magneto-resistance effect in hexagonal cadmium sulphide single crystal have been observed in several impurity-doped conducting and photoconducting crystals. The experimental results indicate some unusual anisotropic behaviours. They seem to suggest that the relaxation time anisotropy plays some important roles in transport phenomena of cadmium sulphide single crystals having hexagonal crystal structure.

§ 1. Introduction

A great many of theoretical and experimental investigations about the electronic energy band structure of semiconductors and metals[1),2)] have been made in recent years. Extensive investigations of electrical, magnetic and optical properties on a crystal provide some useful knowledges about the electronic band structures in the crystal. In particular, experiments on the cyclotron resonance, infrared absorption, magneto-absorption, de Haas-van Alphen effect, and the galvanomagnetic effect play significant roles in the study of usual semiconductors such as germanium, silicon and indium antimonide[2)].

The author has studied the magneto-resistance effect in hexagonal cadmium sulphide[3),4)], the electronic band structure of which has not been investigated yet[5)] though we have a large number of investigations about the photoconductive properties in the crystal[6)]. The experimental results on the magneto-resistance effect in cadmium sulphide give some useful knowledges about the energy band structures of conduction band and scattering mechanisms for free electrons, whereas the experiments on galvanomagnetic effect in semiconductors generally do not supply the individual informations about the anisotropies of energy surfaces and scattering mechanisms. Nevertheless, temperature dependences of the transverse magneto-resistance effect in cadmium sulphide show an unusual anisotropic behaviour as shown later, that is considered to be one of the most remarkable features of galvanomagnetic effect in this crystal. These situations seem to warn that we should pay our attentions to the existence of the anisotropic scattering mechanisms for conduction electrons in hexagonal cadmium sulphide, even though the energy surfaces of conduction band in the crystal are not sufficiently clarified.

We shall show the experimental results on the anisotropic temperature dependences of electrical resistivity and magneto-resistance effect in cadmium sulphide and discuss the probability of existence of the relaxation time anisotropy in cadmium sulphide based on these experimental results.

§ 2. Experimental Procedures

The samples used for the experiments are conducting thin flakes and blocks doped with Ga or Cl or with excess-Cd and also photoconducting flakes of cadmium sulphide single crystals that have hexagonal crystal structure, being of Wurtzite lattice type. In flaky crystals, the *c*-axis of the crystal lies in the flaky surface and the surface is perpendicular to one of the three *a*-axes. From a large flake, we have cut out the two specimens each direction of which is the $[01\bar{1}0]$ or [0001] direction as shown in Fig. 1 (a) and (b). We have used some rods made from block crystals merely as subsidiary specimen for the measurement of magneto-resistance effect that were ground by carborundum to have specified direction with help of X-rays. The conduction of the crystal is n-type and the resistivity of samples ranges from $\rho=0.05\sim5$ ohm cm with Hall coefficient $R=10\sim10^3$ cm^3/coulomb at room temperature for impurity doped crystals to $\rho=10^6\sim10^{10}$ ohm cm for photoconducting crystals in dark at room temperature. Sizes of specimens are of the order of $3\sim5\,\text{mm}\times1\sim2\,\text{mm}\times0.02\sim0.2\,\text{mm}$ with the longitudinal direction $[01\bar{1}0]$ or [0001], along which the directions of current $\boldsymbol{I}$ are fixed. The electrodes are indium-soldered ones forming good ohmic contacts whose contact resistance may be sufficiently negligible. The two specimens cut out from the same parent flake the one of which has the $\boldsymbol{I}$-direction of $[01\bar{1}0]$ and the another the $\boldsymbol{I}$-direction of [0001] were soldered in the same block of of indium metal at one end of each sample so that they have a common electrode and keep almost a common temperature at the same time as possible.

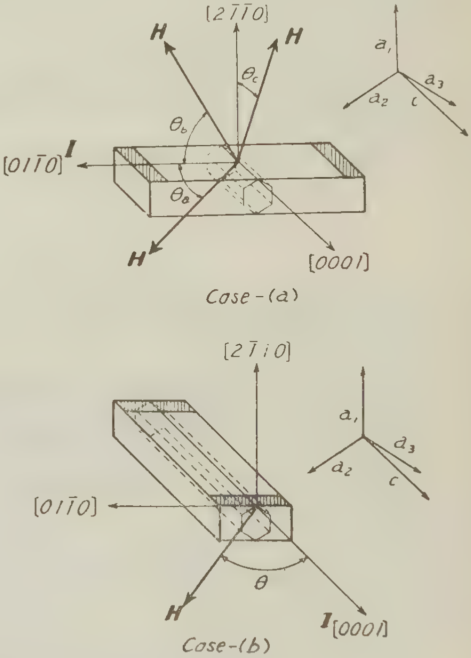

Fig. 1. Schematic Arrangements of the $\boldsymbol{I}$- and $\boldsymbol{H}$-directions for the orientations of hexagonal cadmium sulphide single crystals.

Another electrode of each specimen was attached independently separated with each other. The electrodes are used for both current and potential leads. A source of errors in magneto-resistance measurement[7),8),9)] due to such an arrangement has been checked not to be serious in the experiments as discussed in the previous paper[4)].

Measurements of electrical resistivity and magneto-resistance effect have been made by measuring the potential differences between two ends of the sample and their changes with application of magnetic field passing a fixed current less than 10 mA at most. The voltages and their changes across the sample were measured by potentiometer with help of DC-bridge adjusted suitably and the resistivity measurements for high resistive photoconducting crystals were done by high sensitive DC amplifier. For the measurements of magneto-resistance effect in impurity-doped crystals, magnetic fields ***H*** up to 12 kilogauss are produced by an electromagnet, and the misalignment of ***H*** and ***I*** was decreased as possible. As the elimination of photoeffect in these intrinsic photoconductors is very important even in this case, sufficient cares must be taken. Samples were contained in a enclosed cryostat avoiding the temperature drifts strictly. The observed temperature dependences of electrical resistivity and magneto-resistance effect in the experiment range from 100°K to 300°K.

§ 3. Experimental Results

Experimental results have been expressed in the form of temperature dependences of "relative resistivities" both for the current direction of ***I***-[01$\bar{1}$0] and ***I***-[0001] or their ratios normalized at room temperature for electrical resistivity. For magneto-resistance effect, results have been shown in the form of "their relative changes due to magnetic field ***H***", $(\rho-\rho_0)/\rho_0=(\Delta\rho)_H/\rho$, as a function of magnetic field strength H and the angle θ between the current ***I*** (or the direction of the fixed axis in some cases) and ***H***, and also of temperature T.

An example of anisotropic temperature dependences of electrical resistivities for the two current directions [01$\bar{1}$0] and [0001] is shown in Fig. 2 in logarithmic scale. It is natural that each temperature dependence shows the common appearances in its qualitative sense, however, it should be noticed that there is the quantitative difference between them. This difference may be primarily considered to be due to the anisotropic temperature dependences of mobility of electrons in these crystals, for the concentration of free electrons should have the same temperature dependence in the two crystals cut out from the same parent crystal. If we define the anisotropy parameter $K_\rho(T)$ by the relation,

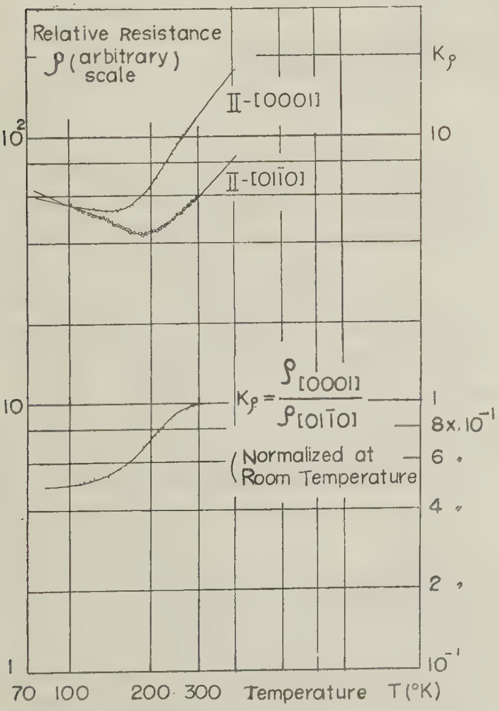

Fig. 2. Anisotropic temperature dependences of electrical resistivity for CdS-Cl specified with $\rho_{[0001]}\simeq1.0$ ohm-cm at room temperature.

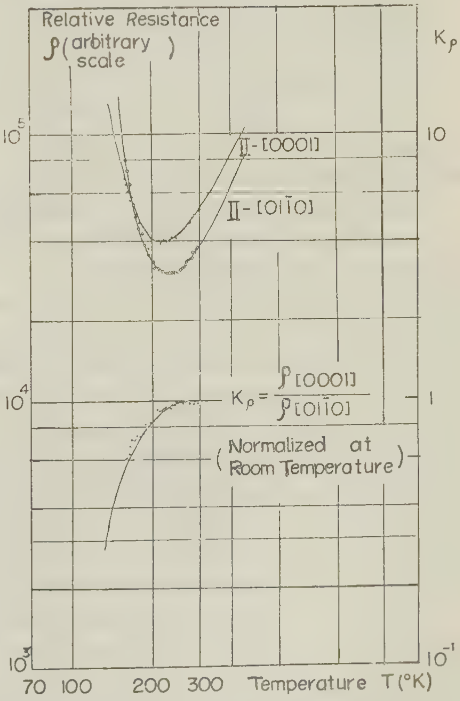

Fig. 3. Anisotropic temperature dependences of electrical reistivity for photoconductive CdS (inverse of photoconductivity). specified with dark resistivity $\rho_{[0001]}=10^6\sim10^{10}$ ohm-cm at room temperature.

$$K_\rho(T)=\frac{R_{[0001]}(T)}{R_{[01\bar{1}0]}(T)}\Big/\frac{R_{[0001]}(300^\circ\mathrm{K})}{R_{[01\bar{1}0]}(300^\circ\mathrm{K})} \qquad (3.1)$$

where $R_{[0001]}(T)$, $R_{[01\bar{1}0]}(T)$ are the observed resistances for the current directions of I-[0001] and I-[01$\bar{1}$0], $K_\rho(T)$ indicates the anisotropic behaviours of two mobilities $\mu_{[0001]}(T)$ and $\mu_{[01\bar{1}0]}(T)$ for temperature, because

$$K_\rho(T)=\frac{\rho_{[0001]}(T)}{\rho_{[01\bar{1}0]}(T)}\Big/\frac{\rho_{[0001]}(300^\circ\mathrm{K})}{\rho_{[01\bar{1}0]}(300^\circ\mathrm{K})}$$

$$=\frac{\mu_{[01\bar{1}0]}(T)}{\mu_{[0001]}(T)}\Big/\frac{\mu_{[01\bar{1}0]}(300^\circ\mathrm{K})}{\mu_{[0001]}(300^\circ\mathrm{K})} \qquad (3.1')$$

Fig. 2 shows the temperature dependence of $K_\rho(T)$ in the logarithmic scale. Remarkable features in the curve are the deviation of K_ρ from the unity in low temperature region (160∼200°K) and its restoring appearance in lower temperature region (100∼160°K). In order to interpret these behaviours, the following observation would be useful.

Similar experiments on high resistive photoconducting CdS crystals had been made and the results of the measurements of resistivity under the illumination of light with the fixed

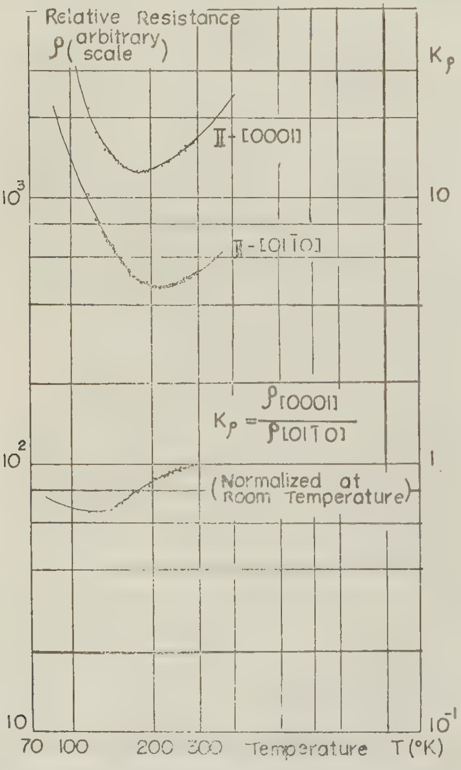

Fig. 4. Anisotropic temperature dependences of electrical resistivity for CdS-Cl specified with $\rho_{[0001]}\simeq0{\cdot}75$ ohm-cm at room temperature.

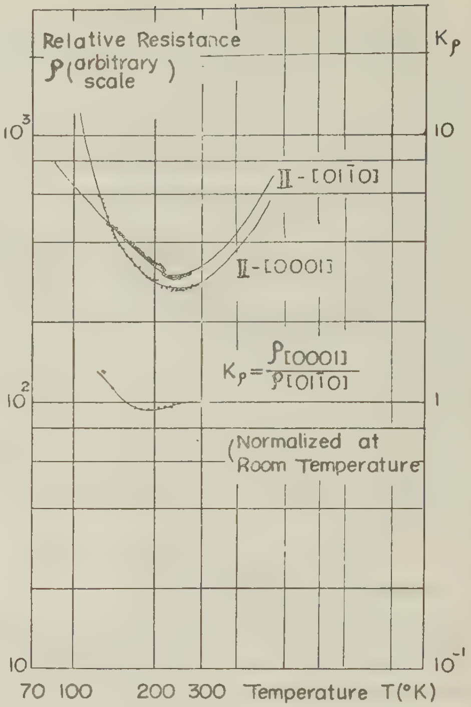

Fig. 5. Anisotropic temperature dependences of electrical resistivity for CdS-Ga specified with $\rho_{[0001]}=0.15$ ohm-cm at room temperature.

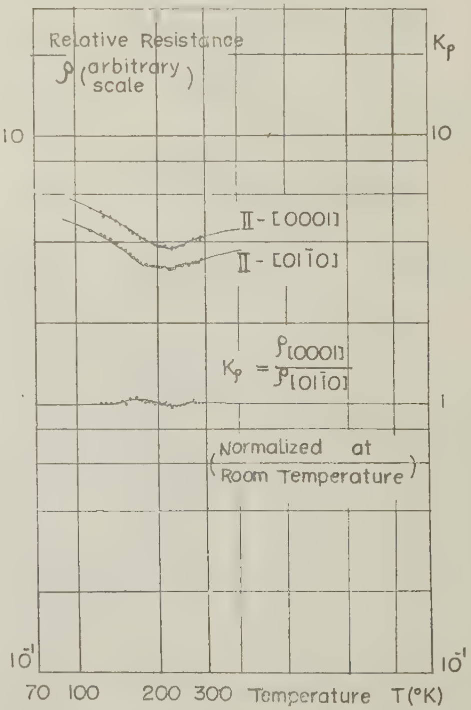

Fig. 6. Amisotropic temperature dependences of electrical resistivity for CdS-Cl spedified with $\rho_{[0001]}\simeq0.05$ hom-cm at room temperature.

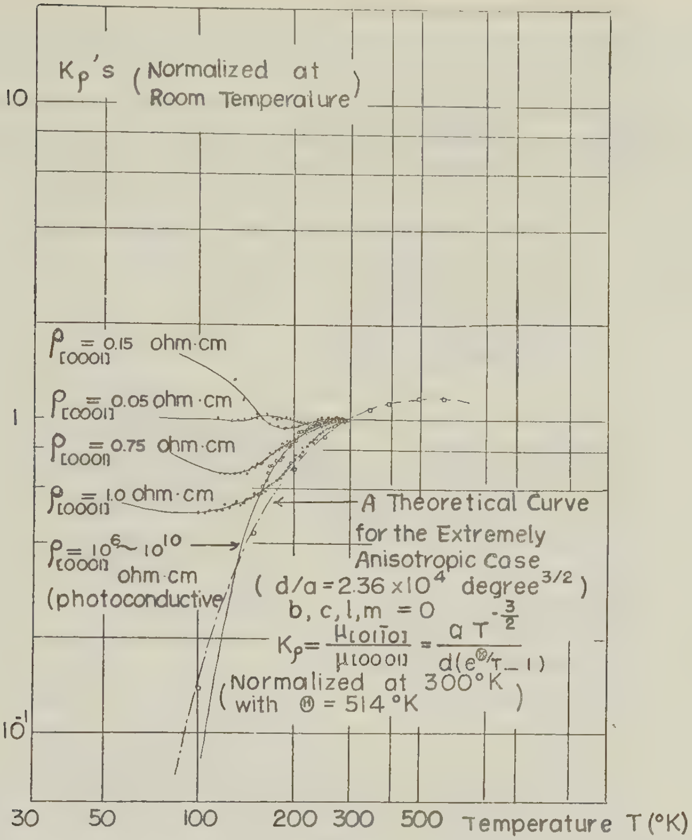

Fig. 7 (a). Summarized temperature dependence of Kρ's, for the CdS crystals with various grades of resistivity and comparison with the calculated curve.

intensity (i.e. inverse of photoconductivity) is shown in Fig. 3. Inferring from the general feature in this case, it may be unlikely that the restoring behaviours of K_ρ would appear in the lower temperature region.

Furthermore, the experimental results of similar observations on lower resistive CdS–Cl or CdS–Ga crystals shown in Fig. 4, 5 and 6, give some additive informations about the abnormal behaviours of K_ρ. The restoring characteristic of K_ρ in impurity doped crystals seem to become more appreciable as the decrease of resistivity though the situation is semi-quantitative.

The summarized results of temperature dependences of K_ρ's normalized at room temperature for the crystals with various values of relative resistivity are illustrated in Fig. 7(a) and these situations show some interesting features about the anisotropic temperature dependence of electrical resistivity in hexagonal cadmium sulphide single crystal.

These results suggest us that the similar anisotropic temperature dependences of mobility will be found also in the experiment of the magneto-resistance effect. Some examples of the angular dependences of magneto-resistance effect, $(\Delta\rho)_H/\rho H^2$, upon θ with a fixed strength of magnetic field at the fixed temperatures are illustrated in Fig. 8 and 9 for the ***I***-direction [01$\bar{1}$0] and [0001] in CdS–Ga crystals. Experimental details of the results and their general features are to be published in the another paper,4) and then, here, we would merely add some temperature dependences for various combination of ***H*** and ***I*** and a few corrections.

Temperature dependences of magneto-resistance effects for the ***I***-direction [01$\bar{1}$0] and ***H*** having the angle θ from 0 to 90 degrees between the directions [01$\bar{1}$0] and and [2$\bar{1}\bar{1}$0] are shown in Fig. 10 and similar dependences for the ***I***-direction [0001] and ***H***

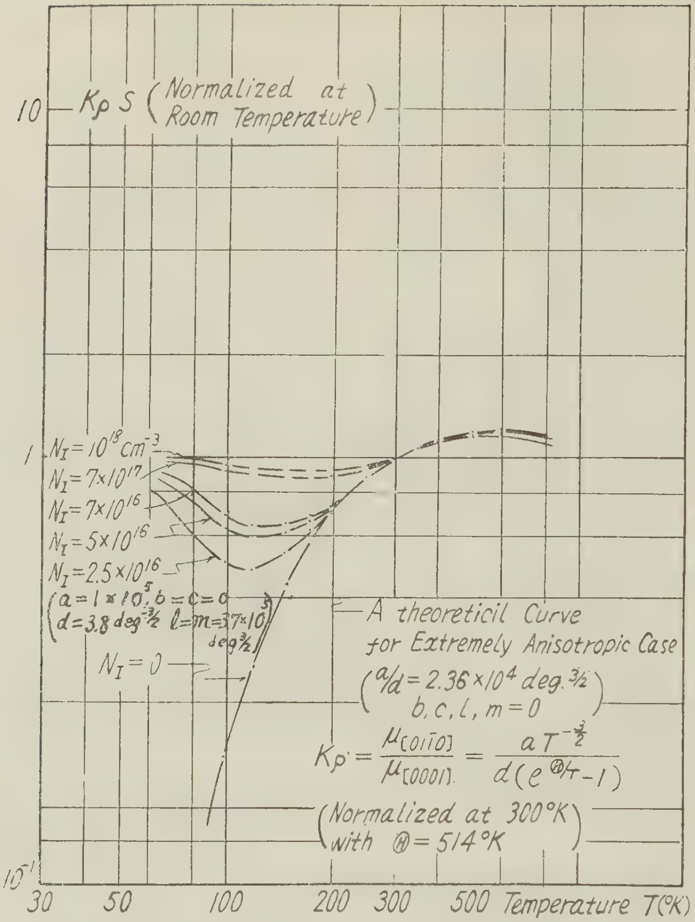

Fig. 7 (b). Calculated temperature dependences of Kρ'S for CdS crystals with several grades of impurity concentration N_I.
($N_I=2.5\times10^{16}$ cm^{-3} corresponds to $\rho_{[0001]}=1.0$ ohm-cm at room temperature with the value of mobility $\mu_n=200$ cm^2/volt. sec).

having the angle θ between the directions [0001] and [$2\bar{1}\bar{1}0$] in Fig. 11*. Generally, the transverse magneto-resistance effects for the both current directions with common **H**-[$2\bar{1}\bar{1}0$] show the similar temperature dependences with slopes whose values are clearly larger than −3 and also the longitudinal effect for the **I**-direction [0001], while the longitudinal effect for the **I**-direction [$01\bar{1}0$] has scarecely observed at each temperature.

But one of the more characteristic features of the magneto-resistance effects in cadmium

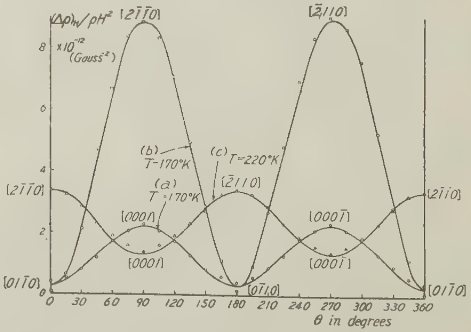

Fig. 8. $(\Delta\rho)_H\rho H^2$ versus θ in CdS-Ga at low temperatures for the fixed direction of **I**-[$01\bar{1}0$] with H=8900 Gauss.

---

* Relative values of transverse magneto-resistance effect for the I-direction [$01\bar{1}0$] seem to be corrected to be rather smaller than that for the I-direction [0001], at a fixed temperature, though the semi-quantitative result is reported in the previous paper[4)], where we described the former to be slightly larger than the latter.

sulphide is the anisotropic temperature dependences of the transverse effects for the $\boldsymbol{I}$-direction $[01\bar{1}0]$ illustrated in Fig. 12. It is most remarkable that there is a clear difference between the temperature dependences of the transverse effect with $\boldsymbol{H}$-[0001] and that with $\boldsymbol{H}$-$[2\bar{1}\bar{1}0]$. Although the former varies nearly as T^{-3} as observed in germanium by Pearson and Suhl[10], the latter presents a slightly different appearance. If we define the another parameter $K_{(\Delta\rho)_H/\rho H^2}$ analogous to K_ρ by the relation,

$$K_{(\Delta\rho)_H/\rho H^2}=\frac{(\Delta\rho_{[01\bar{1}0]})_H/\rho_{[01\bar{1}0]}\,H^2{}_{[0001]}}{(\Delta\rho_{[01\bar{1}0]})_H/\rho_{[01\bar{1}0]}\,H^2{}_{[2\bar{1}\bar{1}0]}}\,, \qquad (3.2)$$

we obtain the temperature dependence curve of $K_{(\Delta\rho)_H/\rho H^2}$ similar with the curve of K_ρ versus T, although the measurements of $(\Delta\rho)_H/\rho H^2$ and therefore $K_{(\Delta\rho)_H/\rho H^2}$'s involve more amounts of experimental errors than that of ρ and K_ρ. The general tendency of $K_{(\Delta\rho)_H/\rho H^2}-T$ curve shows a plausible agreement with that of the $K_\rho-T$ curve in its qualitative sense.

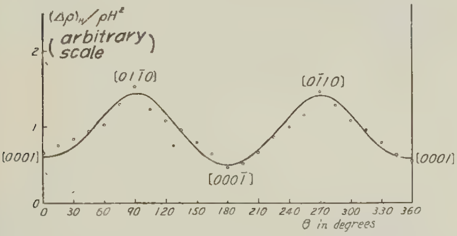

Fig. 9. $(\Delta\rho)_H/\rho H^2$ versus θ in CdS-Ga at 180°K for the fixed direction of I-[0001] with H=9350 Gauss.

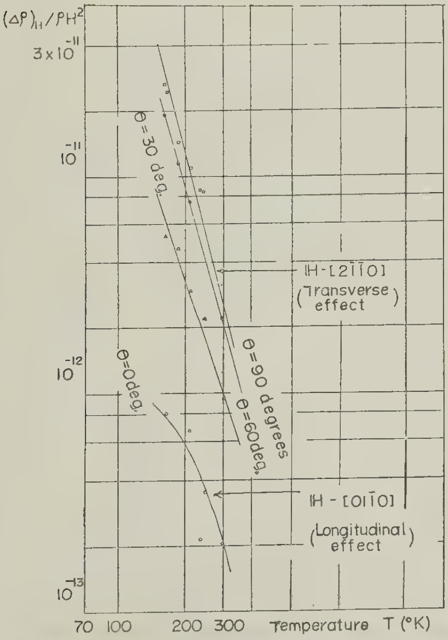

Fig. 10. Temperature dependence of magneto-Resistance effects in CdS-Cl for the fixed direction of II-$[01\bar{1}0]$.

Therefore, it may be considered that these experimental results suggest the special features of galvanomagnetic effect in hexagonal cadmium sulphide.

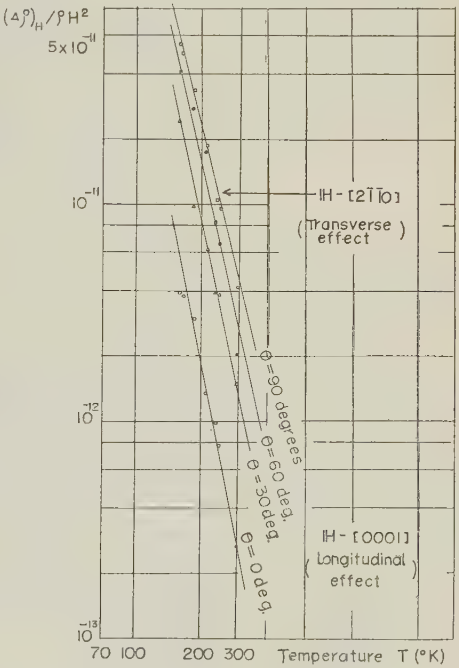

Fig. 11. Temperature dependence of magneto-resistance effects in CdS-Cl for the fixed direction of II-[0001].

§ 4. Discussions

It has been shown that there are unusual anisotropic temperature dependences of the galvanomagnetic effects in hexagonal cadmium sulphide single crystal and these behaviours have been studied through the anisotropy parameters K_ρ and $K_{(\Delta\rho)_H/\rho H^2}$ for several photoconducting and impurity-doped conducting crystals.

K_ρ or $K_{(\Delta\rho)_H/\rho H^2}$ defined by the preceeding relations is able to be written as follow, for example,

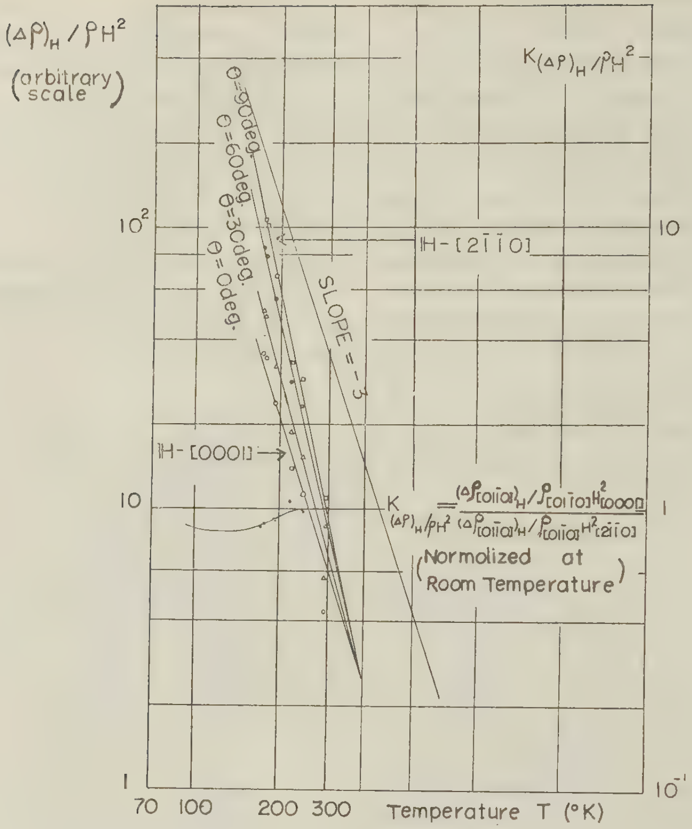

Fig. 12. Anisotropic temperature rependences of transverse magneto-resistance effects in CdS-Ga for the fixed direction of II-[01$\bar{1}$0].

$$K_\rho(T)=\frac{\mu_{[01\bar{1}0]}(T)}{\mu_{[0001]}(T)}\Big/\frac{\mu_{[01\bar{1}0]}(300^\circ\mathrm{K})}{\mu_{[0001]}(300^\circ\mathrm{K})}=\frac{K_m(T)}{K_\tau(T)}$$
$$=\left[\frac{m^*_{[0001]}(T)}{m^*_{[01\bar{1}0]}(T)}\Big/\frac{m^*_{[0001]}(300^\circ\mathrm{K})}{m^*_{[01\bar{1}0]}(300^\circ\mathrm{K})}\right]$$
$$\times\left[\frac{\tau_{[01\bar{1}0]}(T)}{\tau_{[0001]}(T)}\Big/\frac{\tau_{[01\bar{1}0]}(300^\circ\mathrm{K})}{\tau_{[0001]}(300^\circ\mathrm{K})}\right] \tag{4.1}$$

where m^*'s are the effective masses, τ's the relaxation times, $K_m(T)$ and $K_\tau(T)$ the effective mass ratio and the relaxation time anisotropy parameter normalized at 300°K, the suffixes specify the crystal orientations, and we have used a single simple valley model because of the lack of clear informations for the energy surfaces. Then, it may be expected that K_ρ and $K_{(\Delta\rho)_H/\rho H^2}$ are independent of temperature in usual isotropic media, because the effective masses and their ratio are independent of temperature for the crystal having usual carrier concentration and canceled out apparently, and the relaxation times τ's also have the similar temperature dependences for the different directions. Glicksman[11] discussed about the probability of existence of different "type" scattering entering with an anisotropic temperature dependence or the anisotropic impurity scattering in order to explain the deviation of relaxation time anisotropy K_τ from the unity in germanium which is strongly concentration dependent and/or temperature dependent. But he considered these situations to be unlikely and Goldberg[12],[13] also determined the relaxation time anisotropy $K_\tau \fallingdotseq 1.0$ for lattice scattering and $K_\tau > 1$ for moderate amounts of impurity scattering from the magnetoconductance measurements and the cyclotron resonance value for the mass ratio K_m. In hexagonal cadmium sulphide, however, it may be considered that the relaxation time anisotropy is still an important factor for the interpretation of the experimental result of galvanomagnetic effect.

These situations suggest that a possible phenomenological interpretation for the anisotropic temperature dependences of electrical resistivity and magneto-resistance effects in cadmium sulphide rises from the anisotropic weighting for the both types of scattering at the acoustical vibrational modes and the longitudinal optical modes of the lattice in their competitive process, and the impurity scattering also plays subsidiary roles in some cases. Some trial drawings of K_ρ involving the anisotropic relaxation time

$$K_\rho = k\cdot\frac{\rho_{[0001]}}{\rho_{[01\bar{1}0]}} = k\cdot\frac{\mu_{[01\bar{1}0]}}{\mu_{[0001]}} = k\cdot\frac{\left[\dfrac{a}{\mu_{op[0001]}}+\dfrac{c}{\mu_{ac[0001]}}+\dfrac{l}{\mu_{imp[0001]}}\right]}{\left[\dfrac{b}{\mu_{op[01\bar{1}0]}}+\dfrac{d}{\mu_{ac[01\bar{1}0]}}+\dfrac{m}{\mu_{imp[0'\bar{1}0]}}\right]} \tag{4.2}$$

and

$$\mu_{op} = \alpha\cdot\{\exp(\Theta/T)-1\}$$

$$\mu_{ac} = \beta T^{-3/2}$$

$$\mu_{imp} = \gamma\cdot T^{3/2}$$

is plotted in Fig. 7 (a) and (b), where the constants are properly chosen taking accounts of the anisotropic weighting that is considered to be probable from magneto-resistance data and normalizing K_ρ at room temperature, and Debye temperature Θ has the value obtained from the infrared absorption data by Yoshinaga et al.[14]. General behaviour of calculated K_ρ shows a fairly good agreement with that of observed K_ρ for the medium resistive and photoconductive crystals in the temperature region from 160~300°K in qualitative sense. The restoring behaviours of K_ρ in lower temperature region for impurity-doped crystals seem to be partly due to the apparent restoring of lattice and partly due to the impurity scattering, as shown in Fig. 7 (b).

But these situations are not completely justified because other factors such as detailed structure of energy band and so on also may play some roles in the present phenomena. For example, the non-vanishing longitudinal magneto-resistance effects for the I-direction [0001] and vanishing longitudinal effects for the I-direction [01$\bar{1}$0] can not be explained generally by the Herring's so-called "simple many valley energy band" model[15] usually considered in germanium and in silicon, and more complicated model may be necessary. Besides the situation, the crystals may contain some crystal imperfections such as point imperfections, dislocations, stacking faults and possibly boundary planes which give rise to some extra temperature dependences. But it would be unlikely that these extra dependences play an important role in the present experiment. Therefore, the foregoing interpretation seems to be one of the plausible proposals even though it is not completely definite. Further investigations to confirm these situations are now in progress.[16]

In any case, our experimental results about the anisotropic temperature dependences of electrical resistivity and transverse magneto-resistance effects in Fig. 7 and Fig. 12 reveal us the existence of anisotropic scattering mechanisms in hexagonal cadmium sulphide being of Wurtzite lattice type.

§ 5. Acknowledgements

The author would like to express his sincere gratitudes to Professor Y. Suge, Professor T. Inui and Professor S. Tanaka of Tokyo University for their continual encouragements, and, Professor Y. Uemura of Tokyo University, Dr. H. Miyazawa of Matsuda Research Laboratories of Tokyo-Shibaura Electric Company and Dr. F. A. Kroeger of Philips Research Laboratories for their kind discussions. He is also indebted to Dr. Miyazawa and, independently, Dr. S. Ibuki of Mitsubishi Electric Manufacturing Company for their supplying the cadmium sulphide single crystals. Sincere thanks are also, especially, due Dr. H. Mimura, Dr. T. Tanaka and Dr. M. Kobayashi for their most helpful discussions.

Quantum Theory of Galvanomagnetic Effect. I. Basic Considerations

Ryogo KUBO, Hiroshi HASEGAWA
Department of Physics, University of Tokyo
and Natsuki HASHITSUME
Ochanomizu University

(Received October 4, 1958)

A quantummechanical theory of galvanomagnetic effect is developed on the basis of the general theory of irreversible processes previously reported by Kubo (J. Phys. Soc. Japan **12** (1957) 570). The present theory applies to arbitrary shape of Fermi surface, as far as it makes a closed surface in the momentum space. Complications due to the interband effect and Harper's broadening effect are neglected here. On these assumptions it is proved that the static conductivity can be expressed generally in terms of the migration process of the center coordinate of the cyclotron motion. This is based on the assumption that the relative coordinates to describe the cyclotron motion are essentially bounded quantities in classical and also in quantummechanical sense. Without referring to any dubious use of transport theory, a very satisfactory logical basis is thus obtained for treating galvanomagnetic effect. This method is particularly useful for strong field. Applications will be reported in a subsequent paper.

§ 1. Introduction

The elementary theory of galvanomagnetic effect as one finds in standard textbooks[1] usually starts from the transport equation of electrons which describes the time change of the velocity distribution function by the drift due to the external electric force and the Lorentz force and by the collision term due to the scattering of electrons by phonons or lattice defects. Although the scattering is usually treated by quantum-mechanical perturbation theory, this transport equation is essentially classical or semi-classical, because it does not take into account the quantization of electron orbits by the presence of magnetic field. This is an approximation which is legitimate only in weak field, and so the elementary theory does not account for some peculiar effects which appear when the magnetic field becomes strong.

It is now well known that the quantization of electron orbits in magnetic field gives rise to some interesting and important phenomena. Such quantum effect is most clearly exhibited in the de Haas-van Alphen effect²⁾ in diamagnetic susceptibility and in the diamagnetic or cyclotron resonance phenomena³⁾. De Haas-van Alphen like oscillations are observed in transport phenomena such as magneto-resistance⁴⁾, Hall effect⁵⁾, thermoelectric power⁶⁾ and thermal conduction⁷⁾. Similar oscillation is seen also in optical absorption spectra of semiconductors⁸⁾. Besides such oscillations the quantization effect will completely change the transport properties of metals and semiconductors at very high magnetic field from the prediction of the elementary theory. The magneto-resistance, for instance, will show saturation according to the elementary theory when the magnetic field becomes so strong that the condition

$$\omega_0 \tau_r \gg 1 \tag{1.1}$$

is satisfied. Here ω_0 is a measure of the cyclotron frequencies determined by the magnetic field H and τ_r is that of the relaxation time. The condition (1.1) is that the electrons will complete many cycles of cyclotron motion before they get scattered. This classical saturation will be violated at very high magnetic field where the energy spacing of Landau levels becomes comparable to the Fermi potential. This was pointed out by Titeica⁹⁾ many years ago who made the first attempt for a quantum-mechanical theory of magneto-resistance. By Titeica's calculation, the magneto-resistance should increase linearly with the magnetic field at extremely high magnetic field. This conclusion should not, however, be taken as an explanation of the linear increase of magneto-resistance often observed by experiments at moderately strong magnetic fields¹⁰⁾.

The oscillatory effect of magneto-resistance was first discussed theoretically by Davydov and Pomeranchuk¹¹⁾. They treated the case of impurity scattering and applied the theory to the case of bismuth. More recently Lifshitz and his coworkers¹²⁾ treated the conduction problem by extending the kinetic equation to include the non-diagonal elements of the density matrix but without much examination of the collision term. Their conclusion is that the oscillation of magneto-resistance is essentially due to the oscillatory change of state density so that it is parallel to the de Haas-van Alphen effect oscillation. Similar theories have been also developed by Adams and Argyres¹³⁾. They treated the longitudinal magnetoresistance. Argyres further examined the transverse magnetoresistance¹⁴⁾.

The present authors started this work three years ago. Some of the results have been already reported on several occasions¹⁵⁾, although a full report has not been made yet. We have found that the quantum theory of galvanomagnetic effect can be constructed quite consistently on a very sound basis. The logical basis is more satisfactory than that of usual theory of conduction. This point has not been made clear in any of the previous work. This is the main reason why we now publish our work.

Our work is based upon the general theory of conductivity as developed by one of the present authors¹⁶⁾. The conductivity tensor can be rigorously expressed as a time integral of a sort of correlation function (response function, to be rigorous) which describes the spontaneous fluctuation of the current in the system under consideration in the absence of electric field. We now apply this formula by analyzing the dynamical motion of an electron in a magnetic field. It is seen that the cyclotron motion of crystal electrons with rather arbitrary energy function can be most conveniently described by a new set of canonical variables which consists of the center coordinates (X, Y), the relative coordinates (ξ, η) and the coordinate and momentum in the direction of the magnetic field (z, p_z). Thus the electric current in the x–y plane may be split into two parts, the current due to the displacement of the center and the current due to the relative motion. It will be shown that the symmetric part of conductivity tensor is completely expressed in terms of the center migration. On the other hand, the relative current contributes to the antisymmetric part a finite value which corresponds to its ideal value for vanishing scattering. The present theory thus gives a very clearcut formulation for the calculation of the galvanomagnetic coefficients, which can be applied to various cases, to metals or to semiconductors, with phonon scattering or with impurity scattering. When applied to metals with phonon scattering, the result will be the same as given by

Titeica[9] long time ago. If the scattering is due to impurities, it will be much the same as that discussed by Davydov and Pomeranchuk[11]. These authors, however, assumed rather intuitively that the conduction is interpreted by the center migration process. Our present theory will give a proof for their assumption and a more rigorous formulation.

§ 2. Dynamics of a Crystal Electron in Magnetic Field

Let us begin with a discussion of dynamics of a crystal electron in magnetic field. We consider crystal electrons which are described by the Bloch states $E_0(\boldsymbol{p})$ where $\boldsymbol{p}$ is crystal momentum $\hbar\boldsymbol{k}$, $\boldsymbol{k}$ being the Bloch wave vector. In a magnetic field $\boldsymbol{H}$, which is generaetd from the vector potential $\boldsymbol{A}$,

$$\mathrm{rot}\,\boldsymbol{A}=\boldsymbol{H}$$

and in the presence of a perturbation potential U, the crystal electrons may be approximately described by the effective Hamiltonian,

$$\mathcal{H}=E_0(\boldsymbol{\pi})+U(\boldsymbol{r})\,, \tag{2.1}$$

where $\boldsymbol{\pi}$ is the quasi-momentum defined by

$$\boldsymbol{\pi}=\boldsymbol{p}+\frac{e}{c}\boldsymbol{A}$$

satisfying the commutation rule,

$$\pi\times\pi=\frac{\hbar e}{ic}\boldsymbol{H}\,.$$

Or, if the direction of $\boldsymbol{H}$ is chosen as the z-axis, the definitions are

$$\left.\begin{aligned}\pi_x&=p_x+\frac{e}{c}A_x\,,\\ \pi_y&=p_y+\frac{e}{c}A_y\,,\\ \pi_z&=p_z\end{aligned}\right\} \tag{2.2}$$

and the commutation relations are

$$\left.\begin{aligned}&[\pi_x,\ \pi_y]=\frac{\hbar e}{ic}H\,,\\ &[\pi_x,\ x]=[\pi_y,\ y]=\hbar/i\end{aligned}\right\} \tag{2.3}$$

and other obvious ones.

Eq. (2.1) is based on the work of Peierls and Luttinger[17]. We shall use this Hamiltonian throughout the present work, so that we may briefly summarize the assumptions involved.

1) Since $E_0(\boldsymbol{p})$ represents a particular band, we have tacitly assumed that the interband effect (due to the change of wave functions in magnetic field) may be neglected. Some time ago, Adams pointed out that the interband effect is important for the large diamagnetism of bismuth[18]. It has not, however, been made clear how important the same effect would be for the galvanomagnetic effect particularly for those semimetals or semiconductors which have rather small energy gaps between bands. We here leave this question open for a future study.

2) We treat the coordinate $\boldsymbol{r}$ in (2.1) as a continuous variable although it is in fact discrete labeling the expansion coefficients in terms of the Wannier functions. This is perfectly correct as far as no approximation is introduced for the function $E_0(\boldsymbol{p})$ and so $E_0(\hbar\nabla/i)$ is a differential operator with infinite order. But here we may allow approximations such as the effective mass approximation under circumstances. We thus neglect such a broadening effect of the Landau levels as discussed by Harper and Zilberman[19].

Now let us introduce a new set of variables instead of the cartesian coordinates and their conjugate momenta. We define namely the variables,

$$\xi=\frac{c}{eH}\pi_y\,,\quad \eta=-\frac{c}{eH}\pi_x\,, \tag{2.4}$$

and

$$X=x-\xi\,,\quad Y=y-\eta\,, \tag{2.5}$$

From Eq. (2.3) we see at once that

$$[\xi,\ \eta]=\frac{\hbar}{i}\frac{c}{eH}\equiv\frac{l^2}{i}\,, \tag{2.6a}$$

$$[X,\ Y]=-\frac{\hbar}{i}\frac{c}{eH}\equiv-\frac{l^2}{i}\,, \tag{2.6b}$$

$$[\xi,\ X]=[\eta,\ X]=[\xi,\ Y]=[\eta,\ Y]=0\,. \tag{2.6c}$$

By these commutation rules the variables

$$(\xi,\ \eta)\,,\quad (X,\ Y)\quad \text{and}\quad (p_z,\ z) \tag{2.7}$$

make a complete set of canonical variables. There are of course other choice of canonical variables, for instance

$$(x,\ \eta)\,,\quad (X,\ y)\quad \text{and}\quad (p_z,\ z)\,.$$

This set is obtained from (2.7) by the canonical transformation

$$e^{-i\eta X/l^2}\xi e^{i\eta X/l^2}=\xi+X=x\,,$$

$$e^{-i\eta X/l^2}Ye^{i\eta X/l^2}=Y+\eta=y\,.$$

This can be regarded also as a gauge transformation.

The physical meaning of the variables (2.7) can easily be seen from the equation of motion. Consider the motion of an electron in the absence of the perturbation U. Since the Hamiltonian $E_0(\boldsymbol{\pi})$ does not involve X and Y, these variables do not change in time. Therefore the coordinates (X, Y) specify the position of the cyclotron motion in the x–y plane perpendicular to the magnetic field. We shall call X and Y the *center coordinates*. By Eq. (2.5) ξ and η are then the *relative coordinates* to specify the cyclotron motion relative to the center (X, Y). The center coordinates, X and Y, have, according to (2.6b), the quantum-mechanical uncertainty

$$\Delta X \Delta Y = 2\pi l^2 \equiv hc/eH$$

from which follows the well known fact that each eigen-state of $E_0(\pi_x, \pi_y, p_z)$ has the degeneracy of $1/2\pi l^2$ per unit area of the x–y plane. Here l corresponds to the classical radius of the lowest Landau level for an electron with a spherical mass. A similar uncertainty relation holds for the relative coordinates, ξ and η, for they are the canonical variables for one-dimensional periodic motion.

More generally, even in the presence of the perturbation potential U, we may use the center and relative coordinates. The equation of motion, either classical or quantum-mechanical, is easily obtained from the assumed Hamiltonian (2.1). (The function $E_0(\boldsymbol{\pi})$ must be well ordered in the noncommutable variables π_x and π_y). Namely,

$$\left.\begin{aligned} \dot{\xi} &= \frac{\partial E_0}{\partial \pi_x} - \frac{c}{eH}\frac{\partial U}{\partial y}, \\ \dot{\eta} &= \frac{\partial E_0}{\partial \pi_y} + \frac{c}{eH}\frac{\partial U}{\partial x}, \end{aligned}\right\} \tag{2.8a}$$

$$\left.\begin{aligned} \dot{X} &= \frac{c}{eH}\frac{\partial U}{\partial y}, \\ \dot{Y} &= -\frac{c}{eH}\frac{\partial U}{\partial x}, \end{aligned}\right\} \tag{2.8b}$$

$$\dot{p}_z = -\frac{\partial U}{\partial z}, \quad \dot{z} = \frac{\partial E_0}{\partial p_z}. \tag{2.8c}$$

Eq. (2.8a) may alternatively be written as

$$\left.\begin{aligned} \dot{\pi}_x &= -\frac{eH}{c}\frac{\partial E_0}{\partial \pi_y} - \frac{\partial U}{\partial x}, \\ \dot{\pi}_y &= \frac{eH}{c}\frac{\partial E_0}{\partial \pi_x} - \frac{\partial U}{\partial y}. \end{aligned}\right\} \tag{2.9}$$

It should be further noticed that the velocity $\boldsymbol{v} = (v_x, v_y, v_z)$ is written as

$$\left.\begin{aligned} v_x &\equiv \dot{x} = \dot{\xi} + \dot{X} = \frac{\partial E_0}{\partial \pi_x}, \\ v_y &\equiv \dot{y} = \dot{\eta} + \dot{Y} = \frac{\partial E_0}{\partial \pi_y}, \\ v_z &\equiv \dot{z} = \frac{\partial E_0}{\partial p_z}. \end{aligned}\right\} \tag{2.10}$$

As one sees by Eq. (2.8b), the motion of the center coordinates is induced by the perturbation potential U. When U induces scattering, the center will make jumps as shown schematically in Fig. 1. It is also easily verified that the equation (2.8) is equivalent to the familiar equation of motion written in terms of the Lorentz force.

For the sake of illustration and also for a later reference, we treat the simplest case where the potential U gives a constant force field, namely

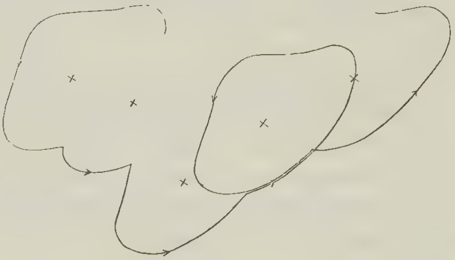

Fig. 1. Migration of centre.

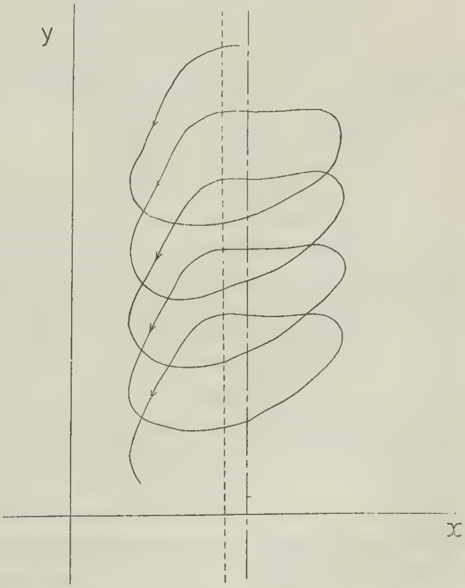

Fig. 2. Drift of centre in crossed uniform magnetic and electric fields. —·—·— is the locus of the centre coordinate, while -------- represents the locus if there wave no drift motion.

$$\frac{\partial U}{\partial x} = -eE\,, \quad \frac{\partial U}{\partial y} = 0\,. \tag{2.11}$$

Then Eq. (2.8b) shows that

$$\dot{Y} = cE/H\,. \tag{2.12}$$

The center makes a drift with the velocity (2.12) perpendicularly to the direction of the magnetic field and the force field (see Fig. 2). This holds quite generally irrespective of the form of the energy function $E_0(\boldsymbol{p})$. This drift motion is generally accompanied by a shift of the relative coordinates. This shift is determined by the condition that

$$\overline{\frac{\partial E_0}{\partial \pi_x}} = 0\,, \quad \overline{\frac{\partial E_0}{\partial \pi_y}} = \dot{Y} = \frac{cE}{H} \tag{2.13}$$

where the bar denotes the time average or the quantum-mechanical average with respect to a stationary state. This follows from the assumption that the variables ξ and η are bounded. We shall later come back to this point (§ 5).

§ 3. General Formula of the Conductivity Tensor

In a previous paper[16] (referred as K), one of the present authors showed that the conductivity tensor can be generally expressed by the formula (K. (5.11))

$$\sigma_{\mu\nu}(\omega) = \int_0^\infty dt e^{-i\omega t} \int_0^\beta d\lambda \langle \mathfrak{j}_\nu(-i\hbar\lambda) \mathfrak{j}_\mu(t) \rangle \qquad (\mu,\ \nu = x,\ y,\ z) \tag{3.1}$$

which gives, in particular for the static conductivity,

$$\sigma_{\mu\nu} = \int_0^\infty dt \int_0^\beta d\lambda \langle \mathfrak{j}_\nu(-i\hbar\lambda) \mathfrak{j}_\mu(t) \rangle\,. \tag{3.2}$$

In these expressions, β is $1/kT$ and $\mathfrak{j}_\nu$ is the current density operator in ν-direction. We shall use for the sake of convenience the second quantization formalism and write

$$\mathfrak{j}_\nu = \int_{\text{unit volume}} \psi^\dagger j_\nu \psi d\boldsymbol{r} \tag{3.3}$$

where j_ν is the current operator for one electron,

$$j_\nu = -ev_\nu \tag{3.4}$$

and $\psi^\dagger$ and ψ are quantized wave functions normalized per unit volume. In the following, density operators like (3.3) will be denoted by gothic letters.

In Eqs. (3.1) and (3.2), the time dependence of the current density means its motion induced by the *natural motion* of the system in the *absence* of the electric field. The average denoted by the bracket is taken over the equilibrium ensemble. Namely it means as usual the operation

$$\langle A \rangle = \mathrm{Tr}\,\rho A$$

where ρ is the equilibrium density matrix.

In the classical limit Eq. (3.1) goes into

$$\sigma_{\mu\nu}(\omega) = \int_0^\infty dt e^{-i\omega t} \langle \mathfrak{j}_\nu(0) \mathfrak{j}_\mu(t) \rangle \tag{3.5}$$

so that the conductivity is essentially the time integral of the correlation function of the current density which fluctuates in thermal equilibrium. Eq. (3.1) takes care of all possible quantum-mechanical complications by the integration over the imaginary parameter $i\hbar\lambda$ involved in $\mathfrak{j}_\nu(-i\hbar\lambda)$. The integrand

$$\int_0^\beta d\lambda \langle \mathfrak{j}_\nu(-i\hbar\lambda) \mathfrak{j}_\mu(t) \rangle = \phi_{\mu\nu}(t) \tag{3.6}$$

is not itself the correlation function, but it represents the response of the system revealed in the current component $\mathfrak{j}_\mu$ to the pulse of electric field applied in ν-direction so that it is the *response function* (which is essentially reduced to the correlation function in the classical limit).

It is possible, however, to write the conductivity in terms of the correlation function of the current fluctuation, for the symmetric part of the tensor, but not for the antisymmetric part, in the following expression,

$$\sigma_{\mu\nu}{}^s(\omega) = \frac{1}{2E_\beta(\omega)} \int_{-\infty}^\infty \frac{1}{2} \langle \{\mathfrak{j}_\nu(0) \mathfrak{j}_\mu(t)\} + \{\mathfrak{j}_\mu(0) \mathfrak{j}_\nu(t)\} \rangle e^{-i\omega t} dt \tag{3.7}$$

where the curly bracket means the symmetrized product of the two operators inside and $E_\beta(\omega)$ is

$$E_\beta(\omega) = \frac{\hbar\omega}{2} \coth \frac{\beta\hbar\omega}{2}\,.$$

This equation reduces to

$$\sigma_{\mu\nu}{}^s = \frac{1}{2kT} \int_{-\infty}^\infty \frac{1}{2} \langle \{\mathfrak{j}_\nu(0) \mathfrak{j}_\mu(t)\} + \{\mathfrak{j}_\mu(0) \mathfrak{j}_\nu(t)\} \rangle dt \tag{3.8}$$

for the static conductivity (K (7.14), (7.17)).

The above would be enough for the present purpose. A more detailed discussion of the general theory is referred to K. It should be emphasized, however, that these basic formulae are quite rigorous so that they provide us the safest ground from where we may proceed to actual calculation for any specific model even when the traditional method of using the Boltzmann-Bloch type transport equation can not be trusted.

We add here a brief remark for illustration that the simplest case of classical formula of the galvanomagnetic effect is easily obtained from Eq. (3.1) if the response functions (3.6) are assumed to be

$$\left.\begin{aligned} \phi_{xx}=\phi_{yy}&=\frac{e^2n}{m}e^{-t/\tau}\cos\omega_0 t\,,\\ \phi_{xy}=-\phi_{yx}&=-\frac{e^2n}{m}e^{-t/\tau}\sin\omega_0 t\,,\\ \phi_{zz}&=\frac{e^2n}{m}e^{-t/\tau}\,, \end{aligned}\right\}\tag{3.10}$$

where n is the electron density, m the electron mass, ω_0 the cyclotron frequency eH/mc, and τ the ordinary relaxation time. τ may be regarded also the correlation time for the electron velocity. The initial values of these response functions, $\phi_{xx}(0)$, $\phi_{xy}(0)$, etc. are in accordance with the same rules (K, Eqs. (8.5), (8.15) and (8.18)). By inserting (3.10) into (3.2) we get

$$\sigma=\frac{e^2n}{m}\begin{pmatrix} \dfrac{\tau}{1+\omega_0{}^2\tau^2} & -\dfrac{\omega_0\tau^2}{1+\omega_0{}^2\tau^2} & 0\\ \dfrac{\omega_0\tau^2}{1+\omega_0{}^2\tau^2} & \dfrac{\tau}{1+\omega_0{}^2\tau^2} & 0\\ 0 & 0 & \tau \end{pmatrix}\tag{3.11}$$

which is a well-known formula of the conductivity tensor of electrons with spherical mass and isotropic relaxation time.

§ 4. The v-representation and the ξ–X Representation of the Conductivity Tensor. Illustration by a Simple Model

We have seen in § 2 that the velocity of an electron in the x–y plane, which is normal to the direction of the magnetic field, can be split into two components, the center velocity and the relative velocity. Therefore the current density in Eq. (3.1) may be written as

$$\begin{pmatrix}\mathfrak{j}_x\\ \mathfrak{j}_y\end{pmatrix}\equiv -e\begin{pmatrix}\mathfrak{v}_x\\ \mathfrak{v}_y\end{pmatrix}=-e\begin{pmatrix}\dot{\mathfrak{X}}\\ \dot{\mathfrak{Y}}\end{pmatrix}-e\begin{pmatrix}\dot{\xi}\\ \dot{\eta}\end{pmatrix},\tag{4.1}$$

where the gothic letters are expressions like Eq. (3.3) with various velocity components. If the holes are considered the sign of e should be reversed. The conductivity tensor may be thus expressed in two ways. One representation is to write it in terms of (v_x, v_y) operators. We call this the *v-representation*. The other way is to split the whole expression into the center velocity and the relative velocity components. This will be called the *ξ–X representation.*

These two representations are of course correct and give the same answer if they are treated correctly. But they may be applied with advantage in different conditions. The v-representation is useful for weak field and also in moderately strong field. The ξ–X representation is particularly convenient for strong field.

It is very instructive to consider the following simple example in order to see how these two representations are related to each other.

Let us consider classical electrons. Each electron is supposed to be making cyclotron motion in the x–y plane with the cyclotron frequency ω_0, the mass being assumed to be spherical. The radius of the orbit is also assumed to be constant for the sake of simplicity. These simplifications will not spoil the essential things in our consideration. The scattering is supposed to occur with the mean free time τ_0 and the scattering angle α, which varies statistically. Our model is thus illustrated by Fig. 3, where the circular arcs represent the orbit of an electron, which suffers scattering at the points P_1, P_2, P_3 and so on at the time t_1, t_2, $t_3\cdots$. The center makes then a zig-zag motion $C_0C_1C_2\cdots$.

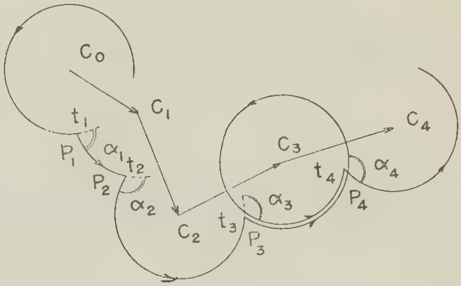

Fig. 3.

It is convenient to introduce the complex representation,

$$\left.\begin{aligned} u&=v_x+iv_y\,,\\ R&=X+iY\,,\\ \gamma&=\xi+i\eta\,, \end{aligned}\right\}\tag{4.2}$$

in which we may write

$$\left.\begin{aligned} u(t)&=u_0e^{i\omega_0t}\exp\{i\textstyle\sum\alpha_jF(t-t_j)\}\ ,\\ \dot{R}(t)&=\textstyle\sum\varDelta_jR\delta(t-t_j)\ ,\\ \dot{r}(t)&=u(t)+\textstyle\sum\varDelta_jr\delta(t-t_j)\ ,\end{aligned}\right\}\qquad(4.3)$$

where

$$F(t)=\begin{cases}1\ , & t>0\\ 0\ , & t<0\end{cases}$$

and

$$\varDelta_jR=-\varDelta_jr=e\exp\{i(\omega_0t_j+\sum^{j-1}\alpha_k)\}(1-e^{i\alpha_j})u_0/i\omega_0\qquad(4.4)$$

is the jump of the center by the j-th scattering. Eq. (4.3) describes the stochastic change of our variables. By assumptions we have

$$\langle e^{-i\nu(t_j-t_{j-1})}\rangle=\int_0^\infty e^{-i\nu t}e^{-t/\tau_0}dt/\tau_0=\frac{1}{1+i\nu\tau_0}\qquad(4.5)$$

for any ν and also

$$\langle e^{i\alpha}\rangle=\langle\cos\alpha\rangle=c\qquad(4.6)$$

for the scattering angle.

From Eqs. (4.3) and (4.4) with the help of (4.5) and (4.6) we may easily calculate the correlation functions and their Fourier transforms. Giving the details of the calculation in the Appendix, we summarize here only the results.

$$\int_0^\infty\langle v_x(0)v_x(t)\rangle e^{-i\omega t}dt=\int_0^\infty\langle v_y(0)v_y(t)\rangle e^{-i\omega t}dt=\frac{\tau}{2}\overline{v_x^2}\left\{\frac{1}{1+i(\omega-\omega_0)\tau}+\frac{1}{1+i(\omega+\omega_0)\tau}\right\}\ ,\qquad(4.7a)$$

$$\int_0^\infty\langle v_x(0)v_y(t)\rangle e^{-i\omega t}dt=-\int_0^\infty\langle v_y(0)v_x(t)\rangle e^{-i\omega t}dt=\frac{\tau}{2i}\overline{v_x^2}\left\{\frac{1}{1+i(\omega-\omega_0)\tau}-\frac{1}{1+i(\omega+\omega_0)\tau}\right\}\ ,\qquad(4.7b)$$

$$\int_0^\infty\langle\dot{X}(0)\dot{X}(t)\rangle e^{-i\omega t}dt=\int_0^\infty\langle\dot{Y}(0)\dot{Y}(t)\rangle e^{-i\omega t}dt=\frac{i\overline{v_x^2}}{2\omega_0}\left\{\frac{\omega-\omega_0}{1+i(\omega-\omega_0)\tau}+\frac{\omega+\omega_0}{1+i(\omega+\omega_0)\tau}\right\}\ ,\qquad(4.8a)$$

$$\int_0^\infty\langle\dot{X}(0)\dot{Y}(t)\rangle e^{-i\omega t}dt=-\int_0^\infty\langle\dot{Y}(0)\dot{X}(t)\rangle e^{-i\omega t}dt=\frac{\overline{v_x^2}}{2\omega_0^2}\left\{\frac{\omega-\omega_0}{1+i(\omega-\omega_0)\tau}-\frac{\omega+\omega_0}{1+i(\omega+\omega_0)\tau}\right\}\ ,\qquad(4.8b)$$

$$\int_0^\infty\langle\dot{\xi}(0)\dot{\xi}(t)\rangle e^{-i\omega t}dt=\int_0^\infty\langle\dot{\eta}(0)\dot{\eta}(t)\rangle e^{-i\omega t}dt=\frac{i\omega}{2}\frac{\overline{v_x^2}}{\omega_0^2}\left\{\frac{1-i\omega_0\tau}{1+i(\omega-\omega_0)\tau}+\frac{1+i\omega_0\tau}{1+i(\omega+\omega_0)\tau}\right\}\ ,\qquad(4.9a)$$

$$\int_0^\infty\langle\dot{\xi}(0)\dot{\eta}(t)\rangle e^{-i\omega t}dt=-\int_0^\infty\langle\dot{\eta}(0)\dot{\xi}(t)\rangle e^{-i\omega t}dt=\frac{\overline{v_x^2}}{2\omega_0^2}\left\{2\omega_0+\frac{\omega(1-i\omega_0\tau)}{1+i(\omega-\omega_0)\tau}-\frac{\omega(1+i\omega_0\tau)}{1+i(\omega+\omega_0)\tau}\right\}\ ,\qquad(4.9b)$$

$$\int_0^\infty\langle\dot{\xi}(0)\dot{X}(t)\rangle e^{-i\omega t}dt=\int_0^\infty\langle\dot{X}(0)\dot{\xi}(t)\rangle e^{-i\omega t}dt=-\frac{i\omega}{2}\frac{\overline{v_x^2}}{\omega_0^2}\left\{\frac{1}{1+i(\omega-\omega_0)\tau}+\frac{1}{1+i(\omega+\omega_0)\tau}\right\}\ ,\qquad(4.10a)$$

$$\int_0^\infty\langle\dot{\xi}(0)\dot{Y}(t)\rangle e^{-i\omega t}dt=\int_0^\infty\langle\dot{X}(0)\dot{\eta}(t)\rangle e^{-i\omega t}dt=-\frac{\omega}{2}\frac{\overline{v_x^2}}{\omega_0^2}\left\{\frac{1}{1+i(\omega-\omega_0)\tau}-\frac{1}{1+i(\omega+\omega_0)\tau}\right\}\ ,\qquad(4.10b)$$

where

$$\tau=\tau_0/(1-c)$$

is the ordinary relaxation time for the electrons.

The conductivity tensor and its components in the center and the relative velocities can be easily obtained from these equations since they are essentially these Fourier integrals of the corresponding correlation functions multiplied by ne^2/kT, where n is the electron density. By the equipartition law, we may put

$$\overline{v_x^2}/kT=1/m$$

so that we have, for instance,

$$\left.\begin{aligned}\sigma_{xx}(\omega)&=\frac{ne^2}{m}\frac{\tau}{2}\left\{\frac{1}{1+i(\omega-\omega_0)\tau}+\frac{1}{1+i(\omega+\omega_0)\tau}\right\}\ ,\\ \sigma_{yx}(\omega)&=\frac{ne^2}{m}\frac{\tau}{2i}\left\{\frac{1}{1+i(\omega-\omega_0)\tau}-\frac{1}{1+i(\omega+\omega_0)\tau}\right\}\ .\end{aligned}\right\}\qquad(4.11)$$

This is the classical formula obtained by inserting (3.10) into (3.5). The quantization effect is not taken into account in the present model, but we can see from the above results several things which help very much the understanding of the real situation.

The real part of the conductivity $\sigma_{xx}(\omega)$ is written as (K, (7.18))

$$\mathrm{Re}\,\sigma_{xx}(\omega)=\frac{ne^2}{kT}\,\mathrm{Re}\int_0^\infty\langle v_x(0)v_x(t)\rangle e^{-i\omega t}dt=\pi\frac{ne^2}{kT}\langle|v_x(\omega)|^2\rangle\,, \tag{4.12}$$

where $v_x(\omega)$ is the Fourier component of the fluctuating velocity v_x and so $\langle|v_x(\omega)|^2\rangle$ is its spectral density. This is shown in Fig. 4 by the bold curve. Similar spectral densities are also shown in the figure. They of course satisfy the relation

$$\langle|\dot{X}(\omega)|^2\rangle+\langle|\dot{\xi}(\omega)|^2\rangle+2\,\mathrm{Re}\,\langle\dot{X}(\omega)\dot{\xi}(\omega)\rangle=\langle|v_x(\omega)|^2\rangle\,. \tag{4.13}$$

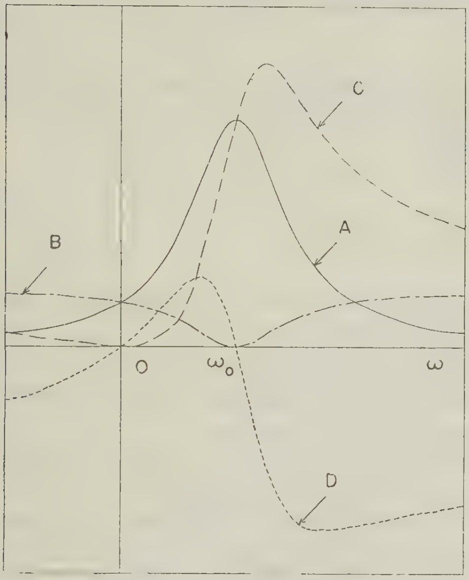

Fig. 4. Fourier components of the symmetric part of correlation functions. Curve A shows the real part of the first term of Eq. (4.7a). In the same way B corresponds to Eq. (4.8a), C. to Eq. (4.9a), and D to Eq. (4.10a).

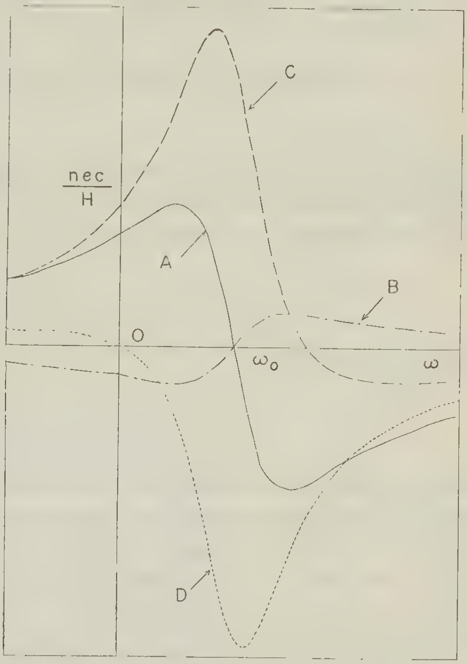

Fig. 5. Fourier components of the antisymmetric part of correlation functions. Curve A shows the real part of the first term of Eq. (4.7b). In the same way B corresponds to Eq. (4.8b), and C to Eq. (4.9b). Curve B is twice the real part of the first term of Eq. (4.10b).

Now the spectral density $\langle|v_x(\omega)|^2\rangle$ in this model has a resonance peak at the cyclotron frequency ω_0. This is the cyclotron resonance, which is broadened by the scattering processes. If we want to find the static conductivity, it means that we must then know the exact form of the broadened line in the tail at the frequency zero. The Lorentzian form in the present model is merely due to our great simplifications. The general problem of calculating the static conductivity in the v-representation is thus reduced to the line shape problem of the cyclotron resonance. The traditional method of using the transport equation involves an implicit assumption with regard to the type of the line shape, which is hard to prove in general and is in fact valid only in a certain limited condition.

In Fig. 4, we see that

$$\langle|\dot{X}(\omega)|^2\rangle_{\omega=0}=\langle|v_x(\omega)|^2\rangle_{\omega=0} \tag{4.14}$$

and other spectral densities vanish at $\omega=0$, i.e.,

$$\langle|\dot{\xi}(\omega)|^2\rangle_{\omega=0}=\langle\dot{\xi}(\omega)\dot{X}(\omega)\rangle_{\omega=0}=0 \tag{4.15}$$

(see Eqs. (4.7a–4.10a)).

This means that the static conductivity can be expressed as

$$\sigma_{xx}=\frac{ne^2}{kT}\int_0^\infty\langle\dot{X}(0)\dot{X}(t)\rangle dt\ . \tag{4.16}$$

It should be noticed that this expresses the Einstein relation,

$$\sigma_{xx}=\frac{ne^2}{kT}D \tag{4.17}$$

where D is the diffusion constant of the center. This is seen easily by rewriting Eq. (4.16) as

$$\sigma_{xx}=\frac{ne^2}{kT}\lim_{t\to\infty}\frac{1}{2t}\int_0^t\int_0^t\langle\dot{X}(t')\dot{X}(t'')\rangle dt'dt''=\frac{ne^2}{kT}\lim_{t\to\infty}\frac{1}{2t}\langle(X(t)-X(0))^2\rangle\equiv\frac{ne^2}{kT}D$$

(see K, Eq. (9.2))

Fig. 5 shows similarly the frequency dependence of Re $\sigma_{yx}(\omega)$ and its various components in the ξ–X representation. From Eqs. (4.7b)–(4.10b) we see that the cross terms involving the center and relative velocities vanish at $\omega=0$, and that

$$\int_0^\infty\langle\dot{\xi}(0)\dot{\eta}(t)\rangle dt=\overline{v_x^2}/\omega_0\ . \tag{4.19}$$

Therefore we have

$$\sigma_{yx}=\int_0^\infty\langle v_x(0)v_y(t)\rangle dt=\frac{nec}{H}+\frac{ne^2}{kT}\int_0^\infty\langle\dot{X}(0)\dot{Y}(t)\rangle dt \tag{4.20}$$

where the first term coming from Eq. (4.19) coincides with the ideal value which should be attained when the relaxation time τ becomes infinite (vanishing scattering).

Eqs. (4.16) and (4.20) suggest that the ξ–X representation can be used conveniently only for the calculation of the static conductivity. The vanishing of various terms mentioned above occurs only in the static limit. But it has certainly a great advantage over the v-representation as far as the static conductivity is concerned, particularly when the cyclotron frequency is large (strong magnetic field), because it is not the cyclotron resonance picture but is essentially the migration picture of the center coordinate. This limitation and the advantage of the ξ–X representation must be borne in mind. In the following section we shall prove (4.16) and (4.20) in a general way.

Another important point to be seen by our model is that the correlation of the successive jump of the center is strong when $\omega_0\tau$ is small and decreases with the increase of $\omega_0\tau$. This is easily seen because the center positions C_0, C_1, $C_2\cdots$ will be on a circle if $\omega_0\tau\sim0$, which means that the jumps C_0C_1, C_1C_2, $\cdots$ are correlated. An explicit calculation can be made by using Eq. (4.4) to obtain

$$\left.\begin{aligned}&\langle(\Delta_1X)^2\rangle=\langle(\Delta_1Y)^2\rangle=\frac{2\overline{v_x^2}}{\omega_0^2}(1-c)\ ,\\&\langle\Delta_1X\Delta_jX)\rangle=\langle\Delta_1Y\Delta_jY\rangle=-\frac{\overline{v_x^2}}{\omega_0^2}(1-c)^2c^{j-2}\,\mathrm{Re}\,(1-i\omega_0\tau)^{-(j-1)}\ ,\qquad(j\geqq2)\end{aligned}\right\} \tag{4.21}$$

$$\left.\begin{aligned}&\langle\Delta_1X\Delta_1Y\rangle=0\ ,\\&\langle\Delta_1X\Delta_jY\rangle=\langle\Delta_1Y\Delta_jX\rangle=-\frac{\overline{v_x^2}}{\omega_0^2}(1-c)^2c^{j-2}\,\mathrm{Im}\,(1-i\omega_0\tau)^{-(j-1)}\ ,\qquad(j\geqq2)\end{aligned}\right\} \tag{4.22}$$

From this we see that the correlation between the jumps $\overrightarrow{C_0C_1}$ and $\overrightarrow{C_{j-1}C_j}$ is of the order of

$(\omega_0\tau)^{-(j-1)}$ when the magnetic field is strong ($\omega_0\tau \gg 1$).

The expressions (4.16) and (4.20) are calculated with the use of the formula (see Appendix)

$$\int_0^\infty \langle \dot{R}^*(0)\dot{R}(t)\rangle dt = \frac{1}{\tau_0}\left\{\frac{1}{2}\langle \Delta_1 R^* \Delta_1 R\rangle + \sum_{j=2}^{\infty}\langle \Delta_1 R^* \Delta_j R\rangle\right\} = \frac{\overline{v_x^2}+\overline{v_y^2}}{i\omega_0}\frac{1}{1-i\omega_0\tau} . \tag{4.23}$$

The result, of course, coincides with (3.11).

The above consideration shows the important fact that the calculation of conductivity can be simplified very much under the condition of strong field, because then the correlation of the successive jumps may be neglected.

§ 5. Conductivity Expressed in Terms of the Center Migration

We shall now show that the basic equation (3.1) may be simplified by certain assumptions, to equations similar to (4.16) and (4.20). Namely the static conductivity components can be expressed in terms of the center velocity.

It is convenient to use the complex variables u, R and γ defined by (4.2) and also the corresponding current densities

$$\left.\begin{aligned} \boldsymbol{u} &= \int \psi^\dagger u \psi d\boldsymbol{r} = \int \psi^\dagger (v_x + i v_y)\psi d\boldsymbol{r} , \\ \dot{\boldsymbol{R}} &= \int \psi^\dagger \dot{R}\psi d\boldsymbol{r} = \int \psi^\dagger (\dot{X}+i\dot{Y})\psi d\boldsymbol{r} , \\ \dot{\boldsymbol{\gamma}} &= \int \psi^\dagger \dot{\gamma}\psi d\boldsymbol{r} = \int \psi^\dagger (\dot{\xi}+i\dot{\eta})\psi d\boldsymbol{r} . \qquad (\boldsymbol{u}=\dot{\boldsymbol{R}}+\dot{\boldsymbol{\gamma}}) \end{aligned}\right\} \tag{5.1}$$

Then the conductivity tensor components may be written as

$$\left.\begin{aligned} \sigma_{xx}+\sigma_{yy} &= \frac{e^2}{2}\int_0^\infty dt \int_0^\beta d\lambda \{\langle \boldsymbol{u}^*(-i\hbar\lambda)\boldsymbol{u}(t)\rangle + \langle \boldsymbol{u}(-i\hbar\lambda)\boldsymbol{u}^*(t)\rangle\} , \\ \sigma_{xx}-\sigma_{yy} &= \frac{e^2}{2}\int_0^\infty dt \int_0^\beta d\lambda \{\langle \boldsymbol{u}(-i\hbar\lambda)\boldsymbol{u}(t)\rangle + \langle \boldsymbol{u}^*(-i\hbar\lambda)\boldsymbol{u}^*(t)\rangle\} , \\ \sigma_{yx}-\sigma_{xy} &= \frac{e^2}{2i}\int_0^\infty dt \int_0^\beta d\lambda \{\langle \boldsymbol{u}^*(-i\hbar\lambda)\boldsymbol{u}(t)\rangle - \langle \boldsymbol{u}(-i\hbar\lambda)\boldsymbol{u}^*(t)\rangle\} , \\ \sigma_{yx}+\sigma_{xy} &= \frac{e^2}{2i}\int_0^\infty dt \int_0^\beta d\lambda \{\langle \boldsymbol{u}(-i\hbar\lambda)\boldsymbol{u}(t)\rangle - \langle \boldsymbol{u}^*(-i\hbar\lambda)\boldsymbol{u}^*(t)\rangle\} , \end{aligned}\right\} \tag{5.2}$$

$$\sigma_{xz}+i\sigma_{yz} = e^2\int_0^\infty dt \int_0^\beta d\lambda \langle \boldsymbol{v}_z(-i\hbar\lambda)\boldsymbol{u}(t)\rangle . \tag{5.3}$$

Each of the terms on the right-hand side of Eq. (5.2) is expressed in the ξ-X representation, in which it consists of four terms.

Let us first consider the term which involves the relative velocities $\dot{\gamma}$ and $\dot{\gamma}^*$, which will be transformed as follows.

$$\begin{aligned} \int_0^\infty dt \int_0^\beta d\lambda \langle \dot{\boldsymbol{\gamma}}^*(-i\hbar\lambda)\dot{\boldsymbol{\gamma}}(t)\rangle &= -\int_0^\beta d\lambda \langle \dot{\boldsymbol{\gamma}}^*(-i\hbar\lambda)\boldsymbol{\gamma}(0)\rangle \\ &= -\frac{1}{i\hbar}\,\mathrm{Tr}\,[\rho\boldsymbol{\gamma}^*]\boldsymbol{\gamma} = -\frac{1}{i\hbar}\,\mathrm{Tr}\,\rho[\boldsymbol{\gamma}^*, \boldsymbol{\gamma}] = -2\frac{nc}{eHi} , \end{aligned} \tag{5.4}$$

where n is the electron density. The last expression is obtained from the commutation law

$$[\boldsymbol{\gamma}^*, \boldsymbol{\gamma}] = \int \psi^\dagger [\gamma^*, \gamma]\psi d\boldsymbol{r} = 2l^2 \int \psi^\dagger \psi d\boldsymbol{r} = 2l^2 n \tag{5.5}$$

(see (2.6a)). To rewrite the second line of (5.4) we used the identity,

$$\frac{1}{i\hbar}[\rho,\ A]=\int_0^\beta \rho\dot{A}(-i\hbar\lambda)d\lambda \tag{5.6}$$

which holds for a canonical density matrix $\rho=C\exp(-\beta\mathcal{H})$ (K, Eq. (3.9)). The second line is obtained from the first by simple integration with the assumption that

$$\lim_{t\to\infty}\int_0^\beta d\lambda\langle\dot{\gamma}^*(-i\hbar\lambda)\gamma(t)\rangle=\lim_{t\to\infty}\frac{1}{i\hbar}\langle[\gamma^*(0),\ \gamma(t)]\rangle=0\ . \tag{5.7a}$$

Here again Eq. (5.6) is used.

Similarly, if we assume

$$\lim_{t\to\infty}\int_0^\beta d\lambda\langle\dot{\gamma}(-i\hbar\lambda)\gamma(t)\rangle=\lim_{t\to\infty}\frac{1}{i\hbar}\langle[\gamma(0),\ \gamma(t)]\rangle=0 \tag{5.7b}$$

and the conjugates of (5.7a, b), we get

$$\left.\begin{aligned}&\int_0^\infty dt\int_0^\beta d\lambda\langle\dot{\gamma}(-i\hbar\lambda)\dot{\gamma}^*(t)\rangle=\frac{2cn}{eHi}\ ,\\&\int_0^\infty dt\int_0^\beta d\lambda\langle\dot{\gamma}(-i\hbar\lambda)\dot{\gamma}(t)\rangle=0\ ,\\&\int_0^\infty dt\int_0^\beta d\lambda\langle\dot{\gamma}^*(-i\hbar\lambda)\dot{\gamma}^*(t)\rangle=0\ .\end{aligned}\right\} \tag{5.8}$$

Eqs. (5.4) and (5.8) show that

$$(\sigma_{xx})_{\dot{\gamma}\dot{\gamma}}=(\sigma_{yy})_{\dot{\gamma}\dot{\gamma}}=0\ ,\qquad(\sigma_{yx})_{\dot{\gamma}\dot{\gamma}}=-(\sigma_{xy})_{\dot{\gamma}\dot{\gamma}}=\frac{nec}{H}\ , \tag{5.9}$$

where the suffix means the contribution from the relative velocity. Therefore, if the conditions (5.7) are fulfilled the relative velocity gives only the ideal value $(-enc/H)$ to the antisymmetric conductivity. This is in accordance with what we saw by Eq. (4.19) for our simple model.

The conditions (5.7) will be satisfied if the variables ξ and η are *bounded*. Then it is admissible to put

$$\lim_{t\to\infty}\int_0^\beta d\lambda\langle\dot{\gamma}^*(-i\hbar\lambda)\gamma(t)\rangle=\int_0^\beta d\lambda\langle\dot{\gamma}^*(-i\hbar\lambda)\rangle\langle\gamma\rangle\ , \tag{5.10}$$

where we assumed essentially an ergodic property of the variable γ (see K, § 3). Or simply this means that the correlation between the variables $\dot{\gamma}^*(-i\hbar\lambda)$ and $\gamma(t)$ will be lost as the time t grows infinite. In the last expression we have

$$\langle\dot{\gamma}(-i\hbar\lambda)\rangle=\langle\dot{\gamma}\rangle=0 \tag{5.11}$$

because of the bounded nature of γ. This gives (5.7a). Other conditions, (5.7b) and the conjugates, are understood in the same way.

Next we consider the cross terms involving the relative and the center velocities. Like Eq. (5.4) they may be transformed as

$$\begin{aligned}\int_0^\infty dt\int_0^\beta d\lambda\langle\dot{\boldsymbol{R}}(-i\hbar\lambda)\dot{\gamma}(t)\rangle&=-\int_0^\beta d\lambda\langle\dot{\boldsymbol{R}}(-i\hbar\lambda)\gamma(0)\rangle\\&=-\frac{1}{i\hbar}\mathrm{Tr}\,[\rho,\ \boldsymbol{R}]\gamma=-\frac{1}{i\hbar}\mathrm{Tr}\,\rho[\boldsymbol{R},\ \gamma]=0\ ,\end{aligned} \tag{5.12}$$

$$\begin{aligned}\int_0^\infty dt\int_0^\beta d\lambda\langle\dot{\gamma}(-i\hbar\lambda)\dot{\boldsymbol{R}}(t)\rangle&=\int_0^\infty dt\int_0^\beta d\lambda\langle\dot{\gamma}(-t)\dot{\boldsymbol{R}}(i\hbar\lambda)\rangle=\int_{-\infty}^0 dt\int_0^\beta d\lambda\langle\dot{\gamma}(t)\dot{\boldsymbol{R}}(i\hbar\lambda)\rangle\\&=\int_0^\beta d\lambda\langle\gamma(0)\dot{\boldsymbol{R}}(i\hbar\lambda)\rangle=\int_0^\beta d\lambda\langle\dot{\boldsymbol{R}}(-i\hbar\lambda)\gamma(0)\rangle=0\ ,\end{aligned} \tag{5.13}$$

where we made the assumptions

$$\lim_{t\to\infty}\int_0^\beta d\lambda\langle\dot{\boldsymbol{R}}(-i\hbar\lambda)\boldsymbol{\gamma}(t)\rangle=0\ ,\qquad \lim_{t\to\infty}\int_0^\beta d\lambda\langle\boldsymbol{\gamma}(-t)\dot{\boldsymbol{R}}(i\hbar\lambda)\rangle=0\ . \tag{5.14}$$

If Eqs. (5.12) and (5.13) (and their conjugates) are right, we see from (5.2) that

$$(\sigma_{xx})_{\dot{R}\dot{\gamma}}=(\sigma_{yy})_{\dot{R}\dot{\gamma}}=(\sigma_{yx})_{\dot{R}\dot{\gamma}}=(\sigma_{xy})_{\dot{R}\dot{\gamma}}=0\ . \tag{5.15}$$

Namely the cross terms involving the relative and the center velocities do not contribute anything to the static conductivity. This is again in accord with our former consideration.

The assumptions (5.14) are similar to (5.7) and are understood in a similar manner. Namely they are based on the assumptions that γ is *bounded* and that

$$\langle\dot{\boldsymbol{R}}\rangle=0\ . \tag{5.16}$$

The last assumption should be true, because otherwise there would be a constant current flowing in the absence of the applied electric field.

Another point to be remarked in the transformation (5.12) is the last step which interchanges the order of the operators in the trace operation. The classical correspondence of this is the partial integration of the type

$$\iiiint dXdYd\xi d\eta\left\{\frac{\partial}{\partial X}\exp(-\beta\mathscr{H})\right\}\cdot\xi$$
$$=\iiint dYd\xi d\eta[\{\exp(-\beta\mathscr{H})\}_{X=X_2}-\{\exp(-\beta\mathscr{H})\}_{X=X_1}]\cdot\xi-\iiiint dXdYd\xi d\eta\exp(-\beta\mathscr{H})\frac{\partial\xi}{\partial X}\ ,$$

where X_1 and X_2 are the boundaries of the domain under consideration. This surface contribution will vanish since the electron density is constant on the average even when there the perturbation potential U.

Thus, we have seen that the static conductivity is rather simply expressed in the ξ–X re-exists presentation as

$$\sigma_{xx}=e^2\int_0^\infty dt\int_0^\beta d\lambda\langle\dot{\boldsymbol{X}}(-i\hbar\lambda)\dot{\boldsymbol{X}}(t)\rangle\ ,\qquad \sigma_{yy}=e^2\int_0^\infty dt\int_0^\beta d\lambda\langle\dot{\boldsymbol{Y}}(-i\hbar\lambda)\dot{\boldsymbol{Y}}(t)\rangle\ , \tag{5.17a}$$

$$\sigma_{yx}=\frac{nec}{H}+e^2\int_0^\infty dt\int_0^\beta d\lambda\langle\dot{\boldsymbol{X}}(-i\hbar\lambda)\dot{\boldsymbol{Y}}(t)\rangle\ ,\qquad \sigma_{xy}=-\frac{nec}{H}+e^2\int_0^\infty dt\int_0^\beta d\lambda\langle\dot{\boldsymbol{Y}}(-i\hbar\lambda)\dot{\boldsymbol{X}}(t)\rangle \tag{5.17b}$$

if the condition is satisfied that the variables ξ and η are *bounded*.

This is satisfied when the electrons are free with a constant mass or when the effective mass theory is valid. It will be so more generally when the cyclotron orbits (in semiclassical sense) are closed in the momentum space. In these cases, the probability amplitudes in the momentum space will be limited in a certain neighborhood of the classical paths. Since the general canonical distribution, or the Fermi distribution in the case of independent electrons, will cut off the larger orbits with higher energies, the quasimomenta and therefore the relative coordinates can be regarded as bounded even in a quantummechanical sense. This consideration shows also that we should treat holes rather than electrons if the band in consideration is almost full as we do usually. This of course will change the sign of the first term of (5.17b).

Therefore, by neglecting the interband effect and Harper's broadening effect (§ 2) and by excluding the existence of the extended orbits[12] we may expect the bounded character of the relative coordinates and so use Eq. (5.17), which expresses the conductivity in terms of the migration of the center coordinate.

It should be remarked also that Eq. (5.17) may be written in another form as far as the symmetric part is concerned.

As was indicated by (3.8), the symmetric part can be written in terms of the correlation function (see K, § 3). So we have

$$\left.\begin{aligned}\sigma_{xx}&=\frac{e^2}{2kT}\int_{-\infty}^{\infty}dt\langle\{\dot{X}(0)\dot{X}(t)\}\rangle dt\,,\\ \sigma_{yy}&=\frac{e^2}{2kT}\int_{-\infty}^{\infty}dt\langle\{\dot{Y}(0)\dot{Y}(t)\}\rangle dt\,,\\ \sigma_{yx}+\sigma_{xy}&=\frac{e^2}{2kT}\int_{-\infty}^{\infty}dt\langle\{\dot{X}(0)\dot{Y}(t)+\dot{Y}(0)\dot{X}(t)\}\rangle\,,\end{aligned}\right\}\tag{5.18}$$

where the right hand sides are the correlation functions of the center current densities. These equations are the generalization of Eq. (4.16) and the Einstein relation to correlate the conductivity and the diffusion constant of the center coordinate.

It may be added that the components σ_{xz} and σ_{yz} are expressed as

$$\sigma_{xz}=e^2\int_0^\infty dt\int_0^\beta d\lambda\langle v_z(-i\hbar\lambda)\dot{X}(t)\rangle\,,\qquad \sigma_{yz}=e^2\int_0^\infty dt\int_0^\beta d\lambda\langle v_z(-i\hbar\lambda)\dot{Y}(t)\rangle\,.\tag{5.19}$$

This is seen from (5.3) by writing it in the ξ-X representation and by transforming it like (5.12) with the use of an assumption similar to (5.14).

Before concluding this section, the nature of the above derived equations, (5.17), (5.18) and (5.19), should be briefly discussed. It is noticed that all of these expressions will vanish if there exists no scattering potential U, except $\sigma_{yx}=-\sigma_{xy}$ which goes into enc/H. This is obvious, since the electrons will then simply drift with the velocity cE/H at right angles to the directions of the magnetic field and the electric field (Eq. (2.12)).

The important point here, however, is that the integrals in Eqs. (5.17)~(5.19) vanish with the perturbation potential. In other words, these are very convenient expressions to start from the limit of strong field. The potential U may then be treated by some sort of perturbation calculation. By complete calculation of such perturbation series, these equations will of course give the correct answer for all values of the magnetic field. But the strong field case could be treated by some lower order calculation of the perturbation.

§ 6. Approximations for Strong Field

Let us now apply the results of the previous section to the case where the magnetic field is so strong that the condition (1.1) is satisfied.

In the classical theory, this is the condition that the expansion

$$\frac{\tau}{1+\omega_0^2\tau^2}=\frac{1}{\omega_0^2\tau}\left\{1-\frac{1}{\omega_0^2\tau^2}+\cdots\right\}\tag{6.1}$$

can be used. This series is a sort of perturbation expansion since $1/\tau$ is essentially the second order quantity in the perturbation potential U. We also remark that the first term of (6.1) may as well be regarded as the first term of the expansion (4.23) in the correlation of successive jumps of the center displacement.

Guided by this classical consideration, two different standpoints can be conceived for the calculation of the strong field properties.

a) The first standpoint is to regard the peaturbation U as weak and use the direct perturbation calculation or its modification if necessary.

b) The second standpoint is that the perturbation potential is considered as local. This means that the electrons are free most of the time and collide the scattering center (the perturbation may be strong in its direct neighborhood) with short duration of collision. Then the correlation of the successive jumps is neglected so that the problem is reduced to the calculation of the scattering in the presence of the magnetic field.

6.1) *Perturbational Calculation.*

By the equation of motion (2.8b), the integrand of Eq. (5.18) is already second order in U. Therefore, from the standpoint (a), the lowest perturbation calculation will give

$$\sigma_{xx} \sim \frac{e^2}{2kT}\int_{-\infty}^{\infty} dt \langle \dot{\boldsymbol{X}}(0)\dot{\boldsymbol{X}}^0(t)\rangle_0 \,, \tag{6.2}$$

where

$$\dot{\boldsymbol{X}} = \int \psi^\dagger \dot{X}\psi d\boldsymbol{r} = \int \psi^\dagger \frac{1}{i\hbar}[X,\ U]\psi d\boldsymbol{r} = \frac{c}{eH}\int \psi^\dagger \frac{\partial U}{\partial y}\psi d\boldsymbol{r} \tag{6.3}$$

and $\dot{\boldsymbol{X}}^0(t)$ means the motion of $\dot{\boldsymbol{X}}$ induced by the unperturbed Hamiltonian

$$\mathcal{H}_0 = \int \psi^\dagger E_0(\pi)\psi d\boldsymbol{r} + \mathcal{H}_s \tag{6.4}$$

(see Eq. (2.1)), whereas the total Hamiltonian is

$$\mathcal{H} = \mathcal{H}_0 + \boldsymbol{U} = \mathcal{H}_0 + \int \psi^\dagger U \psi d\boldsymbol{r} \,. \tag{6.5}$$

In Eq. (6.4) $\mathcal{H}_s$ is the Hamiltonian for the scatters and is assumed to be commutable with the first term. The suffix 0 in (6.2) after the bracket means that the average is taken over the grand canonical distribution

$$\rho_0 = C_0 \exp(-\beta\mathcal{H}_0 + \beta\zeta N) \,, \qquad N = \int \psi^\dagger \psi d\boldsymbol{r}$$

instead of the true distribution $\rho = C\exp(-\beta\mathcal{H} + \beta\zeta N)$.

As one sees by (6.3), the expression (6.2) is proportional to U^2/H^2, disregarding the H-dependence of other factors.

In one-electron operators, Eq. (6.2) may be written as

$$\sigma_{xx} \sim 2\frac{e^2}{2kT}\int_{-\infty}^{\infty} dt \langle \mathrm{Tr}\, f(E_0)\dot{X}(1-f(E_0))\dot{X}^0(t)\rangle_s \tag{6.6}$$

where f is the Fermi distribution

$$f(E_0) = \{\exp[\beta(E_0(\pi) - \zeta)] + 1\}^{-1} \,,$$

ζ being the Fermi potential, and $\langle\ \ \rangle_s$ means the average over the distribution of scatterers. The factor 2 in front takes care of the spin weight. $\dot{X}^0(t)$ represents the unperturbed motion of $\dot{X}$,

$$\begin{aligned} \dot{X}^0(t) &= \exp\{i(E_0 + \mathcal{H}_s)t/\hbar\}\dot{X}\exp\{-i(E_0 + \mathcal{H}_s)t/\hbar\} \\ &= \frac{1}{i\hbar}[X,\ \exp\{i(E_0 + \mathcal{H}_s)t/\hbar\}U\exp\{-i(E_0 + \mathcal{H}_s)t/\hbar\}] \\ &= \frac{1}{i\hbar}[X,\ \exp(iE_0t/\hbar)U^0(t)\exp(-iE_0t/\hbar)] \,, \end{aligned} \tag{6.7}$$

where $U^0(t)$ is the time change of the perturbation caused by the natural motion of the scatterers. If U is due to lattice defects such as impurities it will be static.

The eigenvalues of

$$E_0(\pi) = E_0(\pi_x,\ \pi_y,\ p_z) \tag{6.8}$$

will be denoted by $E_{\nu' p_z'}$, and the eigenstates and eigenvalues of the scatterers are denoted by α' and $E_{\alpha'}$. By the commutation law (2.6b) each of $E_{\nu' p_z'}$ is degenerate with the multiplicity $L^2/2\pi l^2$ if we take the domain with the volume L^3 in order to see the dimensional relation clearly. These degenerate states may be labeled by X' or Y' depending on the choice of the representation. Summations over p_z' and X' should be replaced by the integrals as follows:

$$\sum_{p_z'} \to \frac{L}{h}\int_{-\infty}^{\infty} dp_z' , \qquad \sum_{X'} \to \frac{L}{2\pi l^2}\int_0^L dX' .$$

By these considerations, Eq. (6.6) can be written as

$$\begin{aligned}\sigma_{xx} \sim 2\frac{e^2}{2kT}\sum_{\nu'}\frac{1}{h}\int dp_z' \, \frac{1}{2\pi l^2}\int \frac{dX'}{L} f(E_{\nu' p_z'}) \\ \times \sum_{\nu''}\frac{L}{h}\int dp_z'' \cdot \frac{L}{2\pi l^2}\int_L dX''(X'-X'')^2 \cdot (1-f(E_{\nu'' p_z''}))W(\nu' p_z' X', \nu'' p_z'' X'')\end{aligned} \tag{6.9}$$

when W represents the transition probability for an electron to be scattered from the state $\nu' p_z' X'$ to $\nu'' p_z'' X''$. Here W is explicitly calculated to be

$$W(\nu' p_z' X', \nu'' p_z'' X'')$$

$$= \frac{1}{\hbar^2}\int_{-\infty}^{\infty} dt \langle (\nu' p_z' X' | U | \nu'' p_z'' X'')(\nu'' p_z'' X'' | U^0(t) | \nu' p_z' X')\rangle_s \exp\{i(E_{\nu'' p_z''} - E_{\nu' p_z'})t/\hbar\} \tag{6.10a}$$

$$= \frac{2\pi}{\hbar}\sum_{\alpha'}\sum_{\alpha''} P_{\alpha'} |(\nu' p_z' X' \alpha' | U | \nu'' p_z'' X'' \alpha'')|^2 \delta(E_{\nu' p_z'} + E_{\alpha'} - E_{\nu'' p_z''} - E_{\alpha''}) \tag{6.10b}$$

by Eq. (6.7), where $P_{\alpha'}$ is the probability distribution of the scatterer states.

The potential U is a sum of single scatterer potential

$$U = \sum_{\text{scatterers}} U_j , \tag{6.11}$$

which are randomly distributed in the whole space. The product of the matrix elements

$$(\nu' p_z' X' | U_j | \nu'' p_z'' X'')(\nu'' p_z'' X'' | U_l | \nu' p_z' X') \tag{6.12}$$

will vanish if the scatterers j and l are far apart in space. Therefore (6.10) is essentially proportional to the total number N_s of scatterers in space. The expression (6.9) itself depends, however, only on the number density of scatterers N_s/L^3 as it should be.

Eq. (6.9) is similar to the Einstein relation,

$$\sigma_{xx} = \frac{e^2}{2kT} n_{\text{eff}} \cdot D . \tag{6.13}$$

If we consider the present problem in a semiclassical way we would expect that this equation will be written as

$$\begin{aligned}\sigma_{xx} = 2\frac{e^2}{2kT}\sum_{\nu'}\frac{1}{h}\iint dp_z' dz' \, \frac{1}{2\pi l^2}\iint dX' dY' f(E_{\nu' p_z'}) \\ \times \int dp_z'' \iint dX'' dY'' \cdot (X'-X'')^2 (1-f(E_{\nu'' p_z''}))\Phi(\nu' p_z' X' Y', \nu'' p_z'' X'' Y'') ,\end{aligned} \tag{6.14}$$

where Φ is the transition probability by scattering in which an electron jumps from $(\nu' p_z')$ to $(\nu'' p_z'')$ with the center displacement from $(X'Y')$ to $(X''Y'')$. Eq. (6.9) takes account of the fact that the center coordinates X and Y have the uncertainty of $2\pi l^2$. The relation of (6.14) and (6.9) may easily be seen.

Eq. (6.2) or (6.9) can be applied to calculation of the case of phonon scattering. In fact, the example of metals with isotropic mass has been calculated. The result agrees with that obtained by Titeica[9)]. It is important to note that, this simplest perturbational calculation does not give convergent answers if the scattering potential is static, for instance, caused by lattice imperfections like impurities. Therefore, in order to get any reasonable answer, we must go at least one step further than this simplest Born approximation.

The reason for this bad divergence may be seen from the following consideration. For simplicity we take the mass as spherical. An electron passing through a scattering potential along the z-direction will spend the time of the order of

$$\tau_d \sim a/v_z = ma/p_z$$

in the potential. By the equation of motion (2.8b), the center displacement will be then of the order of

$$\Delta X \sim \frac{c}{eH}\frac{\overline{\partial U}}{\partial y}\cdot\tau_d\,,$$

where $\overline{\partial U/\partial y}$ is a time average of $\partial U/\partial y$. This rough estimation corresponds to the Born approximation. Then we would have

$$n_s\sigma_s\int v_z dp_z\cdot(\Delta X)^2 \propto \int\frac{dp_z}{p_z} \tag{6.15}$$

for the calculation of conductivity. Here n_s is the scatterer density, σ_s the cross section, so that $n_s\sigma_s v_z$ is the mean free time. The divergence of the type (6.15) is exactly that appears in (6.9) when applied to impurity scattering. This could be interpreted also in another way. An electron with p_z equal to zero will hit a scatterer again and again, if the scattering occurs really at a point scatterer. This infinite repetition is the source of the divergence.

6.2) *Higher Approximations*

For a better calculation, we go back to (5.18a) or its equivalent,

$$\sigma_{xx} = 2\frac{e^2}{2kT}\int_{-\infty}^{\infty} dt\,\mathrm{Tr}\,\{f(\mathcal{H})\dot{X}(1-f(\mathcal{H}))\dot{X}(t)\}\,, \tag{6.18}$$

where $\mathcal{H}$ is the one-electron Hamiltonian

$$\mathcal{H} = E_0 + U\,.$$

Since the potential U is assumed to be static (6.18) can be transformed into

$$\sigma_{xx} = 2\int_{-\infty}^{\infty} dE\left(-\frac{\partial f}{\partial E}\right)G_{xx}(E)\,, \tag{6.19}$$

where

$$G_{xx}(E) = \pi\hbar e^2\,\mathrm{Tr}\,\{\delta(E-\mathcal{H})\dot{X}\delta(E-\mathcal{H})\dot{X}\} = e^2\rho(E)\frac{1}{2}\int_{-\infty}^{\infty} dt\langle\dot{X}\dot{X}(t)\rangle_E\,. \tag{6.20}$$

Here $\rho(E)$ is the state density

$$\rho(E) = \mathrm{Tr}\,\delta(E-\mathcal{H})$$

and $\langle\ \rangle_E$ means the microcanonical average for a given E.

Now the resolvent for $\mathcal{H}$ is defined by

$$R(\gamma) = \frac{1}{\mathcal{H}-\gamma}\,. \tag{6.21}$$

With the use of this, $\delta(E-\mathcal{H})$ is expressed as[20)]

$$\delta(E-\mathcal{H}) = \lim_{\eta\to+0}\frac{1}{2\pi i}(R(E+i\eta)-R(E-i\eta)) = \lim_{\eta\to+0}\frac{1}{2\pi}\frac{\eta}{(\mathcal{H}-E)^2+\eta^2}\,, \tag{6.22}$$

so (6.20) may be calculated by any useful approximation for $R(\gamma)$. A damping-theoretical expansion of $R(\gamma)$ is given by[20)]

$$R(\gamma) = D(\gamma) - D(\gamma)UD(\gamma) + \cdots \tag{6.23}$$

where

$$D(\gamma)=\frac{1}{E_0+G(\gamma)-\gamma} \tag{6.24}$$

is the diagonal part of $R(\gamma)$ with respect to E_0. $G(\gamma)$ here determines the shift and broadening in the limit $\gamma\rightarrow E\pm i0$ and is obtained by solving the integral equation of the form

$$G(\gamma)=-\{UD(\gamma)U\}_{\text{diagonal}}+\cdots . \tag{6.25}$$

The diagonal part of $\delta(E-\mathcal{H})$, Eq. (6.22), thus calculated will be denoted by $S(E)$,

$$S(E)=\{\delta(E-\mathcal{H})\}_{\text{diag.}} \tag{6.26}$$

Eq. (6.20) is then replaced by

$$G_{xx}(E)\sim\pi\hbar e^2\,\mathrm{Tr}\,\{S(E)\dot{X}S(E)\dot{X}\}=\frac{\pi e^2}{\hbar}\,\mathrm{Tr}\,\{S(E)[X,\ U]S(E)[U,\ X]\}\,. \tag{6.27}$$

This is a higher approximation by which the broadening of the quantum levels is taken into account and the divergence above mentioned is avoided. Davydov and Pomeranchuk[11] in fact tacitly used this approximation. More detailed discussion of this will be given in the next paper.

A brief remark may be added about the standpoint (b) mentioned at the beginning of this section. Eq. (6.20) may be approximated by

$$G_{xx}(E)=e^2\rho(E)\sum_j\frac{1}{2\hbar^2}\int_{-\infty}^{\infty}dt\langle[X,\ U_j][U_j,\ X]_t\rangle_E \tag{6.28}$$

where the sum is taken over the scatterers in a unit volume. The cross terms which involve different scatterers are omitted here. Furthermore the time change $[U_j,\ X]_t$ is considered only in the neighborhood of the particular scatterer j. Namely the electron is supposed to move there only under the influence of U_j. Therefore, this approximation starts from solving the scattering problem in which an electron is scattered from $\nu' p_z' X'$ to $\nu'' p_z'' X''$. If the exact solution of this is obtained, Eq. (6.19) and (6.28) may be used to calculate σ_{xx}. The divergence of the type (6.15) will not occur in this method so that one should get finite answer even if the broadening is neglected in the state density. The broadening is however, important particularly for the amplitude of de Haas-van Alphen like oscillations, so that it may be necessary to take account of it.

§ 7. Conclusion

We have seen in the present paper that the description by the migration of the center of cyclotron motion is particularly useful for the understanding and for practical calculations of conductivity at high magnetic field. A general treatment is developed here on the basis of the new theory of transport phenomena given by one of the present authors. A great advantage of this method is that it avoids any dubious use of transport equations so that the logical structure of the theory is even more satisfactory than the ordinary conduction theory. After the proof of general formulae for the conductivity expressed in terms of the center velocities, approximation methods have been discussed. Detailed applications to metals and semiconductors will be reported soon in a forthcoming paper which makes the second part of the series.

Appendix

By Eqs. (4.3), (4.5) and (4.6), we have

$$\left\langle u^*(0)\int_0^\infty u(t)e^{-i\omega t}dt\right\rangle = \left\langle u_0^*\sum_{k=0}^{\infty}\int_{t_k}^{t_{k+1}} e^{i\overset{k}{\Sigma}\alpha_j}\, e^{-i(\omega-\omega_0)t}dt\cdot u_0\right\rangle$$

$$=\frac{\overline{u_0^*u_0}}{i(\omega-\omega_0)}\left\langle\sum_{k=0}^{\infty} e^{i\overset{k}{\Sigma}\alpha_j}(e^{-ij(\omega-\omega_0)t_k}-e^{-i(\omega-\omega_0)t_{k+1}})\right\rangle$$

$$=\frac{\overline{u_0^*u_0}}{i(\omega-\omega_0)}\sum_{k=0}^{\infty}c^k[\{1+i(\omega-\omega_0)\tau_0\}^{-k}-\{1+i(\omega-\omega_0)\tau_0\}^{-k-1}]$$

$$=\overline{u_0^*u_0}\frac{\tau_0}{1-c+i(\omega-\omega_0)\tau_0}=\overline{u_0^*u_0}\frac{\tau}{1+i(\omega-\omega_0)\tau}\,. \tag{A.1}$$

Similarly

$$\int_0^\infty\langle u(0)u^*(t)\rangle e^{-i\omega t}dt=\overline{u_0^*u_0}\frac{\tau}{1+i(\omega+\omega_0)\tau} \tag{A.2}$$

which may be obtained from (A.1) by replacing ω by $-\omega$ and i by $-i$. Also by the assumption that

$$\overline{v_xv_y}=0\,,\qquad \overline{v_x^2}=\overline{v_y^2}$$

we have

$$\int_0^\infty\langle u(0)u(t)\rangle e^{-i\omega t}dt=\int_0^\infty\langle u^*(0)u^*(t)\rangle e^{-i\omega t}dt=0\,. \tag{A.3}$$

Eqs. (4.7a) and (4.7b) in the text follow from (A.1), (A.2) and (A.3).

The correlations of center velocities are calculated as follows:

$$\int_0^\infty\langle\dot{R}^*(0)\dot{R}(t)\rangle e^{-i\omega t}dt=\lim_{T\to\infty}\frac{1}{T}\int_0^T dt'\int_0^\infty\langle\dot{R}^*(t')\dot{R}(t'+t)\rangle e^{-i\omega t}dt$$

$$=\frac{1}{\tau_0}\left[\frac{1}{2}\langle\Delta_1R^*\Delta_1R\rangle+\sum_{k=2}^{\infty}\langle\Delta_1R^*\Delta_kRe^{-i\omega(t_k-t_1)}\rangle\right]. \tag{A.4}$$

By Eq. (4.4) we get

$$\left.\begin{aligned}&\langle\Delta_1R^*\Delta_1R\rangle=\frac{\overline{u_0^*u_0}}{\omega_0^2}\langle(1-e^{-i\alpha_1})(1-e^{i\alpha_1})\rangle=\frac{2\overline{u_0^*u_0}}{\omega_0^2}(1-c)\,,\\&\langle\Delta_1R^*\Delta_kRe^{-i\omega(t_k-t_1)}\rangle\\&\quad=\frac{\overline{u_0^*u_0}}{\omega_0^2}\langle(1-e^{-i\alpha_1})(e^{i\overset{k-1}{\Sigma}\alpha_j}-e^{i\overset{k}{\Sigma}\alpha_j})e^{i(\omega_0-\omega)(t_k-t_1)}\rangle=-\frac{\overline{u_0^*u_0}}{\omega_0^2}c^{k-2}(1-c)^2\left\{\frac{1}{1+i(\omega-\omega_0)\tau_0}\right\}^{k-1}.\end{aligned}\right\} \tag{A.5}$$

These formulas give (4.21) and (4.22) for $\omega=0$. When (A.5) is inserted into (A.4), Eq. (A.4) is reduced to

$$\int_0^\infty\langle\dot{R}^*(0)\dot{R}(t)\rangle e^{-i\omega t}dt=\frac{1-c}{\tau_0}\left[1-\frac{1-c}{1-c+i(\omega-\omega_0)\tau_0}\right]\frac{\overline{u_0^*u_0}}{\omega_0^2}=\frac{\overline{u_0^*u_0}}{\omega_0^2}\frac{i(\omega-\omega_0)}{1+i(\omega-\omega_0)\tau}\,. \tag{A.6}$$

Similarly

$$\int_0^\infty\langle\dot{R}(0)\dot{R}^*(t)\rangle e^{-i\omega t}dt=\frac{\overline{u_0^*u_0}}{\omega_0^2}\frac{i(\omega+\omega_0)}{1+i(\omega+\omega_0)\tau}\,. \tag{A.7}$$

Eqs. (A.6) and (A.7) give Eqs. (4.8a) and (4.8b). Eqs. (4.10a) and (4.10b) are obtained from

$$\int_0^\infty \langle \dot{R}^*(0)u(t)\rangle e^{-i\omega t}dt = -\frac{i\overline{u_0^*u_0}}{\omega_0^2}\,\frac{1}{1+i(\omega-\omega_0)\tau}$$

and

$$\int_0^\infty \langle u^*(0)\dot{R}(t)\rangle e^{-i\omega t}dt = \frac{i\overline{u_0^*u_0}}{\omega_0^2}\,\frac{1}{1+i(\omega+\omega_0)\tau}$$

which are derived by similar calculation. The correlation of $\langle\dot{\gamma}^*(0)\dot{\gamma}(t)\rangle$ can be calculated in the same way, so these calculations are omitted here.

Excitation of the Molecular Vibration by Collision

By Kazuo TAKAYANAGI

Department of Physics, Saitama University, Urawa

(Received September 18, 1958)

Excitation of the molecular vibration in H_2+H_2 collision is studied using the so-called modified wave number method. The same problem has been investigated quite recently by Salkoff and Bauer who applied the distorted wave method thoroughly without making the modified wave number approximation. Thus the present work serves as a test of the accuracy of the modified wave number method which has been used by many authors to study this sort of problem. The result obtained here is in good agreement with the result by Salkoff and Bauer.

§ 1. Introduction

It has been believed that the method of distorted waves[1] is suitable for calculating the probability of the collisional transition of the molecular vibrations.* When we apply this method to a particular case, there are two problems we have to work out—the determination of the potential function and the three-dimensional treatment of the collision problem. The intermolecular potential function, especially its dependence on the internal coordinates of the colliding molecules, is very hard to obtain either theoretically or experimentally. Theoretical calculation of the potential involves the usual difficulty of the many-body problem. Therefore, we have to content ourselves with assuming a function inferred from an insufficient amount of the experimental data. On the other hand, the three-dimensional treatment of a collision process forces us to solve a great number of the radial equations. It is not usual that a hundred or more equations have to be solved for the thermal collision. Although the numerical integration makes it always possible to get the answer, it is too laborious and not worth doing for an ambiguous potential.

The modified wave number method (MWN method) was then introduced to save the labour. The outline of the method will be given in § 2. This method has been applied by many authors[2)~9)] to the various cases. The results are in more or less reasonable agreement with the observed data. However, because of the ambiguity in the potential used, we could not definitely say something about the accuracy of the MWN method.

The recent development of the electronic computing technic has improved the situation and encourages us to treat the three-dimensional collision problem thoroughly for various potential functions. Salkoff and Bauer[10] were the first to carry out this sort of calculation. They studied the vibrational transition in the hydrogen molecule using the Morse type intermolecular potential. They applied the distorted wave method without making the MWN approximation. This gives us a good chance to test the accuracy of the MWN method. What we have to do is to calculate the transition probability using the MWN method for the same potential function as used by Salkoff and Bauer. Fortunately, the one-dimensional problem for the Morse type potential has been solved analytically[11], so that the whole calculations can be done within a few days by using a hand-operated calculating machine. This has been done and will be reported in § 3, which will be followed by some discussions in § 4.

§ 2. Modified Wave Number Approximation

In the distorted wave method, the effective cross section for the inelastic transition $n\rightarrow m$ is given by

$$Q_{n\rightarrow m}$$
$$=4\pi\frac{k_m}{k_n}\sum_j(2j+1)\left|\int_0^\infty 2\mu F_m{}^jF_n{}^jV_{mn}\,dR\right|^2, \quad (1)$$

where k_n, k_m are the initial and the final wave numbers, μ the reduced mass, and V_{mn} is the matrix element of the intermolecular potential V with respect to the internal states

---

* Rotational transitions have generally large probabilities, except for the hydrogen molecule, so that the distorted wave method which is essentially the first order perturbation method can not be applied adequately to the rotational transitions.

m, n. We have assumed here that the scattering potential V_{nn} and V_{mm} are spherically symmetric, so that the radial parts F_n, F_m of the distorted waves are obtained by solving the radial equations of the form†

$$\{d^2/dR^2 - j(j+1)/R^2 + k_l^2 - 2\mu V_{ll}(R)\}F_l^j(R) = 0\,. \tag{2}$$

These radial functions are normalized asymptotically as

$$F_l^j(R) \xrightarrow[R\to\infty]{} \sin(k_l R - \tfrac{1}{2}\pi j + \eta_{lj})/k_l\,;$$

$Q_{n\to m}$ can be written as

$$Q_{n\to m} = (\pi/k_n^2)\sum_j (2j+1)\,p^j_{n\to m}(k_n)\,, \tag{3}$$

where

$$p^j_{n\to m}(k_n) = 4k_n k_m \left|\int_0^\infty 2\mu F_m^j F_n^j V_{mn}\, dR\right|^2 \tag{4}$$

is the transition probability for the partial wave with given j.

The basic assumption in the MWN approximation is to regard the centrifugal potential $j(j+1)/R^2$ as a slowly varying function when compared with the scattering potential $2\mu V_{ll}$, at least in the limited region of R where the main contribution to the integral in (4) comes from. Then we may replace $k_l^2 - j(j+1)/R^2$ by an effective wave number $\tilde{k}_l^2 \equiv k_l^2 - j(j+1)/R_0^2$, where R_0 is a constant distance chosen in the most important region. This means that we replace $p^j_{n\to m}(k_n)$ in (3) by $p^0_{n\to m}(\tilde{k}_n)$. Thus the three-dimensional problem is reduced to the one-dimensional problem. The objection to this procedure will be that the centrifugal potential is not a gentle function for large j. Furthermore, $\tilde{k}_l^2$ becomes negative for very large j. However, a large value of j means that the collision is a distant one, so that the contribution to the transition from such partial waves will be unimportant. Thus we may safely omit the contribution from the higher j for which $\tilde{k}_n^2$ or $\tilde{k}_m^2$ becomes negative.

§ 3. Vibrational Transition in the Hydrogen Molecule

If the scattering potentials V_{nn}, V_{mm} and the transition matrix element V_{mn} are assumed as

$$V_{nn}(R) = V_{mm}(R) = \mathcal{E}\cdot[\exp\{-\alpha(R-R')\} - 2\exp\{-\alpha(R-R')/2\}] \tag{5a}$$

$$V_{mn}(R) = U\cdot[\exp\{-\alpha(R-R'-\zeta)\} - 2\exp\{-\alpha(R-R'-\zeta)/2\}]\,, \tag{5b}$$

the transition probability per collision in the one-dimensional problem (or S-wave collision) is given by[11]

$$p^0_{n\to m}(k_n) = \frac{\pi^2}{4}\left|\frac{U}{\mathcal{E}}\right|^2 \frac{\sinh 2\pi q_n \sinh 2\pi q_m}{(\cosh 2\pi q_n - \cosh 2\pi q_m)^2}(q_n^2 - q_m^2)^2$$
$$\times e^{4\beta}[\{1-(2e^{-\beta}-1)\delta\}\phi + \{1+(2e^{-\beta}-1)\delta\}\phi^{-1}]^2\,, \tag{6}$$

where

$$q_l = 2k_l/\alpha\,,\qquad \delta = 2d/(q_n^2 - q_m^2)\,,\qquad d = 2\sqrt{2\mu\mathcal{E}}/\alpha\,,\qquad \beta = \alpha\zeta/2\,,$$

and

$$\phi = |\Gamma(\tfrac{1}{2} - iq_m - d)|/|\Gamma(\tfrac{1}{2} - iq_n - d)|\,.$$

Salkoff and Bauer[10] studied the inelastic collision:

$$\begin{array}{ccc} H_2 + H_2 & \longrightarrow & H_2^* + H_2\,, \\ \text{(state 0)} & & \text{(state 1)} \end{array}$$

where H_2^* means a hydrogen molecule in the first excited state of the vibration. They assumed the potential functions which can be rewritten in the form (5a, b) where $\mathcal{E} = 1.045 \times 10^{-4}$, $\alpha = 1.832$, $R' = 6.427$, $U = 1.465 \times 10^{-6}$, and $\zeta = 1.200$. Thus we can apply the formula (6) to obtain the one-dimensional probability $p_{0\to 1}$ for the transition from the state 0 to the state 1. We have taken the following values for the other parameters needed: $2\mu = 3675.$, the vibrational energy change $\Delta E = 2.004 \times 10^{-2}$. The resulting probability is shown in Fig. 1.

---

† Atomic units are used in this paper, unless otherwise stated.

The contribution from the partial wave with given j to the effective cross section for the inelastic process is

$$\sigma_j=(\pi/k_0^2)(2j+1)p^0_{0\to1}(\tilde{k}_0)\ , \quad \tilde{k}_0^2\simeq k_0^2-j^2/R_0^2\ . \tag{7}$$

For the potential function used here, the effective scattering potential $V_{\mathrm{eff}}(R)=V_{00}(R)+j(j+1)/2\mu R^2$ is shown in Fig. 2 for several values of j. In the energy region we are going to consider, the classical turning points (abbreviated as ctp. hereafter) for the initial and the final kinetic energies are in the range $3\lesssim R\lesssim 5$. Therefore, we shall first take $R_0=4.0$ in the following calculations. As an example, σ_j for $q_0=22.0$ (the corresponding incident energy is 3.01 ev) is plotted in Fig. 3. This curve is very similar to the curve obtained by Salkoff and Bauer for 3 ev.

By replacing the summation (3) with an integration over $\tilde{k}_0$, the effective cross section

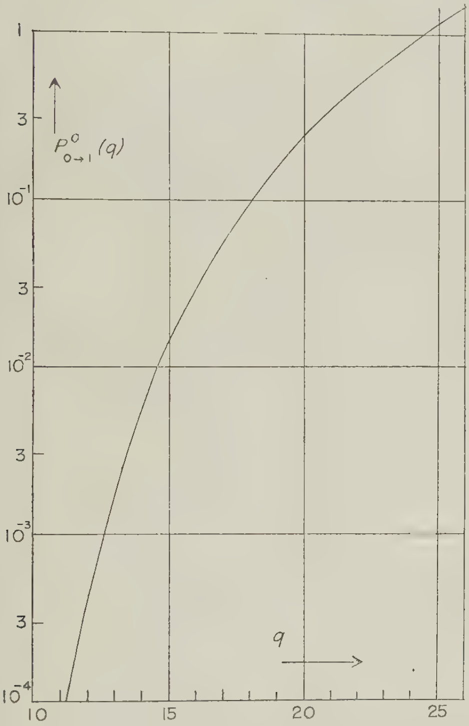

Fig. 1. One-dimensional transition probability $p^0_{0\to1}$ as a function of $q=2k/\alpha$.

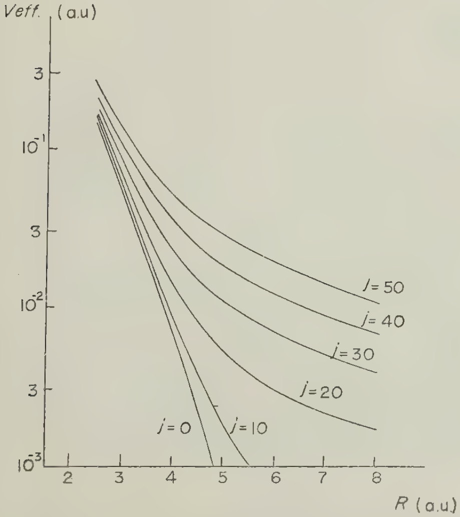

Fig. 2. $V_{\mathrm{eff}}=V_{00}(R)+j(j+1)2\mu R^2$.

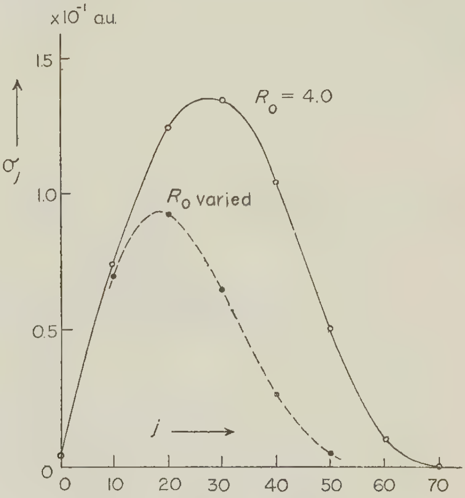

Fig. 3. Partial cross section σ_j for $q_0=22.0$.

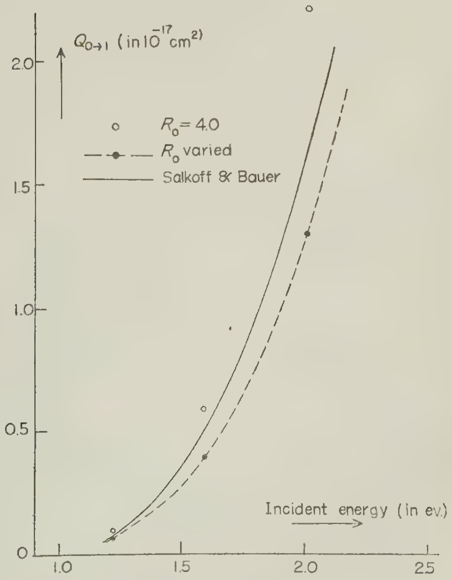

Fig. 4. Effective cross section $Q_{0\to1}$.

for the transition 0→1 is given by

$$Q_{0\to1}=(2\pi R_0^2/k_0^2)\int_0^{k_0} p_{0\to1}^0(\tilde{k})\tilde{k}\,d\tilde{k}\,. \qquad (8)$$

The integrations have been carried out numerically. The effective cross section thus obtained is shown in Fig. 4 and Fig. 5, where the corresponding curves by Salkoff and Bauer and also by Bauer (semi-classical calculation)[12] are shown for comparison.

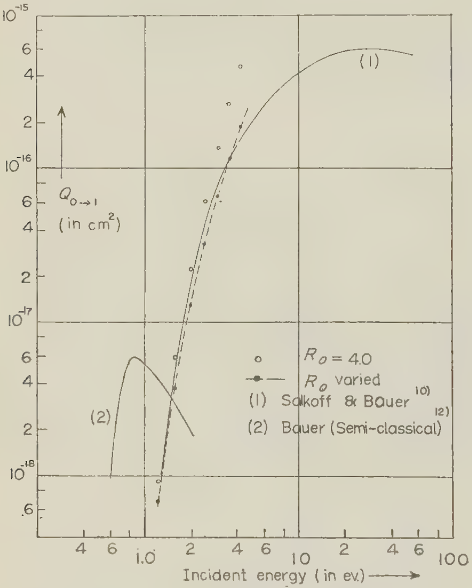

Fig. 5. Effective cross section $Q_{0\to1}$.

It is seen in these figures that the agreement of our result with the result by Salkoff and Bauer is fairly good. However, the discrepancy becomes appreciable in the high energy region. To explain this, it must be noted that in our expression (7) of σ_j, $p^0(\tilde{k})$ is generally a monotonously increasing, steep function of $\tilde{k}$ (see Fig. 1). Since $\tilde{k}$ is an increasing function of R_0 for given k and j, a larger value of R_0 will give a larger σ_j. The choice of R_0 in our calculation is rather arbitrary. A reasonable choice may, however, be made by taking the ctp. for the mean wave number $\bar{k}=\frac{1}{2}(k_0+k_1)$. Since the ctp. for $\bar{k}$ for the high energy collision is much smaller than 4.0 (see Fig. 2), it is expected that the reasonable choice of R_0 will reduce the discrepancy we are considering. The broken lines in Figs. 3, 4, 5 show the result after making this improvement. In Fig. 3 the ctp. for each value of j and $\bar{k}$ (=19.19 in this case) has been chosen as R_0, while in Figs. 4 and 5 the ctp. for k_0 and $j=30$ has been adopted.* The discrepancy between our values and those obtained by Salkoff and Bauer now lies within a factor 1.5 for the whole energy region investigated. Thus we may have some confidence in the validity of the MWN method in this sort of problem.

§ 4. Discussions

We shall now examine the small discrepancy between our result (after the improvement at the end of § 3) and the result obtained by Salkoff and Bauer. For the most part of the energy region we have studied, our cross section is slightly smaller than theirs. This will be explained as follows: Generally speaking, the steeper the repulsive part of the potential is, the larger the transition probability will be.[4),13)] In MWN method, the function $j(j+1)/R^2$ is replaced by a constant. This makes the effective potential V_{eff} less steep and so the probability becomes smaller than the true value. This will probably be the major reason for the discrepancy.

In the high energy region, our cross section goes up quickly and becomes larger than their value. The reason for this will be found in the formula (6). This formula was obtained under the condition that the wave functions should vanish at $R\to-\infty$. However, in the three-dimensional problems, we have to impose the condition that the radial wave functions vanish at $R=0$. This difference in the boundary condition may become important for the high energy collision in which the wave functions can penetrate deeply into the repulsive potential. When we use the formula (6), the wave functions penetrate more deeply, because the boundary condition is less strict. This will explain the discrepancy in the high energy region.

The one-dimensional probability $p_{0\to1}^0$ becomes larger than unity for $q_0>24$ as is seen in Fig. 1. Corresponding to this, the result obtained for $q_0>24$ (the incident energy > 3.58 ev) is unreliable. The distorted wave approximation have to be given up then.

Since the hydrogen is an extreme case with the very high vibrational frequency, it is desirable that the other examples with lower frequencies are also investigated with and without the MWN approximation.

---

* The ctp. for k_0 is very near the ctp. for $\bar{k}$, except for the low energy collisions.

On the Viscosity of Irradiated Polymers I.

By Mitio INOKUTI

Department of Applied Physics, Faculty of Engineering,
University of Tokyo, Tokyo, Japan

(Received September 18, 1958)

The change of the intrinsic viscosity of a polymeric substance due to irradiation with high-energy radiations is discussed for various types of initial molecular size distributions. It is shown that the intrinsic viscosity can at first decrease in certain cases by irradiation, even if it reaches infinity finally at the gel point. It is further concluded that such a behavior of the intrinsic viscosity is possible, only if the initial molecular size distribution is sufficiently broad.

§ 1. Introduction

A polymeric substance undergoes crosslinking and/or degradation under irradiation with high-energy radiations. Crosslinking or degradation naturally causes changes of molecular size distribution and then of physical and chemical properties of the polymeric substance. Among them the intrinsic viscosity of the polymer in an appropriate solvent is not only one of the most important quantities that reveal molecular size distribution, but has also been experimentally studied by many workers.

Theories of molecular size distribution in crosslinked and/or degraded polymers, proposed by Flory, Stockmayer and Charlesby are unfortunately inconvenient for calculation of the intrinsic viscosity. Recently Saito[1)-3)] developed a theory that can be used to calculate it. He also noted that in the course of irradiation the intrinsic viscosity can in certain cases decrease at first and then increase to reach infinity finally.[3)] Such a sort of phenomenon has really been observed in some experiments[4),5)]. However, he carried out explicit calculation only for the case where the initial molecular size distribution is Poisson-like,[3)] although his formulation is in practice applicable to an arbitrary initial distribution.

In the present paper we discuss the intrinsic viscosity of irradiated polymers according to Saito's theory for various types of initial distributions so as to clarify relationship between the initial distribution and the radiation-induced change of intrinsic viscosity.

§ 2. General Formulation

Let N be the total number of monomers in a polymeric substance, and $N\ m(p,\ R)\ dp$ be the number of polymers whose degree of polymerization lies between p and $p+dp$ when the substance is irradiated up to radiation dose R. The molecular size distribution function $m(p,\ R)$ satisfies a normalization condition because of the constancy of N, namely,

$$\int_0^\infty pm(p,\ R)dp=1\ . \tag{1}$$

If high-energy radiations introduce cross-linking with probability $\dot{c}$ per monomer unit per unit radiation dose and degradation with probability $\dot{r}$ per monomer unit per unit radiation dose, $m(p,\ R)$ will be given by the following procedure according to Saito's theory. It is convenient to define two variables

$$t=\dot{c}R \tag{2}$$

$$\tau=\dot{r}R \tag{3}$$

and to regard the distribution function $m(p,\ R)$ as a function of p, t and τ, i.e., $m(p,\ t,\ \tau)$. Then $m(p,\ t,\ \tau)$ is the solution of an integro-differential equation

$$\frac{\partial m(p,\ t,\ \tau)}{\partial t}+2pm(p,\ t,\ \tau)=\int_0^p l(p-l)m(l,\ t,\ \tau)m(p-l,\ t,\ \tau)dl \tag{4}$$

under the initial condition

$$m(p,\ 0,\ \tau)=\left\{m(p,0)+2\tau F(p)+\tau^2\int_p^\infty F(p')\,dp'\right\}e^{-p\tau}\ , \tag{5}$$

where $m(p,\ 0)$ is the initial distribution function and

$$F(p)=\int_p^\infty m(p',\ 0)\,dp'\ . \tag{6}$$

Further we define the following notations for $\beta\geqq 0$:

$$f_\beta(t,\ \tau)=\int_0^\infty m(p,\ t,\ \tau)p^\beta dp\ , \tag{8}$$

$$f_\beta(0)=\int_0^\infty m(p,\ 0)p^\beta dp\ . \tag{9}$$

According to Staudinger's law the intrinsic viscosity $\eta(R)$ at radiation dose R is proportional to $f_{\alpha+1}(t,\ \tau)$, where α is characteristic of the polymer species and $1/2\leqq\alpha<1$; namely,

$$\frac{\eta(R)}{\eta(0)}=\frac{f_{\alpha+1}(t,\ \tau)}{f_{\alpha+1}(0)}\ . \tag{10}$$

The formal solution that can be obtained by making use of Laplace transform is generally inconvenient for explicit calculation of $m(p,\ t,\ \tau)$ and $f_{\alpha+1}(t,\ \tau)$ for an arbitrary initial distribution. For the present we take interest in the initial derivative of the intrinsic viscosity with respect to radiation dose, or the coefficient $A_1(\lambda,\ \alpha)$ in the expansion

$$\eta(R)/\eta(0)=1+A_1(\lambda,\ \alpha)R+A_2(\lambda,\ \alpha)R^2+\cdots, \tag{11}$$

where

$$\lambda=\dot{r}/\dot{c}\ . \tag{12}$$

To obtain $A_1(\lambda,\ \alpha)$ we first establish a power-series expansion with respect to R.

If we put

$$m(p,\ t,\ \tau)=e^{-2\nu t}\sum_{k=0}^{\infty}\varphi_k(p,\ \tau)t^k \tag{13}$$

in (4), we have the recurrence formula for $\varphi_k(p,\ \tau)$

$$(k+1)\varphi_{k+1}(p,\ \tau)=\sum_{j=0}^{k}\int_0^p l(p-l)\varphi_j(l,\ \tau)\varphi_{k-j}(p-l,\ \tau)dl\ . \tag{13}$$

It is evident by (13) that

$$\varphi_0(p,\ \tau)=m(p,\ 0,\ \tau)\ . \tag{14}$$

Then we have by (13) and (14)

$$\varphi_1(p,\ \tau)=e^{-p\tau}\left[\int_0^p l(p-l)m(l,\ 0)m(p-l,\ 0)dl+4\tau\int_0^p l(p-l)m(l,\ 0)F(p-l)dl+O(\tau^2)\right]. \tag{15}$$

Taking note of the relation

$$\tau=\lambda t \tag{16}$$

obtained by (2), (3) and (12), and substituting (14) and (15) into (13), we have

$$m(p,\ t,\ \tau)=m(p,\ 0)+\{\psi(p)-(\lambda+2)pm(p,\ 0)\}t+O(t^2)\ , \tag{17}$$

where $\psi(p)$ is defined by

$$\psi(p)=2\lambda F(p)+\int_0^p l(p-l)m(l,\ 0)m(p-l,\ 0)dl\ . \tag{18}$$

Therefore

$$f_{\alpha+1}(t,\ \tau)=f_{\alpha+1}(0)+t\int_0^{\infty}\{\psi(p)-(\lambda+2)pm(p,\ 0)\}p^{\alpha+1}dp+O(t^2)\ . \tag{19}$$

Comparing (19) with (9) and (10), we arrive at the expression for $A_1(\lambda,\ \alpha)$, namely,

$$A_1(\lambda,\ \alpha)=\frac{\dot{c}}{f_{\alpha+1}(0)}\left\{\int_0^{\infty}\psi(p)p^{\alpha+1}dp-(\lambda+2)f_{\alpha+2}(0)\right\}. \tag{20}$$

Taking note of (18) and the relation

$$\int_0^{\infty}F(p)p^{\alpha+1}dp=\frac{1}{\alpha+2}f_{\alpha+2}(0)\ , \tag{21}$$

we can reduce (20) to the final result

$$A_1(\lambda,\ \alpha)=-\left(\frac{\dot{c}\alpha}{\alpha+2}\right)\left\{\frac{f_{\alpha+2}(0)}{f_{\alpha+1}(0)}\right\}\{\lambda-\lambda_0(\alpha)\}\ , \tag{22}$$

where $\lambda_0(\alpha)$ is the zero point of $A_1(\lambda,\ \alpha)$, namely,

$$\lambda_0(\alpha)=\left(\frac{\alpha+2}{\alpha}\right)\left\{\frac{I(\alpha)}{f_{\alpha+2}(0)}-2\right\}, \tag{23}$$

and $I(\alpha)$ stands for the following repeated integral:

$$I(\alpha)=\int_0^{\infty}dp\ p^{\alpha+1}\int_0^p dl\ l(p-l)m(l,\ 0)m(p-l,\ 0) \tag{24–1}$$

$$=\int_0^{\infty}dl\ lm(l,\ 0)\int_0^{\infty}dp(p+l)^{\alpha+1}pm(p,\ 0)\ . \tag{24–2}$$

Now we note a theorem given by Saito[1], which states the condition for formation of a gel, or such a macroscopically large molecular network as can be regarded as a polymer with an infinitely large degree of polymerization.

Theorem. Gel formation occurs as a result of crosslinking and degradation, if and only if $\lambda < 4$, whatever the initial molecular size distribution may be.

In connection with the theorem, Saito[3] pointed out that $\lambda_0(\alpha) < 4$ when the initial distribution is Poisson-like. This fact is physically interesting, because it implies that, for $\lambda_0(\alpha) < \lambda < 4$, the value $\eta(R)/\eta(0)$ decreases in the beginning, even if it reaches infinity at the gel point. (See Fig. 1.)

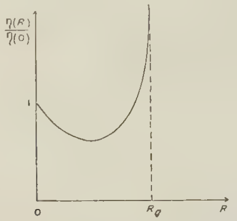

Fig. 1. Schematic representation of the behavior of $\eta(R)/\eta(0)$ for such a value of λ that $\lambda_0(\alpha) < \lambda < 4$, where R_g means the gel point.

Now we examine the relationship between the initial distribution $m(p, 0)$ and $A_1(\lambda, \alpha)$, so as to clarify for what kind of initial distribution such a behavior of the intrinsic viscosity $\eta(R)/\eta(0)$ is possible. A general discussion of the problem mathematically requires a theory of functionals. For the present we will content ourselves with the examination of some particular types of initial distributions.

§ 3. Applications to Some Types of Initial Molecular Size Distributions

1) *Poisson distribution*

When the initial distribution is Poisson-like, namely,

$$m(p, 0) = u^{-2} e^{-p/u}, \tag{25}$$

where u stands for the initial number average degree of polymerization, we have

$$f_\beta(0) = u^{\beta-1} \Gamma(\beta+1), \tag{26}$$

$$I(\alpha) = u^{\alpha+1} \Gamma(\alpha+5)/6. \tag{27}$$

By (22), (23), (26) and (27) we obtain the following result already given by Saito[3]:

$$A_1(\lambda, \alpha) = -\dot{c}\alpha u\{\lambda - \lambda_0(\alpha)\}, \tag{28}$$

where

$$\lambda_0(\alpha) = (\alpha+2)(\alpha+7)/6. \tag{29}$$

Clearly $\lambda_0(\alpha) < 4$ for $1/2 \leqq \alpha < 1$ and therefore $\eta(R)/\eta(0)$ can behave as represented in Fig. 1.

2) *Uniform distribution*

When the initial distribution is uniform, namely,

$$m(p, 0) = \frac{1}{u^2} \delta\left(\frac{p}{u} - 1\right), \tag{30}$$

where u stands for the initial degree of polymerization, we have

$$f_\beta(0) = u^{\beta-1}, \tag{31}$$

$$I(\alpha) = 2^{\alpha+1} u^{\alpha+1}. \tag{32}$$

Substituting (31) and (32) into (22) and (23), we obtain

$$A_1(\lambda, \alpha) = -\left(\frac{\dot{c}u\alpha}{\alpha+2}\right)\{\lambda - \lambda_0(\alpha)\}, \tag{33}$$

$$\lambda_0(\alpha) = \frac{2(\alpha+2)}{\alpha}(2^\alpha - 1). \tag{34}$$

Since $\lambda_0(\alpha) < 4$ for $1/2 \leqq \alpha < 1$ in this case, $\eta(R)/\eta(0)$ never behaves as represented in Fig. 1. In other words, the intrinsic viscosity begins to increase definitely so far as gel formation is possible or $\lambda < 4$. The situation is quite different from that of the case where the initial distribution is Poisson-like.

3) *Rectangular distribution*

We define the rectangular distribution as

$$m(p, 0) = \begin{cases} (2\xi u^2)^{-1} & (1-\xi \leqq p/u \leqq 1+\xi) \\ 0 & \text{(otherwise)}, \end{cases} \tag{35}$$

where u is the number average degree of polymerization and ξ is to be called as dimensionless width parameter. The function is normalized as (1). For the present we regard ξ as a small quantity. Then, for this initial distribution,

$$f_\beta(0)=\frac{u^{\beta-1}}{2(\beta+1)\xi}\{(1+\xi)^{\beta+1}-(1-\xi)^{\beta+1}\}=u^{\beta-1}\left\{1+\frac{\beta(\beta-1)}{3!}\xi^2+\frac{\beta(\beta-1)(\beta-2)(\beta-3)}{5!}\xi^4+\cdots\right\}, \quad (36)$$

$$I(\alpha)=2^{\alpha+1}u^{\alpha+1}\left[\frac{2}{(\alpha+2)(\alpha+3)}+\frac{(\alpha+1)\xi^{-2}}{(\alpha+2)(\alpha+3)(\alpha+5)}\{(1+\xi)^{\alpha+5}+(1-\xi)^{\alpha+5}-2\}\right]$$
$$=2^{\alpha+1}u^{\alpha+1}\left\{1+\frac{(\alpha+1)(\alpha+4)}{12}\xi^2+\frac{\alpha(\alpha+1)^2(\alpha+4)}{360}\xi^4+\cdots\right\}. \quad (37)$$

Substituting (36) and (37) into (22) and (23), we have

$$A_1(\lambda,\ \alpha)=-\left(\frac{\dot{c}u\alpha}{\alpha+2}\right)\left\{1+\frac{(\alpha+1)}{3}\xi^2-\frac{\alpha(\alpha+1)(\alpha+4)}{45}\xi^4+\cdots\right\}\{\lambda-\lambda_0(\alpha)\}, \quad (38)$$

$$\lambda_0(\alpha)=\left(\frac{\alpha+2}{\alpha}\right)\left\{2(2^\alpha-1)-\frac{2^\alpha\alpha(\alpha+1)}{6}\xi^2+\frac{2^\alpha\alpha(\alpha+1)(\alpha+4)(3\alpha+5)}{180}\xi^4+\cdots\right\}. \quad (39)$$

Evidently (38) and (39) agree with (33) and (34) respectively in the limit $\xi\to0$.

According to (38), $\lambda_0(\alpha)<4$ if ξ is sufficiently large. (e.g. $\xi\gtrsim0.42$ for $\alpha=1/2$.) Thus we see that the intrinsic viscosity can behave as represented in Fig. 1, if the initial distribution is sufficiently broad.

4) *Superposition of two uniform distributions*

Let us consider a superposition of two uniform distributions

$$m(p,\ 0)=\frac{1}{2u^2}\left\{\delta\left(\frac{p}{u}-1-\zeta\right)+\delta\left(\frac{p}{u}-1+\zeta\right)\right\}, \quad (40)$$

where u is the number average degree of polymerization and ζ is to be called as dimensionless width parameter. The function is also normalized as (1). Further we regard again ζ as a small quantity. Then, for this initial distribution,

$$f_\beta(0)=\frac{u^{\beta-1}}{2}\{(1+\zeta)^\beta+(1-\zeta)^\beta\}=u^{\beta-1}\left\{1+\frac{\beta(\beta-1)}{2!}\zeta^2+\frac{\beta(\beta-1)(\beta-2)(\beta-3)}{4!}\zeta^4+\cdots\right\}, \quad (41)$$

$$I(\alpha)=2^{\alpha-1}u^{\alpha+1}\{(1+\zeta)^{\alpha+3}+(1-\zeta)^{\alpha+3}+2(1-\zeta^2)\}$$
$$=2^{\alpha+1}u^{\alpha+1}\left\{1+\frac{(\alpha+1)(\alpha+4)}{4}\zeta^2+\frac{\alpha(\alpha+1)(\alpha+2)(\alpha+3)}{12}\zeta^4+\cdots\right\}. \quad (42)$$

Substituting (41) and (42) into (22) and (23), we have

$$A_1(\lambda,\ \alpha)=-\frac{\dot{c}u\alpha}{\alpha+2}\left\{1+(\alpha+1)\zeta^2-\frac{\alpha(\alpha+1)(\alpha+2)}{3}\zeta^4+\cdots\right\}\{\lambda-\lambda_0(\alpha)\}, \quad (43)$$

$$\lambda_0(\alpha)=\frac{\alpha+2}{\alpha}\left\{2(2^\alpha-1)-\frac{2^\alpha\alpha(\alpha+1)}{2}\zeta^2+\frac{2^\alpha\alpha(\alpha+1)(\alpha+2)(2\alpha+5)}{6}\zeta^4+\cdots\right\}. \quad (44)$$

The expressions (43) and (44) again reduce to (33) and (34) respectively in the limit $\zeta\to0$ as expected.

According to (44), $\lambda_0(\alpha)<4$ if ζ is sufficiently large. (e.g. $\zeta\gtrsim0.23$ for $\alpha=1/2$.) The situation is qualitatively similar to the case where the initial distribution is rectangular.

5) *Poisson distribution with cut-off*

Let us consider the Poisson distribution with cut-off

$$m(p,\ 0)=\begin{cases}C\ e^{-p/v} & (p\geqq q)\\ 0 & (q>p\geqq0),\end{cases} \quad (45)$$

where C is the normalization factor, q is the degree of polymerization at the cut-off, and v is the number average degree of polymerization prior to cutting off. This distribution may be approximately realized by fractionation techniques. The normalization condition (1) determines C as follows:

$$C=v^{-2}e^{\sigma}(1+\sigma)^{-1}\,, \tag{46}$$

where

$$\sigma=q/v \tag{47}$$

is a parameter specifying cut-off and will be regarded as small. The number average degree of polymerization u turns out to be

$$u=v+q=v(1+\sigma)\,. \tag{48}$$

Then, for this initial distribution,

$$f_\beta(0)=Cq^{\beta+1}A_\beta(\sigma)\,, \tag{49}$$

$$I(\alpha)=C^2\int_{2q}^{\infty}dp\,p^{\alpha+1}\,e^{-p/v}\int_{q}^{p-q}dl\cdot l(p-l)=\frac{2^{\alpha+3}q^{\alpha+5}C^2}{3}\{2A_{\alpha+4}(2\sigma)-3A_{\alpha+2}(2\sigma)+A_{\alpha+1}(2\sigma)\}\,, \tag{50}$$

where the integral $A_\beta(\sigma)$ is defined as follows:

$$A_\beta(\sigma)=\int_{1}^{\infty}x^\beta e^{-\sigma x}\,dx\,. \tag{51}$$

For small σ, it may be expanded into power series, namely,

$$A_\beta(\sigma)=\int_{0}^{\infty}x^\beta e^{-\sigma x}\,dx-\int_{0}^{1}x^\beta\,e^{-\sigma x}\,dx=\frac{\Gamma(\beta+1)}{\sigma^{\beta+1}}-\sum_{j=0}^{\infty}\frac{(-1)^j\sigma^j}{j!(\beta+1+j)}\,. \tag{52}$$

By employing (22), (23) and (46)–(52), we arrive at the following result:

$$\begin{aligned}A_1(\lambda,\ \alpha)&=-\dot{c}u\alpha(1+\sigma)^{-1}\left\{1+\frac{\sigma^{\alpha+2}}{\Gamma(\alpha+3)}+O(\sigma^{\alpha+3})\right\}\{\lambda-\lambda_0(\alpha)\}\\&=-\dot{c}v\alpha\left\{1+\frac{\sigma^{\alpha+2}}{\Gamma(\alpha+3)}+O(\sigma^{\alpha+3})\right\}\{\lambda-\lambda_0(\alpha)\}\,.\end{aligned} \tag{53}$$

$$\lambda_0(\alpha)=\frac{(\alpha+2)(\alpha+7)}{6}\left\{1+\frac{\sigma^2}{2}+O(\sigma^3)\right\}\,. \tag{54}$$

The expressions (53) and (54) naturally reduce to (28) and (29) respectively in the limit $\sigma\to 0$.

Thus the cut-off introduces the tendency that $A_1(\lambda,\ \alpha)$ increases if λ is kept constant. And the region of λ such that $\lambda_0(\alpha)<\lambda<4$ becomes narrower with the increase of σ. The situation that a sufficient width is necessary for the behavior of the intrinsic viscosity as given in Fig. 1 is quite the same as in other cases discussed in the foregoing paragraphs.

§ 4. Discussions

So far we have examined the relationship between the initial molecular size distribution and the radiation-induced change of intrinsic viscosity. The result can be summarized in the statement that the intrinsic viscosity shows in certain cases a minimum when it is plotted against radiation dose, only if the initial distribution is sufficiently broad. Mathematically this fact may be a consequence of the situation that $I(\alpha)$ involves a type of convolution integral. (See (24–1)).

Our present conclusion must be of significance in connection with analysis of experimental data, since the quantity $A_1(\lambda,\ \alpha)$ is rather easily observed experimentally and the initial distribution can be controlled to some extent. Consequently, by observed values of

$A_1(\lambda, \alpha)$ we can estimate the value of λ, if the initial distribution is given; on the other hand, we can obtain informations about the latter, if the former is determined through other data, for example, gel point, gel fraction etc.

In view of our conclusion, especially interesting is Y. Hirano's observation$^{6)}$ that $A_1(\lambda, \alpha)$ in aqueous solution of polyvinyl alcohol decreases through a treatment which presumably modifies the initial distribution so as to realize approximately the Poisson distribution with the cut-off. Detailed discussion about this experiment as well as its analysis will be reported elsewhere.

It is also remarkable that there exists such λ that $\lambda_0(\alpha) > \lambda > 4$ according to (34), (39) or (44), if the initial distribution is nearly uniform. For such a value of λ, the intrinsic viscosity increases initially, even if degradation dominates over crosslinking so that gel formation is impossible or $\lambda > 4$. This sort of situation seems to have not yet been observed experimentally, perhaps because of difficulty in realizing a sufficiently narrow initial distribution.

Acknowledgements

The author should like to express his sincere thanks to Prof. A. Amemiya of the University of Tokyo and Prof. O. Saito of the Tyûô University for their helpful discussions as well as continuous encouragements. He especially appreciates Prof. Saito's kindness of giving him informations about his own work prior to publication. Further he is grateful to Mr. Y. Hirano, Mr. T. Watanabe and other members of the Group for the Study of Irradiated Polymers of Tokyo for their interest and valuable comments. He is also indebted to the Ministry of Education for the Scientific Research Fund.

Zerosplitting Cone of Nuclear Quadrupole Resonance Spectrum for Spin 5/2

By Kenji SHIMOMURA

Minami Bunkô, Hiroshima University, Hiroshima

and Noriyoshi INOUE

Shinonome Bunkô, Hiroshima University, Hiroshima

(Received September 30, 1958)

Zerosplitting loci of nuclear quadrupole resonance spectrum of iodine nucleus of iodic acid were studied. The directions of axes of zerosplitting cones of $\nu_1(\pm 1/2 \leftrightarrow \pm 3/2)$ and $\nu_2(\pm 3/2 \leftrightarrow \pm 5/2)$ lines have been found to be appreciably different from each other. The situation was interpreted by use of Cohen's theory of Zeeman splitting and zerosplitting condition was presented. The directions of axes of zerosplitting cones of ν_1 and ν_2 lines were shown to be coincident with the y- and z-axes of the principal axes of field gradient tensor at the resonant nucleus, respectively. Cohen's theory was verified by the comparison of the experimental values of zerosplitting angles with the theoretical ones.

§ 1. Introduction

The zerosplitting cone[1] which specifies the direction of zerosplitting of Zeeman line of nuclear quadrupole resonance spectrum is a pair of elliptical or circular cones having D_{2h} symmetry, about one of the principal axes of field gradient tensor at the resonant nucleus. Its form depends only on the nuclear spin and the value of the asymmetry parameter η of field gradient tensor. So a study of zerosplitting cone can reveal the nature of crystalline electric field, i.e., asymmetry parameter and orientations of principal axes of field gradient tensor, and can yield a check on the assignment of transition in the zero-field. And this purpose is also attained by the study of Zeeman splitting, which depends on the nuclear species. However, the zerosplitting method is superior to the Zeeman splitting method in some respects; (1) the relation between zerosplitting angle and asymmetry parameter does hold good to any nucleus of the same spin, (2) the sample may be rotated about any arbitrary axis of the sample[1], (3) measurements of strength of magnetic field and spacings of Zeeman components are not needed. So we can deal simply and immediately with more complex substance by studying the zerosplitting cone.

We have studied the zerosplitting cones for the two transitions $\pm 1/2 \leftrightarrow \pm 3/2$ and $\pm 3/2 \leftrightarrow \pm 5/2$ of pure quadrupole spectrum of iodine nucleus of iodic acid. Livingston et al[2] have presented the extensive study of Zeeman splittings on this substance and observed extra Zeeman component resulting from a proton interaction.

We have found the directions of the axes of the zerosplitting cones for the two transitions are quite different from each other. The situation has been interpreted by use of Cohen's numerical table[3] for the Zeeman-splitting parameter, and the experimental values for zerosplitting angles have been compared with Cohen's theoretical calculations.

§ 2. Experimental Results

A single crystal of iodic acid has been prepared by crystalizing from aqueous solution of iodine pentoxide with small quantity of nitric acid. The crystal was set on the Zeeman analyser[1], which was operated at about 100~320 gauss. The spectrometer was a frequency-modulated superregenerative detector of 6J6 ×2 push-pull Lecher-wire tuned type[4] and the absorption lines were observed on a persistent-screen cathode-ray oscilloscope, and the loci of zerosplitting directions were studied at about 25°C~30°C.

At the first step, $\nu_1(\pm 1/2 \leftrightarrow \pm 3/2)$ line, and at the second step, $\nu_2(\pm 3/2 \leftrightarrow \pm 5/2)$ line were studied with proper hf coils for these resonance frequencies but without changing the setting of the crystal.

The experimental results are shown in Fig. 1 and 2, where y_1, y_2, y_3, y_4; z_1, z_2, z_3, z_4 denote the nonequivalent directions¹⁾ of the axes of zerosplitting cones of ν_1 and ν_2 lines, respectively. As shown in Fig. 1 and 2, the directions of axes of zerosplitting cones associating to ν_1 and ν_2 lines are appreciably different from each other. Additional splitting of zerosplitting component of Zeeman lines due to neighbouring proton has not been observed.

§ 3. Discussions

By taking into consideration of large asymmetry parameter $\eta=0.451^{2),5)}$ at room temperature, we should rather use an exact formula which is applicable to the case of arbitrary η than the approximate one⁶⁾.

For arbitrary η, Cohen³⁾ has given the following formula for the Zeeman splitting of nuclear quadrupole resonance spectrum

$$E_{\pm m}=E_{\pm m}^{0}\mp g\beta H \times[A\cos^2\theta+\tfrac{1}{4}\sin^2\theta(B+2C\cos 2\phi)]^{1/2} \qquad (1)$$

where H denotes a magnetic field, g represents the g-factor of the resonant nucleus, β

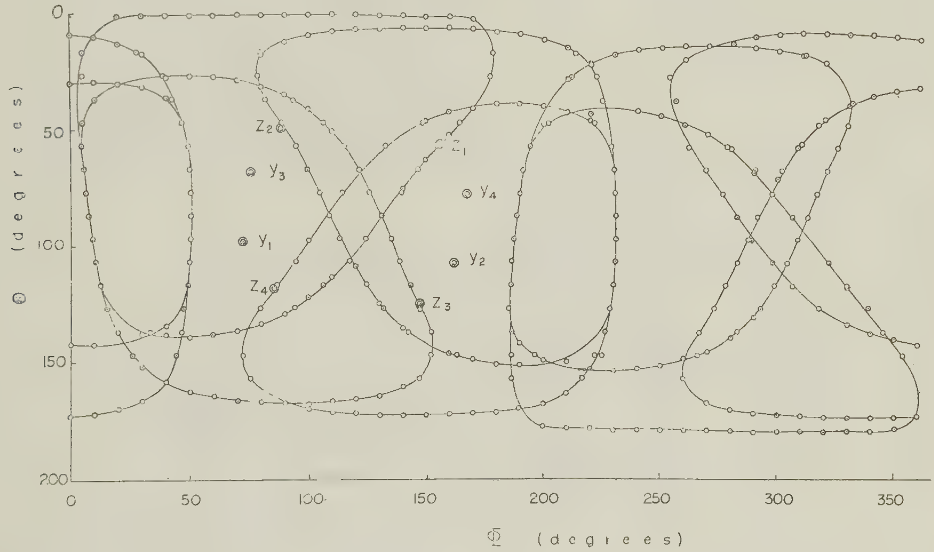

Fig. 1. Zerosplitting-direction pattern of ν_1 line. Θ and Φ are polar angles specifying zerosplitting-direction with respect to an orthogonal coordinate axes fixed to the sample.

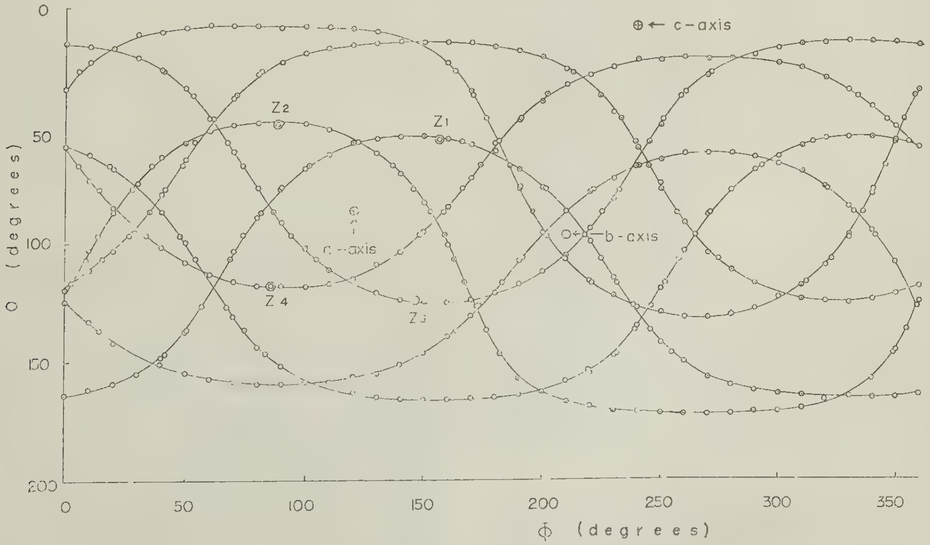

Fig. 2. Zerosplitting-direction pattern of ν_2 line.

is the Bohr magneton, θ and ϕ are the polar angles of H with respect to the principal axes x, y, z, and A, B and C are Zeeman-splitting parameters which have been given in a numerical table by Cohen.

The zerosplitting should be expected when the Zeeman splitting of one level becomes equal to that of the other one, so the zerosplitting condition may be written as

$$\sin^2\theta=\frac{\gamma}{\alpha+\beta\cos 2\phi}, \qquad (2)$$

where α, β and γ are zerosplitting parameters and are given in Table I.

[a] As the Zeeman-splitting parameters for $\eta=0.451$ are not given in Cohen's table, these values were obtained from our calculations of Zeeman-splitting parameters*.

In the case of $\eta=0.4$, it is easily shown from Eq. (2) with proper zerosplitting parameters that θ satisfying the zerosplitting condition may exist for any value of ϕ. While, in the case of $\eta=0.5$ it may be shown that not all values of ϕ can exist; as Fig. 3 shows, θ will increase from the minimum value $\theta_{\min}$ to the maximum value $\pi/2$ with decreasing (or increasing) ϕ from $\pi/2$ to the minimum (or maximum) value $\phi_{\min}$ (or $\pi-\phi_{\min}$). Since a zerosplitting cone always possesses an opposite partner[1)], they make a pair of cones which is parallel to the y-axis** (Fig. 3). Therefore, the direction of axis of zerosplitting cone of ν_1 line should be the y-axis of field gradient tensor. On the contrary, for $\eta=0.4$ a cone which has an axis parallel to the z-axis should be observed. The abrupt

$$\sin^2\theta=\frac{16}{16+\frac{\eta^2}{36}\left[\left(I-\frac{1}{2}\right)\left(I+\frac{1}{2}\right)\left(I+\frac{3}{2}\right)\right]^2}$$

(see reference 6)
circle: experimental points.

change* of the direction of the cone from the z-axis to the y-axis should occur at a critical value of η where $\phi_{\min}$ vanishes. From Fig. 4, we may obtain $\eta=0.41$ as the critical point. On the other hand, for the case of ν_2 even when $\eta=1.0$ the axis of cone should be expected to be coincident with the z-axis from the same treatment.

Since $\eta=0.451$ for I^{127} of HIO_3 at room temperature, we may obtain the y-axis and z-axis from the Zeeman analysis$^{1)}$ of ν_1 and ν_2 lines, respectively. In fact y_1, y_2, y_3, y_4 have been found to be perpendicular to z_1, z_2, z_3, z_4, respectively. After we have determined the y- and z-axes, we may obtain the x-axis. Therefore the experimental relation between θ and ϕ satisfying the zerosplitting condition is obtained from the calculations of the angles between the zerosplitting direction and the principal axes xyz of field gradient tensor, and is compared with the theoretical one which is derived from Cohen's table. The comparisons are shown in Fig. 5 and 6. In Fig. 5 instead of θ and ϕ, θ' and ϕ' which are the polar angles defined in Fig. 5 are used. In terms of θ', ϕ' the zerosplitting condition may be written as

$$\sin^2\theta'=\frac{\alpha-\beta-\gamma}{\alpha-\beta-(\alpha+\beta)\sin^2\phi'}\,. \qquad (3)$$

Our experimental data are in good agreement with the theoretical curves for $\eta=0.451$ in Fig. 5 and 6. They show that the value of $\eta=0.451$ is consistent with our experiments and that Cohen's calculations of Zeeman splitting of pure quadrupole spectrum are borne out by our experiments.

Non-Similarity Theory of Decaying Turbulence

By Yutaka SHIGEMITSU

Transportation Technical Research Institute, Tokyo

(Received September 20, 1958)

As a development of our statistical theory of turbulence, extension of the initial-period similarity-law of decaying turbulence (isotropic turbulence, wake, jet) is attempted so that non-similarity characters may be included. Based upon the cascade conception that large vortices produce small ones successively, we introduce a Poisson process of the mixture of these vortices and derive non-stationary expressions of Reynolds stress and Euler correlation. By evaluating them approximately we obtain decaying law deviating gradually from the linear-decay-law. For the case of isotropic turbulence, double correlation functions are determined by substituting Kármán-Howarth's self-preserving solution into the above formula, and further a triple correlation h is derived by solving Kármán-Howarth's equation with our evaluated u^2 and f. These theoretical results are checked by many previously proposed experimental data.

§ 1. Introduction

In our previous papers, Statistical Theory of Turbulence, I[1], II[2], III[3], turbulence is considered as a chaotic state of flow of vortices. Based upon this physical conception, all the turbulent quantities are expressed in terms of mean values taken over the areas of these vortices in order to make the Reynolds equations conclusive. These area integrals, whose domains are denoted by D, are mathematical foundations of our theory (cf. § 4∼6, I). Then, discussions proceed by dividing turbulent flow essentially into two groups; one has a decaying character in turbulent energy in the direction of the main flow such as turbulent wake behind a body or grid and free jet, and the other has a non-decaying character like pipe flow and boundary layer.

As for the structure of decaying turbulence we proposed the following physical interpretations[1),2)]: Just behind the obstacle vortex motions are formed by taking energy from the main flow. First they are carried away retaining a regular flow pattern, for instance in the form of Kármán vortex street whose stability is proved when the effect of viscosity is neglected, and then their arrangements become gradually irregular. In this chaotic state of vortices, they affect each other chiefly by their viscous force, and many chances happen where new small vortices are produced in discontinuous flow between adjacent vortices by taking their energy. These second vortices produce further the third ones under the same circumstances. Namely, the conception of a vortex chaos motion is accompanied by that of cascade process from large to small vortices. It is the essential feature of decaying turbulence that the turbulent energy is originally supplied by the primary vortices produced just behind the body and then transmitted successively into small vortices of descending order through the cascade process, being partly dissipated into heat. Viewed from the Eulerian point turbulent intensities are decaying along the flow. In the non-decaying turbulence, on the other hand, the turbulent energy does not necessarily decay owing to the strong primary vortices produced everywhere outside the laminar sub-layer.

In the decaying turbulence, statistical studies have been made on an ideal vortex chaos motion consisting of only one type of vortices produced at one position in the field of flow. According to the results[2)] similarity characters in mean velocity, Reynolds stress, Euler correlations, etc. can be all attributed to the two similarity characters, hydrodynamical and statistical; the three-dimensional expressions for them are

$$\overline{V}_*=F_\alpha(r/\sqrt{4\nu t}\,,\theta,\phi)t^{(1/2)-\alpha}\,, \tag{1.1}$$

$$P_*=P_{*\alpha}(r/\sqrt{4\nu t}\,,\theta,\phi;y,z)\,. \tag{1.2}$$

$\overline{V}_*$ is the mean velocity distribution, transmitted to the D-domain, in every vortex nearest to a fixed point x, y, z in the field. t is a time interval since the production of a vortex motion and is connected with x by the mean velocity of flow, α is a parameter relating to the initial condition of a vortex motion, and r, θ, ϕ are the coordinates in the D-domain. P_* is the probability distribution function that a relative location r, θ, ϕ of the nearest vortex filament at an instant to the referring x, y, z-point is moving in the D-domain* with time. The expression (1.1) is due to the exact solution $V_*=F_\alpha'(r/\sqrt{4\nu t})t^{(1/2)-\alpha}$ of Navier-Stokes equations for a single viscous vortex motion (cf. § 9, I). When α is chosen as unity, this similarity law can give the relations $u^2, \overline{uv}, \cdots \backsim t^{-1}$ besides their similarity-preservation characters. These characters are widely found out in decaying turbulence behind the transition region just behind a body. Thus, $\alpha=1$ could be adapted to the primary vortices mentioned above, and this similarity law has been defined as that in the initial period.

It is obvious that the initial-period similarity-law is concerned only with the primary vortices, the cascade phenomena being neglected; the deviation from observed results for the far downstream region is seen clearly in turbulent flow behind a grid, although not so conspicuous in decaying shear turbulence. On the other hand, many investigations have been made since Kolmogoroff on the cascade process in wave number of the spectrum of isotropic turbulence. Even in this case of flow, however, it is not possible to determine completely the energy decay and the spectrum curve as a whole. In these circumstances, it becomes necessary to extend our initial-period similarity-law to include the non-similarity character of cascade process in the general decaying turbulence; that is the objective of the present paper. In the following three sections fundamental descriptions will be given, and then some results will be drawn chiefly in the case of isotropic turbulence so that they may be surveyed in the light of many experimental data.

§ 2. Poisson Process in Vortex Chaos Motions

In such a complicated cascade phenomena as mentioned above, it is impossible to develop a purely hydrodynamical study based upon Navier-Stokes equations only, so that we shall make use of the P_*-function to express the non-similarity nature statistically. At a fixed point in the field, many vortices with different generations produced upstream are being carried away. When the generation is denoted by m, it has an important character to be counted with a round number beginning with $m=1$ of the primary vortices, and this is a function of α at the same time. As the x-ordinate t referring to $m=1$ vortices is taken, with the origin $t=0$ chosen as the time when they come in chaotic states and cascade phenomena begin. The position of outbreak of $m=1$ vortices is fixed just behind a body, but other vortices are being produced from the preceding ones in the whole time interval $0\sim t$. Let us consider the behaviour at t of a group of $m(t_0)$-vortices which were born as the m-generation in the time interval t_0, t_0+dt_0 $(t>t_0)$. In order to formulate the cascade phenomena statistically, we idealize the situations so that some parts of the number of $m(t_0)$-vortices are changing with time into those of the following generations without a loss in total number. Let the probability with which $m(t_0)$-vortices are mixed in the whole generations at t be denoted by $\overline{P}_*'(m(t_0), t)\,dt_0$, and their distribution function in the $D_{m(t_0)}$-domain by $P'_{*m(t_0)}$ as mentioned in § 1, then the P_*-function can take the following general expression (cf. § 7, I),

$$P_*(m(t_0), t)\,dt_0=\overline{P}_*'(m(t_0);\, x(t), y, z) \times P'_{*m(t_0)}(r/\sqrt{4\nu t}, \theta, \phi;\, x(t), y, z)\,dt_0\,. \qquad (2.1)$$

As for the rate of mixture of all the m-vortices produced in $0\sim t$, the following $\overline{P}_*$-function is given

$$\overline{P}_*(m, t)=\int_0^t \overline{P}_*'(m(t_0), t)\,dt_0\,, \qquad (2.2)$$

and by the definition we must have

$$\sum_{m=1}^{\infty} \overline{P}_*(m, t)=1\,, \qquad (2.3)$$

where the variables y, z are omitted for simplicity of expression. In the statistical study of cascade process, it is important to determine the function $\overline{P}_*'(m(t_0), t)\,dt_0$ at first. In the similarity theory, since the P_*-function is concerned only with one type of vortices produced at an instant the above deliberations are not necessary.

---

* Strict definitions of these functions and the similarity conditions were given in § 4, 9, I and § 4, 5, 9, II in an idealized two-dimensional vortex chaos motion.

As mentioned in §1, one vortex, except that of $m=1$, is born from two vortices. In order to determine the $\overline{P}_*'$-function, we introduce the following probability that $m(t_0)$- and $m'(t_0')$-vortices produce new small ones in a unit time interval at t;

$$p_*(m(t_0), m'(t_0'), t)\,. \tag{2.4}$$

Apparently p_* is the rate of total sum of newly born vortices in a unit time interval to that of their parent vortices at the beginning, and this is a transition probability having the dimensions of inverse of time. In the actual state (2.4) may take a complicated functional form, but if p_* is expanded into a power series in the independent variables, the first term remains finite because the cascade phenomena began at $t=0$. Therefore, as a first approximation, we may take

$$p_*(m(t_0), m'(t_0'), t)=p_* \qquad \text{(constant)}\,, \tag{2.5}$$

taking only the first term. This is one of the fundamental hypotheses in our non-similarity theory viewed from the statistical point.

Mathematical derivation of $\overline{P}_*'$- or $\overline{P}_*$-function from (2.5) is well known in statistical mathematics as follows: for the convenience of explanation, let us consider first a discontinuous cascade process, by dividing t into N equal short intervals, so that the transition probability at one step becomes p_*t/N. In such circumstances that the $m=1$ vortices given at $N=0$ and of $m\geqq 2$ vortices are transmitted into their respective next generations at every step of t/N, the probability of the mixture of m-vortices is known as the binomial distribution;

$$\{N!\,(p_*t/N)^{m-1}(1-p_*t)^{N-m+1}\}/\{(m-1)!\,(N-m+1)!\}\,.$$

With a relation $\lim\limits_{N\to\infty}(1-p_*t/N)^N=\exp(-p_*t)$ utilized, this is proved to tend to

$$(p_*t)^{m-1}\exp(-p_*t)/(m-1)!$$

as $N\to\infty$. Also, the probability that $m(t_0)$-vortices exist at t can be proved to be

$$\{(p_*t_0)^{m-2}\exp(-p_*t)/(m-2)!\}\,p_*dt_0\,.$$

Namely, based upon the first approximative character (2.5), $\overline{P}_*'$- or $\overline{P}_*$-function is proved to take the following expression;

$$\left.\begin{aligned}&\overline{P}_*(m,t)=(\tau^{m-1}e^{-\tau})/(m-1)!\,,\quad \tau=p_*t\,,\\&\overline{P}_*'(m(t_0),t)\,dt_0=\{(\tau_0{}^{m-2}e^{-\tau})/(m-2)!\}\,d\tau_0\,,\\&\hspace{14em}(m\geqq 2)\,.\end{aligned}\right\} \tag{2.6}$$

This is well known as the Poisson distribution. (2.6) has the behaviour as shown in Fig. 1, and the conditions (2.2) and (2.3) are clearly fulfilled. It is significant that the variable t and the parameter p_* combine into a new independent variable τ, which facilitates the subsequent analysis. Further, owing to our cascade process of the vortex chaos motion, mean values of turbulent quantities should be expressed in terms of the non-dimensional time τ instead of t, while in the similarity law it is sufficient to take the latter.

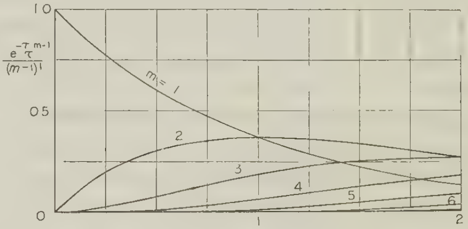

Fig. 1. General view of Poisson process of $\bar{P}_*$-function.

§3. Expressions for Turbulent Intensity and Scale

As mentioned in §1 referring to the similarity law, our statistical theory requires another hydrodynamical hypothesis besides (2.5). As written as (1.1), the $\overline{V}_*$-function for $m(t_0)$-vortices is considered to take the following form,

$$\overline{V}_{*m(t_0)} = F_{\alpha(m)}(r/\sqrt{4\nu(t-t_0)}\,,\,\theta,\,\phi;\,t-t_0)(t-t_0)^{(1/2)-\alpha(m)}, \tag{3.1}$$

but here F_α is a non-similar velocity distribution function of $m(t_0)$-vortices in the $D_{m(t_0)}$-domain and $(t-t_0)^{(1/2)-\alpha}$ is a decaying term. In the study of cascade process it is necessary to relate the generation of vortices m to their classification α. It is deduced from the exact solution of the Navier-Stokes equations for a two-dimensional viscous vortex motion, that the suffix α, being able to take any value larger than 1, is determined by the initial condition of these vortices and every F_α-function has an arbitrary constant in it corresponding to this condition (cf. § 9, I). Moreover the kinetic energy of a vortex motion $\iint_D \rho \overline{V}_*^2 dS$ is proved to be proportional to $t^{2(1-\alpha)}$ in this case (cf. § 6, II). On the other hand, it is widely found out, especially in isotropic turbulence, that the rate of dissipation of fluctuating energy is increasing with the wave number, and so in our cascade conception mentioned in § 1 it is necessary to give large values of α to small scale $m \geqq 2$ vortices. Then, considering our condition $\alpha=1$ for $m=1$, we shall introduce the following simple hydrodynamical assumption;*

$$\alpha(m)=m\ . \tag{3.2}$$

(2.5) and (3.2) are the two fundamental hypotheses in our non-similarity theory.

With the determination of the classification of vortices, it becomes necessary to presume time variation of the mean state of every group of $m(t_0)$-vortices. In the cascade phenomena, $m(t_0)$-vortices are carried away with the flow, being affected by many other vortices. These disturbing effects are not similar in time as suggested by the non-similarity characters of (2.6) and (3.2), and unlike the case of similarity law $\overline{V}_{*m(t_0)}$-function in (3.1) and $P'_{*m(t_0)}$-function in (2.1) are not considered to fulfill the similarity conditions. However, if F- and P_*'-functions are expanded in $t-t_0$, the first terms retain similar forms, so that as a first approximation we can take such similar formulae, using (3.2),

$$\left.\begin{aligned} \overline{V}_{*m(t_0)} &= F_m(r/\sqrt{4\nu(t-t_0)}\,,\theta,\phi)(t-t_0)^{(1/2)-m}\ ,\\ P'_{*m(t_0)} &= P_m'(r/\sqrt{4\nu(t-t_0)}\,,\theta,\phi;y,z)\ . \end{aligned}\right\} \tag{3.3}$$

This character will be called local similarity. In short, we have idealized the situations as follows; every group of $m(t_0)$-vortices holds the respective similarity conditions independently from each other, and non-similarity is characterized only through (2.5). The statements are our basic attitudes required to extend, at the first step, the previous similarity theory into non-similarity one. The above extension can be reduced to the fundamental hypotheses (1.1) and (1.2) of the initial-period similarity-law ($\alpha=1$), when the transition probability p_* is made to vanish in (2.6).

Our previous statistical theory has given fundamental expressions for turbulent quantities in the general case (cf. § 7, I). In vortex chaos motions consisting of all the generations produced in $0 \sim t$, the u-intensity at the $x(t)$, y, z-point is obtained in the form,

$$\boldsymbol{u}^2=\sum_{m=0}^{\infty}\int_0^t\left\{\iiint_{D_{m(t_0)}} P_*(m(t_0),t)\overline{V}^2_{*m(t_0)}\sin^2\theta\sin^2\phi\, dS\right\}dt_0\ ,\qquad dS=r^2\,dr\,d\theta\,d\phi\ , \tag{3.4}$$

by neglecting the fluctuational part V_*' of the V_*-function in view of the independency character mentioned above (cf. § 7, I). Introducing (2.1) and (2.6), we have

$$\left.\begin{aligned} \boldsymbol{u}^2 &= \boldsymbol{u}_1'^2 e^{-\tau}+\sum_{m=2}^{\infty}\int_0^t \boldsymbol{u}'^2_{m(\tau_0)}\{\tau_0{}^{m-2}e^{-\tau}/(m-2)!\}\,d\tau_0\ ,\\ \boldsymbol{u}'^2_{m(\tau_0)} &= \iiint_{D_{m(\tau_0)}} P'_{*m(\tau_0)}\overline{V}^2_{*m(\tau_0)}\sin^2\theta\sin^2\phi\, dS\ , \end{aligned}\right\} \tag{3.5}$$

therefore, by (3.3) we obtain

$$\left.\begin{aligned} \left(\frac{\boldsymbol{u}}{\overline{U}}\right)^2 &= \frac{A_1}{\tau}e^{-\tau}+\sum_{m=2}^{\infty}\int_0^\tau \frac{A_{m(\tau_0)}}{(\tau-\tau_0)^{2m-1}}\,\frac{\tau_0{}^{m-2}e^{-\tau}}{(m-2)!}\,d\tau_0\ ,\\ A_{m(\tau_0)} &= \overline{U}^{-2}\iiint_{D_{m(\tau_0)}} P_m'(r/\sqrt{4\nu(\tau-\tau_0)/p_*},\theta,\phi;y,z)\\ &\quad\times F_m{}^2(r/\sqrt{4\nu(\tau-\tau_0)/p_*},\theta,\phi)\,p_*{}^{2m-1}\sin^2\theta\sin^2\phi\, dS\ . \end{aligned}\right\} \tag{3.6}$$

As an example of turbulent scale, the u-correlation function $f(k,\tau)$ $(=\overline{u(x)u(x+k)}/\boldsymbol{u}^2(x))$ at the x, y, z- and $x+k, y, z$-points will be taken. It is seen by the local similarity (3.3) that a group of $m(\tau_0)$-vortices preserve the respective similar correlation function $f_{m(\tau_0)}(\xi_{m(\tau_0)})$. In the same manner as the above transformation, $f(k, \tau)$ can be formulated, with every f_m-function combined independently into the Poisson process;

---

* By the definition of turbulent dissipation it is seen that u_k-intensity tends to be inversely proportional to wave number k, but an assumption is required to explain that the rate of dissipation $\nu(\partial u_k/\partial x)^2$ is increasing with k.

$$\left(\frac{u}{U}\right)^2 f(k, \tau)=\frac{f_1(\xi_1)A_1}{\tau}e^{-\tau}+\sum_{m=2}^{\infty}\int_0^{\tau}\frac{f_{m(\tau_0)}(\xi_{m(\tau_0)})A_{m(\tau_0)}}{(\tau-\tau_0)^{2m-1}}\frac{\tau_0^{m-2}e^{-\tau}}{(m-2)!}d\tau_0\,, \tag{3.7}$$

where A_m is the same as (3.6) and ξ_m is adjusted to a certain distance k. Of course (3.6) is included in (3.7) as $k=0$. It is easily proved by our fundamental formula, that (3.7) or (3.6) holds for other components of turbulent scale or intensity with different circular functions of θ, ϕ in the coefficient $A_{m(\tau_0)}$ (cf. § 6, I).

In decaying turbulence, $A_{m(\tau_0)}$ depends generally upon y, z as seen in (3.6). If some y_0, z_0-points can be plotted where $P_m' F_m'$ takes a similar functional form in the $D_{m(\tau_0)}$-domain irrespective of $x(\tau)$, $A_{m(\tau_0)}$ is independent of $x(\tau)$. Such a character may be assumed approximately to hold in the actual state of flow. These points in similar relation mean the respective similarity preservation of every $m(\tau_0)$-vortices there, and the dependency of the $\overline{P}_*$-function in (2.1) on y, z can be attributed only to the variation of parametric constant p_*. Thus, (3.7) or (3.6) is regarded as the general formula of transient phenomena along the main flow of the double correlation function or the intensity of decaying turbulence.

§ 4. Initial Condition of a Vortex Motion

For the purpose of evaluating (3.7) or (3.6), it becomes necessary to survey the term A_m precisely. When p_* is made zero in (3.6), it becomes $(u/\overline{U})^2=(A_1/p_*)t^{-1}$, corresponding to the initial period. In isotropic turbulence, it was proved by the conception of the completely irregular arrangement of vortices that P_1' become $1/S_1$ independently of x, y, z by denoting the volume of the spherical D_1-domain of radius R by S_1, and F_1 became $F_1'(r/\sqrt{4\nu t})$ of the exact solution of the Navier-Stokes equations (cf. § 4, II). Therefore, as the coefficient A_1/p_*, we get

$$A_1/p_*=\{3\pi/(16\overline{U}^2\sqrt{s_0}^{\,3})\}\int_0^{s_0}F_1'^2(\sqrt{s})\sqrt{s}\,ds\,,$$

$$R/\sqrt{4\nu t}=s_0\,, \tag{4.1}$$

with t counted since the outbreak of this $m=1$ vortex. In the similarity law, s_0 was taken to be independent of t and A_1/p_* was assumed to be constant for $0\sim t$ along the flow. At $t=0$, A_1/p_* becomes indefinite, and $(u/\overline{U})^2$ diverges if it retains still this constant value. In the initial-period similarity-law, however, this singularity can be excluded from the theory with the origin $t=0$ shifted from the instant of the outbreak to the time when the chaotic states of vortices begin to appear behind the transition region, as has been done in the paper. This treatment of the initial-period similarity-law in isotropic turbulence does not loose the generality in other types of decaying turbulence. In the study of cascade process, however, this problem must be considered directly, as $m\geqq 2$ vortices are produced incessantly in whole the time interval $0\sim t$. In the above-mentioned Navier-Stokes equations which imply molecular diffusion of vorticity concentrated at first at one point, the real state of outbreak of vortex motion is not described. The production and growth seem to depend upon different mechanism, and the above equations concern only with the latter. We suppose that at the beginning of growing period the vortex motion has a finite extent and also has a constant value of (4.1). In the study of turbulence based upon the conception of vortex chaos motion, vortices must be taken into account only in this period. In the production period (4.1) is supposed to become zero at $t=0$. Otherwise, the integration in (3.7) or (3.6) would become divergent at $\tau=\tau_0$, the outbreak instant of $m\geqq 2$ vortices.

The essential problem about the coefficient A_m lies in the determination of the integration constant contained in the F_m-function, rather than in the discussion on this functional form near $\tau=\tau_0$. As mentioned in the last section, this arbitrary constant and the suffix $\alpha(m)$ are determined by the initial condition of the vortex motion of m. For an $\alpha=1$ vortex this constant is known to be related with the circulation which existed at $t=0$,[4] while for others there is no theoretical or experimental ground to suppose this character. If this production mechanism were clarified, the relation of α versus m could be given as a theoretical result as well as this arbitrary constant in F_m. In this section, we shall give rather phenomenological discussions to A_m based on an energy conception in the cascade process, without conjecturing the fine structure, P'_{*m}- and $F_m{}^2$-functions in the D_m-domain. For simplicity, A_m is assumed to be constant with respect to $\tau-\tau_0$ and to avoid the singularity the term $(\tau-\tau_0)^{1-2m}$ in (3.7) is replaced roughly with $(1+\tau-\tau_0)^{1-2m}$. As mentioned in § 1, m-vortices are born with their energy supplied from the preceding m-1-vortices. Then, taking a constant coefficient a we assume approximately

$$(\boldsymbol{u}_1/\overline{U})^2=A_1\tau^{-1}e^{-\tau}\ , \quad A_1=A \quad (\text{constant})\ ,$$

$$(\boldsymbol{u}_2/\overline{U})^2$$
$$=\int_0^\tau a\{(\boldsymbol{u}_1/\overline{U})^2/e^{-\tau}\}(1+\tau-\tau_0)^{-3}e^{-\tau}\,d\tau_0\ ,$$

$$(\boldsymbol{u}_3/\overline{U})^2$$
$$=\int_0^\tau a\{(\boldsymbol{u}_2/\overline{U})^2/(\tau e^{-\tau})\}(1+\tau-\tau_0)^{-5}\tau_0 e^{-\tau}\,d\tau_0\ ,$$

etc.

On the other hand, it was proved that for $\alpha=1$ vortices energy dissipation due to molecular viscosity is zero (cf. § 6, II). Thus, if we derive such a decaying formula as (3.6) in an ideal cascade process of $\alpha(m)=1$ this formula agrees with $\boldsymbol{u}^{-2}\propto\tau$ of the initial period. For this reason a is given as 1.5, and the ratio A_m/A is determined. Namely, we get the following relations,

$$A_m/A=1.5^{m-1}[(\tau-\tau_0)^{2m-1}/\{(1+\tau-\tau_0)^{2m-1}\tau^{m-1}\}]\ ,$$
$$(m\geqq 2)\ , \quad (3.2)'$$

where A is a parametric constant relating to the supplied energy from the main flow to the primary vortices just behind the body. Then, (3.7) becomes

$$\frac{1}{A}\left(\frac{\boldsymbol{u}}{\overline{U}}\right)^2 f(k,\tau)=\frac{f_1(\xi_1)}{\tau}e^{-\tau}$$
$$+\sum_{m=2}^{\infty}\int_0^\tau \frac{1.5^{m-1}f_m(\xi_m)}{(1+\tau-\tau_0)^{2m-1}\tau^{m-1}}\,\frac{\tau_0{}^{m-2}e^{-\tau}}{(m-2)!}d\tau_0\ .$$
$$(3.7)'$$

In spite of such an approximative estimation, probably (3.7)′ may not loose the essentiality of our foregoing discussions.

§ 5. Decaying Law

Substitution of (3.2)′ into (3.6) gives a relative expression of the u-intensity against $x(\tau)$, y_0, z_0-points. As for other components of turbulent intensity, the same functional form is derived with a different coefficient A. Thus, we have obtained the general expression of decaying law in the decaying turbulence. Fig. 2 shows the relation of $(\boldsymbol{u}/\overline{U})^{-2}A$ versus τ. In this figure a computed curve in an ideal case of $\alpha(m)=1$ as mentioned in § 4 is indicated, whose departure from the dotted straight line $(\boldsymbol{u}/\overline{U})^{-2}A=\tau$ is not large until about $\tau=1.7$. In another ideal case of $\alpha(1)=1$ and $\alpha(m\geqq 2)=\infty$ where the effect of viscous dissipation by $m\geqq 2$ vortices is extremely large, the relation $(u/\overline{U})^{-2}A=\tau e^\tau$ is derived with all the integrals in (3.6) vanishing. The relation (3.6) must be located between these two curves, as shown with a thick line. It is not easy to expand (3.6) into a series of τ, but this curve suggests that it is not preferable to express the cascading energy decay

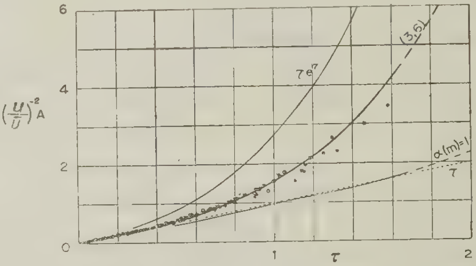

Fig. 2. Decaying law of decaying turbulence. +, Y are our previous data of u-intensity along the $\boldsymbol{u}^2$-maximum- and centre-line behind a circular cylinder of $d=1.5$ cm under $\overline{U}_0=3.74$ m/sec. Others correspond to the observed values behind a grid under the following conditions:

$\overline{U}_0$ is undisturbed velocity, M is mesh-length and d is diameter of rod of grid or the clinder.

with a simple form t^{-n} that is characteristic of the similarity theory.

It is widely observed in isotropic turbulence, that most of the data of energy decay obey the linear-decay-law $u^{-2} \backsim t$ in narrow range of t and then the decaying becomes more rapid. In order to check the above result experimentally, we gathered the recent data whose deviation from the linear-decay-law was clearly recognized. Since A and p_* cannot be determined experimentally, each experimental result is adjusted to this curve with proportional factors multiplied to $(u/\overline{U})^{-2}$ and t. In turbulent wake with a uniform undisturbed velocity, the relation between x and τ is approximately linear except very near the body. Then, our previous data of u-intensity measured until far downstream behind a circular cylinder along the centre- and u^2-maximum-line are replotted in this figure, since these lines seem to consist of $x(\tau), y_0, z_0$-points (cf. § 14, II). Even in the case of non-uniform flow like a circular jet, etc., this criterion becomes possible if the relation of $x \sim \tau$ is determined. It is an important conclusion of Fig. 2 that the previous experimental measurements have attained only considerably narrow range of τ of about 1.6 in the Poisson process. Variation of the mixture of different vortices in this range can be seen in Fig. 1. Although the above criterion is concerned only with the functional form of (3.6), it can cover almost all the data with a single curve including the relation $u^{-2} \backsim t$ near $\tau=0$. If this curve is shown versus t as in the case of similarity law, it requires a family of many curves corresponding to different values of p_*.

§ 6. Double Correlation in Isotropic Turbulence

As an example of double correlation, the f-function of (3.7) will be considered. For the purpose of evaluation in the general case of decaying turbulence, we must know every locally similar function f_m of $m(\tau_0)$-vortices, whose determination should be based upon our previously proposed similarity theory (cf. § 10, II). Since such a quantitative derivation is difficult in the general case, discussions in this section will be limited to the simple case of isotropic turbulence.

In the previous papers it was pointed out that the isotropic turbulence is the completely irregular vortex chaos motion in a uniform flow (cf. § 3, II). Further, in this chaotic motion consisting of a single type of α-vortices double correlation function f' was obtained as a similar form, as evaluated in an ideal two-dimensional vortex chaos motion (cf. § 4, II). Extension from two- to three-dimensional description is not difficult. As for the triple correlation function h', it is easily proved to vanish by the character of spherical symmetry in a single D-domain. Moreover, we had the power-decay-law $u^{-2} \backsim t^{2\alpha-1}$ in this case. These results on f', h' and u^{-2} in isotropic turbulence are the same as the basic assumptions of Kármán-Howarth's self-preserving solution of their equation[11]. Namely, when the independent variable is written as $\xi'=k'/\lambda'$, their equation is reduced to

$$\left.\begin{aligned} &\frac{d^2 f'}{d\xi'^2}+\left(\frac{4}{\xi'}+\frac{5\xi'}{2(2\alpha-1)}\right)\frac{df'}{d\xi'}+5f'=0\,, \\ &\frac{du^2}{dt}=-10\nu\left(\frac{u}{\lambda'}\right)^2, \end{aligned}\right\} \qquad (6.1)$$

and f' in the above ideal case is obtained by solving (6.1).*

In the cascade process of isotropic turbulence, the above statement holds for every locally similar f_m-function in (3.7), where $\alpha=m$ and t is replaced by τ for $m=1$ and by $\tau-\tau_0$ for $m \geqq 2$. Hence, for f_m-function at two points with ascertain distance k, the Kármán-Howarth solution of (6.1) becomes[11]

$$\left.\begin{aligned} &f_m(\xi_m)=(2m-1)^{5/4}\xi_m^{-5/2}\exp\left(-\xi_m^2/(4m-2)\right)M\{(2m-9/4),\,3/4(\xi_m^2/(2m-1))\}\,, \\ &\xi_1=\sqrt{5/4}\,\sqrt{p_*/10}\,(k/\sqrt{\nu\tau}) \quad (=\xi)\,, \qquad \xi_m=\sqrt{(2m-1)\tau/(\tau-\tau_0)}\,\xi \quad (m \geqq 2)\,, \end{aligned}\right\} \qquad (6.2)$$

where

---

* Functional forms of similar double correlation can be integrated by another analysis with $\overline{V}_*$-function used in the D-domain, as has been done in the two-dimensional case (of § 4, II). It can be shown, however, that they agree with the Kármán-Howarth solution without a contradiction in every value of α.

$$M\{a, b(c)\}=c^{(1/2)+b}e^{-(1/2)c}\left\{1+\sum_{i=1}^{\infty}\frac{(b-a+\frac{1}{2})(b-a+\frac{3}{2})\cdots(b-a+(2i-1)/2)}{i!(2b+1)(2b+2)\cdots(2b+i)}c^{i}\right\}.$$

Namely, (3.7)′ and (6.2) determine completely the non-similar double correlation f as a function of ξ and τ.

Concerning with general properties of f, (3.7) indicates $f(0,\tau)=1$, $f(\xi,\tau)<1$ and $f(\xi,0)=f_1(\xi)$. When (6.2) is introduced, it has a character $f_m(\sqrt{(2m-1)\tau/(\tau-\tau_0)}\,\xi)<f_1(\xi)$ and so $f(\xi,\tau)<f_1(\xi)$ holds generally in (3.7). Further, as every $df_m/d\xi_m$ becomes zero of the first order at the origin, $\partial f(0,\tau)/\partial\xi=0$ is easily derived. But, in (6.2) $\partial^2 f_m(0)/\partial\xi_m{}^2=-1$ and so by (3.7)′ we get

$$\frac{1}{A}\left(\frac{u}{U}\right)\frac{\partial^2 f(0,\tau)}{\partial\xi^2}=\frac{-c^{-\tau}}{\tau}\left\{1+\sum_{m=2}^{\infty}\frac{1.5^{m-1}(2m-1)}{(m-2)!}\int_0^{\tau}\frac{\tau}{\tau'}\frac{(1-\tau'/\tau)^{m-2}}{(1+\tau')^{2m-1}}d\tau'\right\},$$

$$\tau'=\tau-\tau_0\,,$$

where all the integrals $\int_0^{\tau}d\tau'$ diverge because the term $(1-\tau'/\tau)^{m-2}/(1+\tau')^{2m-1}$ becomes unity at $\tau'=0$. By the above discussions it is concluded that $f(\xi,\tau)$ has the following characters;

$$\left.\begin{array}{lll} f(0,\tau)=1\,, & f(\xi,0)=f_1(\xi)\,, & f(\xi,\tau)<f_1(\xi)<1\,, \\ \partial f(0,\tau)/\partial\xi=0\,, & \partial^2 f(0,\tau)/\partial\xi^2=-\infty\,. & \end{array}\right\} \tag{6.3}$$

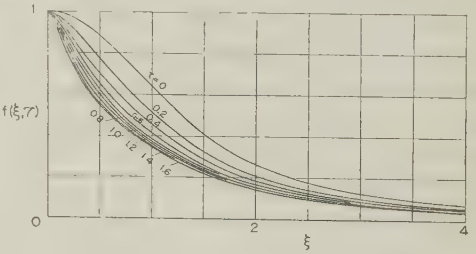

Fig. 3. Theoretical curves of f-correlation function.

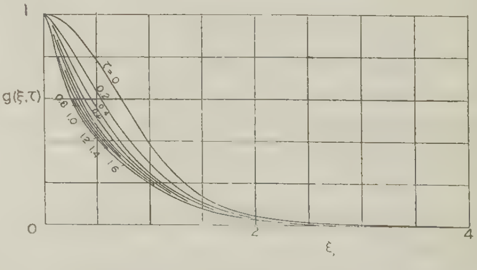

Fig. 4. Theoretical curves of g-correlation function.

In the self-preserving solutions, f'-function can be expanded into a power series of ξ at the origin and λ' in (6.1) is the same[11] as $\sqrt{-2/(d^2f'(0)/dk'^2)}$ which gives the physical meaning of micro-scale to λ'. Physical reason of its non-zero value can be comprehended by remembering that (6.1) is consisting only of one type of vortices with a finite extent except at the instant of production. In the cascade process, however, the last singularity character in (6.3) implies that the micro-scale is zero even if $\sqrt{-10\nu u^2/(du^2/dt)}$ remains finite not being written as $\sqrt{-2/(d^2f'(0)/dk'^2)}$ as shall be mentioned precisely in § 7. This is caused by the condition (3.2)′ where the extents of $m\geqq 2$ vortices have been assumed to grow from zero in the time interval $\tau_0=0\sim\tau$. As mentioned in § 4, in the study of vortex chaos motion vortices should be taken into account only in their growing period with non-zero extents. If some strict discussions are made on the problem of production of a vortex motion, this singularity could be excluded from the analysis.

Fig. 3 shows functional forms of f versus ξ with parametric values of τ, integrated numerically by (3.7)′ and (6.2). As for g-correlation, it can be evaluated in the same manner with a locally similar g_m-function used instead of f_m. The results are shown in Fig. 4. They are also given in Tables I and II. Obviously the continuity condition $g=f+(k/2)(\partial f/\partial k)$ holds between them, as every g_m is connected with f_m by this relation in (3.7). Figs. 3 and 4 suggest that (6.3) may be adaptable widely to double correlation functions of decaying turbulence. Although the mathematical expression of $\partial f/\partial\tau$ is difficult to derive, it is seen in these figures that f or g begins to deviate rapidly from f_1

or g_1 of the self-preserving form and tends to the so-called cascade type with a sharp peak at the origin. This is an important result of our study, together with a character of gradual deviation of the decaying law from that of the initial period as shown in Fig. 2. Thus, the above results suggest that, in general decaying turbulence, the initial-period similarity-law may be useful particularly in the problems of force relation which are all attributed to the distribution of turbulent intensity, such as evaluation of mean-velocity profile, of momentum loss and so forth. On the other hand, in correlation function or spectrum distribution in a total intensity, preferable results cannot be expected without considering the cascade process.

Because of experimental convenience measurements are made chiefly on g-correlation. In Fig. 5, three curves of g at $\tau=0.4$, 1.0, 1.6 are drawn with the abscissa k/L_g, L_g being the integral scale $\int_0^\infty g\,dk$, and the previously observed values are plotted respectively taking a suitable abscissa, as an exact experimental determination of L_g is rather difficult. In these experimental data values of τ are unknown except for few cases, and furthermore the above-mentioned rapidly changing character makes it difficult to check the systematic deviation experimentally. It can be said, however, that experimental data fall almost in the narrow range of these curves and, at the same time, decaying data agree favourably with the theoretical curve in the same range of τ as seen in Fig. 2.

It may be necessary to note on the conception of the final period proposed by Batchelor and Townsend⁵⁾. At the last stage of decay, they derived self-preserving formula by neglecting inertia terms in Kármán-Howarth equation. In our study, this neglect means that the transition probability function $p_*(m(t_0), m'(t_0'), t)$ tends to zero at $t\to\infty$. We suppose this may be true, but since only the first term is taken in p_*-function as indicated by (2.5) our Poisson process should not be extended to the final period in the above meaning. Batchelor and Townsend[5] further obtained self-preserving solution $f=\exp(-\xi^2/2)$ and $\boldsymbol{u}^{-2}\propto t^{5/2}$ by assuming Loitziansky's invariant, which corresponds to our vortex chaos motion consisting only of $\alpha=7/4$ vortices produced at an instant. As seen in Fig. 2, our decaying law includes $\boldsymbol{u}^{-2}\propto t^{5/2}$ in about $\tau=1\sim1.5$, but the correlation function remains in cascade type as shown in Figs. 3 and 4, being different from the above self-preserving type. Batchelor and Townsend[5] observed auto-correlation function instead of f, but if many measurements are made on g- or f-correlation itself at large values of τ, the situations may be more clarified.

As is well known in the study of isotropic turbulence, double correlation and one- or three-dimensional spectrum are related to each other by a simple mathematical formula, based on Taylor's hypothesis. In numerical calculation, however, it is very difficult to transform f into a spectrum function exactly up to such a high wave number as attained by modern hot-wire technique. Then, as the character of spectrum function we shall refer only to the well known $-5/3$-power law, that is equivalent[12] to $1-f\propto k^{2/3}$. It is shown in Fig. 6 that the range being approximated by this relation increases rapidly when the cascade process opens.

§7. Triple Correlation in Isotropic Turbulence

In isotropic turbulence Kármán and Howarth have derived the fundamental equation of motion[11],

$$\frac{\partial(\boldsymbol{u}^2 f)}{\partial t}-2\nu\boldsymbol{u}^2\left(\frac{\partial^2 f}{\partial k^2}+\frac{4}{k}\frac{\partial f}{\partial k}\right)=-2\boldsymbol{u}^3\left(\frac{\partial h}{\partial k}+\frac{4}{k}h\right), \qquad (7.1)$$

where h is the triple correlation function. In principle, (7.1) is a mathematically transformed expression from the Reynolds equations, and it is not closed in itself, since it has three unknown dependent variable $\boldsymbol{u}^2$, f and h. However, since $\boldsymbol{u}^2$ and f were given as functions of τ and ξ in the preceding sections, our original purpose to complete the Reynolds equations has been achieved at least in the case of isotropic turbulence. As interpreted so far, $\boldsymbol{u}^2$ and f have been derived through many simplification of situations, and if this approximative analysis shall be made on h

too such a result $h=0$ will be obtained because every locally similar h_m is zero. Thus, even if our non-similarity characters are well supported experimentally in the forms of $\boldsymbol{u}^2$ and f, it is still interesting to survey them in the form of h-correlation by solving (7.1).

When $\boldsymbol{u}^2$ and f are expressed in terms of functions of τ and ξ, (7.1) takes the following form,

$$\frac{-\partial((\boldsymbol{u}/\overline{U})^2 f)}{\partial\tau}+\frac{(\boldsymbol{u}/\overline{U})^2}{4\xi\tau}\frac{\partial(f+2g)}{\partial\xi}=\frac{1}{\sqrt{2}}\left(\frac{\boldsymbol{u}}{\overline{U}}\right)^3\frac{1}{\sqrt{\tau}}\left(\frac{dh'}{d\xi}+\frac{4}{\xi}h'\right),$$

where

$$h=(\sqrt{p_*}\sqrt{\nu}/\overline{U})h'(\xi,\tau),$$

with the continuity equation used. This is regarded as an ordinary linear differential equation of the first order for h, with a parametric constant τ. Therefore, on integrating under the boundary condition $h=0$ at $\xi=0$, we get

$$\left.\begin{aligned}h(\xi,\tau)&=\left(\sqrt{\frac{2}{A}}\frac{\sqrt{p_*}\sqrt{\nu}}{\overline{U}}\right)\frac{\int_0^\xi H(\xi,\tau)\xi^4\,d\xi}{\xi^4},\\ H(\xi,\tau)&=\left\{-I\tau\frac{\partial(f/I)}{\partial\tau}+\frac{1}{4\xi}\frac{\partial(f+2g)}{\partial\xi}\right\}\sqrt{\frac{I}{\tau}},\\ I&=A(\boldsymbol{u}/U)^{-2}.\end{aligned}\right\}\tag{7.2}$$

In the phenomenological studies, triple correlation h which is caused by the inertia terms in the original Navier-Stokes equations is considered to play a role to transfer fluctuating energy from low- to high-frequency range and to break similarity preservation in double correlation. While, in our statistical study of cascade process the cause of non-similarity has been given through the transition probability p_* as mentioned repeatedly. It is very instructive that based upon the simplified relation $p_*=constant$, h is proved to be connected directly with $\sqrt{p_*}$ as indicated in (7.2).

At the origin $k=0$, (7.1) tends to

$$\left.\begin{aligned}\frac{d\boldsymbol{u}^2}{dt}&=-10\nu\frac{\boldsymbol{u}^2}{\lambda^2},\\ \lambda^{-2}&=\frac{1}{5}\lim_{k\to0}\left\{\frac{\boldsymbol{u}}{\nu}\left(\frac{\partial h}{\partial k}+\frac{4}{k}h\right)-\left(\frac{\partial^2 f}{\partial k^2}+\frac{4}{k}\frac{\partial f}{\partial k}\right)\right\}.\end{aligned}\right\}\tag{7.3}$$

By (6.3) and (7.2) every term in λ^{-2} is proved to be divergent, while λ^{-2} is clearly finite owing to our decaying law shown in Fig. 2, and so it is interpreted that every singularity cancels each other in λ^{-2}. Anyway, it may be necessary to notice that the relation $-10\nu\boldsymbol{u}^2/(d\boldsymbol{u}^2/dt)=-2/(d^2f(0)/dk^2)$ does not hold unless f can be expanded into a power series of k at the origin.

Values of h were determined by computing (7.2) numerically. Near the origin reliable results could not be expected owing to the singular character. Also since numerical differentiations contained in H cannot give sufficiently accurate values, these results in Fig. 7 should be regarded as showing only the general characters of h-function. However, such a tendency can be ascertained that with a given value of p_* the function h is gradually growing with τ, unlike the case of double correlation in Fig. 3 or 4.

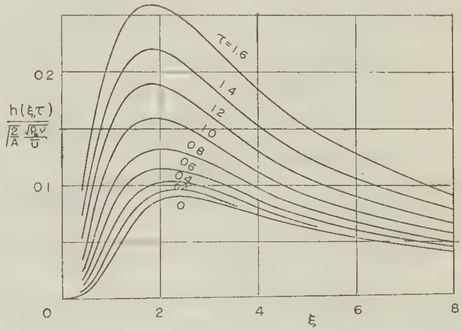

Fig. 7. Computed curves of h-correlation function.

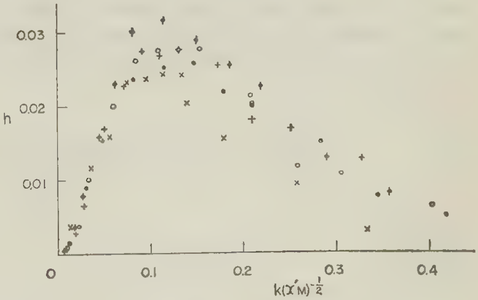

Fig. 8. Time dependency of h-correlation observed behind a grid by R. W. Stewart[16], where × $x/M=20$, ● $x/M=30$, ○ $x/M=60$, + $x/M=90$, ⧫ $x/M=120$ and $R_M=5300$.

We have not so much observation on h-correlation even in isotropic turbulence. Further, as the value of τ is uncertain in the observed results, variation of h versus τ cannot be checked definitely. But, referring to Stewart's data16) inserted in Fig. 8 which have been observed along the x-direction in one case of flow behind a grid, the above-mentioned growing character can be ascertained at least qualitatively. Fortunately, h-correlation was measured together with f-correlation case15) 16)17) by case. Then, in the same manner as in Fig. 5, our computed results of f in the preceding section can be compared with these experimental data, and as for the relative forms of h they also can be checked experimentally at the same time with the same abscissa as in f. Fig. 9 shows the results.

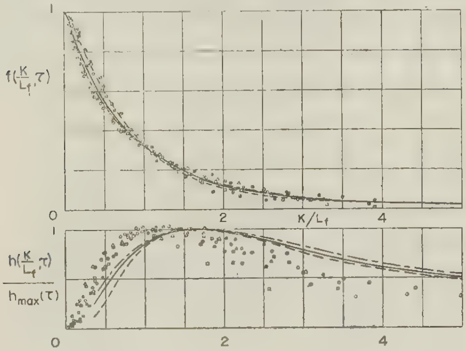

Fig. 9. Comparison of f- and h-correlation with experimental results, plotted against the same abscissa k/L_f. Dotted-, full-, chain-line show the curves respectively of $\tau=0.4$, 1.0, 1.6 in Figs. 3 and 7. Several marks correspond to the observed values of f and h at the same time behind a grid under the following conditions:

△		$R_\lambda=56.2$	Stewart17)

For f-correlation, the theory and experiment agree very well as for g-correlation, but in h-correlation disagreements are found to some extent. It seems that our too simplified picture of cascade process is responsible for the disagreement in h-correlation, although undetectable in the decaying law and double correlations. However, it may need many other experimental results on triple correlation to make this point clearer. Furthermore, the comparison in the form of transfer function in the Fourier-transformed equation of (7.1), may probably give useful results.

Here we should like to say some concluding remarks: (i) The fundamental hypotheses of our non-similarity theory are (2.5) and (3.2), the latter of which is concerned with the production of vortex motion together with (3.2)′, strict discussions being hopeless at present. However, unless such a relation as (3.2) is taken, it becomes difficult to interpret the experimental evidence that turbulent dissipation increases with wave number, and a rough estimation of (3.2)′ seems to have given not very bad result. (ii) It is not so old when the interrelation between (2.5) and (2.6) has come to be clarified, but (2.6) has been used successfully in many other statistical studies of cascade phenomena, such as cascade shower of the cosmic ray18) and so forth. We think, an appropriateness of Poisson process in the decaying turbulence is due to mechanism of this flow that even at the beginning of vortex chaos motion it is accompanied inevitably by the cascade phenomenon from large to small vortices—non-zero transition probability. It seems also to give an apparently favourable effect on our theory that the present experimental technique attains only narrow range of τ. Otherwise, inadequateness of the simple assumption (2.5) could be found out more clearly through experimental observations. (iii) It is a characteristic point of this paper that the theory holds independently of the magnitude of the parametric constant p_*. As mentioned in § 1, p_* is due to disturbing effects of vortices in their chaotic states, and when the irregularity of their states increases, i.e. the functional form of P_* tends to be constant in the D-domain (cf. § 8, I), the value of p_* becomes large. It is due to this character that the deviation from the initial-period similarity-law is found clearly in turbulent wake behind a grid, rather than in decaying shear turbulent flows. Even in shear turbulence, however, this theory may be useful particularly for the purpose of evaluating correlation or spectrum function.

In conclusion the author wishes to express his gratitude to Professor I. Tani and members of the Turbulence Research Group in Japan for their valuable advice and discussions. Thanks are also due to Dr. K. Maeda for

helpful suggestion in mathematical aspect.

Anisotropic Conductivity of CdS Single Crystals

By Shōji TANAKA, Mineo KOBAYASHI
and Taizō MASUMI
Department of Applied Physics,
University of Tokyo, Tokyo, Japan

(Received October 4, 1958)

The conductivity, Hall effect and magneto-resistance effect of CdS single crystal have been investigated by many workers (1)–(7). But the structure of electronic energy band of this material has not been clarified enough up to now. As CdS crystal has the Wurtzite type crystal lattice and not the cubic symmetry, it might have the anisotropic conductivity if the energy band or the relaxation time is anisotropic along the directions of the crystal axis. In this report the conductivity of CdS single crystal has been measured by microwave method in 9500 MC region at room temperature.

The microwave method is very useful for the measurements of the anisotropic natures of crystals, since the free selection of the polarization of electromagnetic waves to the crystal axis is possible and especially in the conductivity measurements no electrical contacts with metal electrodes are required.

Samples used in this experiment are thin flakes of Cl-doped *N*-type CdS single crystals, dimensions of which are about 3∼4 mm in diameter. The *c*-axis of these crystals lies in the face of flat crystals and one of the *a*-axis is perpendicular to this face. The samples are held by the polystyrene bar in the center of H_{011}-mode cavity and the crystal face is parallel to the electric field of the microwave, and these samples can rotate around the bar holder. The microwave power entering into the cavity is absorbed by the conducting crystal and so the *Q*-value greatly decreases. The conductivity of the sample is deduced from the measurement of this *Q*-value.

The typical result is shown in Fig. 1 and it indicates that the conductivity parallel to the *c*-axis is almost twice of that perpendicular to the *c*-axis, and the angular dependence of the conductivity is expressed by elliptic equation (1)

$$\frac{\sigma_\theta}{\sigma_{\parallel}}=1-\frac{\sigma_{\parallel}-\sigma_{\perp}}{\sigma_{\parallel}}\sin^2\theta, \qquad (1)$$

where $\sigma_{\parallel}$ and $\sigma_{\perp}$ are the conductivity of the sample parallel and perpendicular to the *c*-axis respectively, and θ is the angle between the *c*-axis and the electric field. The value of $\sigma_{\perp}/\sigma_{\parallel}$ fluctuates about 20% from sample to sample, and this may be caused by the measurement error.

The conductivity of semiconductor is determined by the effective mass of charge carriers and the scattering mechanism of them with the crystal lattice or impurity centers. As CdS has the hexagonal crystal lattice, it might be considered that the role of the anisotropic scattering could not be neglected. To investigate these problems, the measurements of the anisotropy and temperature dependencies of the magneto-resistance, Hall effect and conductivity are now in progress (7).

Piezoelectric Properties of Triglycine Sulphate Crystal

By Kazuo HUSIMI and Keisuke KATAOKA
Electrical Communication Laboratories, Tokyo

(Received October 4, 1958)

During the study of switching processes by the ultrasonic method, a large piezoelectric voltage was observed in triglycine sulphate[1]. The crystal of triglycine sulphate belongs to C_2 (monoclinic) and has eight independent piezoelectric constants, but here we report only on their tensile components that have been measured by the dynamic method.

The crystal axes of the samples are determined with the aid of X-ray analysis. Table I shows the dimensions of the samples and the measured piezoelectric constants. Measurements were done at 30°C. From the results, it is proved that the piezoelectric constant d_{23} is very large. The resonant characteristic of a typical sample is shown in Fig. 1 which shows a very large coupling factor of 0.44. The values of d_{21} and d_{22} are also shown in the table.

Table I

Sample	l (mm)	f_r (kc/s)	k	d (stat-Cl/dyne)	S^E (cm²/dyne)
c axis No. 1	12.8	102.15	0.44	$d_{23}=2.51\times10^{-6}$	$S_{23}=8{\cdot}71\times10^{-12}$
〃 No. 2	20.5	64.31	0.44	$d_{23}=2.52\times10^{-6}$	$S_{23}=8.57\times10^{-12}$
a axis No. 11	13.0	152.85	0.19	$d_{21}=7.06\times10^{-7}$	$S_{21}=3.77\times10^{-12}$
〃 No. 12	17.8	111.72	0.17	$d_{21}=6.60\times10^{-7}$	$S_{21}=3.76\times10^{-12}$
Thickness No. 21	1.23	1581.0	0.18	$d_{22}=6.60\times10^{-7}$	$S_{22}=3.93\times10^{-12}$

In Fig. 2 is shown the temperature dependence of the piezoelectric output measured by ultrasonic method. In this procedure, a constant ultrasonic excitation is applied to the sample so the output voltage is proportional to the piezoelectric constant. A small error arising from the thermal coefficient of the quartz crystal is involved. In the figure, the characteristic of d_{23} is shown with an arbitrary unit in the ordinate, which has a large peak value with increasing temperature, and a large thermal hysteresis. No piezoelectric output appears above the Curie point, but polarization of the same polarity reappears when the crystal is cooled below the Curie point. This fact seems to indicate that a certain ferroelectric effect remains above the Curie point. The decrease of the piezoelectric output near the Curie point is steep, but is not discontinuous, unlike the case of BaTiO$_3$ single crystal. This shows that the transition is of the second order.

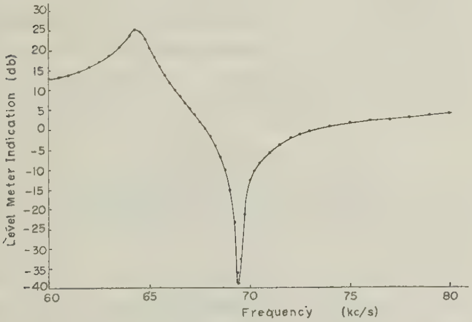

Fig. 1. The resonance characteristic of the typical sample.

The samples used here has been offered by Prof. G. Ōhara of Tōhoku University for which we express our thanks. We also thank to Mr. Y. Niizeki for the X-ray analysis.

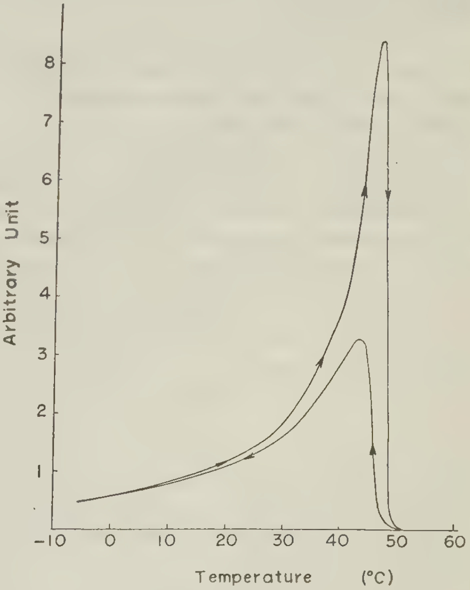

Fig. 2. The temperature characteristic of the piezoelectric output.

On the Transition Temperature of Copper Ferrite

By Haruyuki OHNISHI, Teruo TERANISHI
and Syohei MIYAHARA
Department of Physics, Faculty of Science,
Hokkaido University, Sapporo, Japan

(Received October 30, 1958)

It is well known that slowly cooled copper ferrite has tetragonally deformed spinel structure at room temperature. Snoek[1] and Bertaut[2] examined its tetragonality with quenched specimens and found those quenched above 760°C to have cubic structure. Ohnishi and Miyahara[3] found, however, the temperature of transition from tetragonal to cubic structure is 360°C by means of a high temperature X-ray camera. Recently, Inoue and Iida[7] reported an anomaly of specific heat near the above temperature. In order to clarify the physical meaning of these two temperatures we made further experiments concerning the crystal structure of $CuFe_{2-t}Cr_tO_4$.

All specimens are made from CuO, Fe_2O_3 and Cr_2O_3. Mixtures of these oxides are heated at about 900°C for two weeks and cooled to room temperature at the rate of 0.5°C/min. This treatment prevents eventual reduction of the cupric ion. Lattice parameters and the distributions of cupric ions on 8a (tetrahedral) and 16d (octahedral) sites of spinel structure are determined by a "Norelco" X-ray diffractometer.

Tetragonality $\sigma=(c-a)/a$ at room temperature and the fraction x of cupric ions at 8a site are plotted against the content t of chromium. From these two curves tetragonality σ is given as a function of x as shown in Fig. 1, and the critical value of x beyond which tetragonality vanishes is about 0.25. This value is equal to that of Bertaut's pure copper ferrite specimens quenched from 760°C.

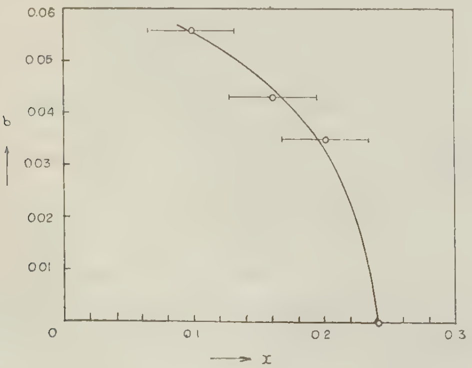

Fig. 1. Variation of tetragonality with copper ion distribution.

Tetragonalities σ of slowly cooled copper ferrite-chromites at various temperatures T are shown in Fig. 2.

Beside the above experiment $CuFe_2O_4$ is quenched from 790°C and annealed at 390°C (A) and 320°C (B), respectively. Specimen A deforms into tetragonal spinel after 15 minutes, while specimen B remains in cubic structure even after 24 hours. From this fact it can be said that the curves in Fig. 2 represent the lattice deformation as functions of temperature where copper ions migrate scarcely. Under this condition $CuFe_2O_4$ transforms from cubic to tetragonal structure at 360°C.

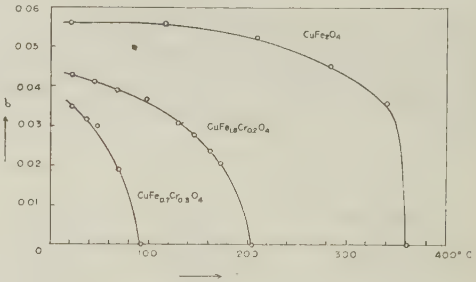

Fig. 2. Variation of tetragonality with temperature.

The origin of tetragonal deformation of $CuFe_2O_4$ is thought to be either the Jahn-Teller effect[5] or covalent force[6] of cupric ions. For $CuFe_2O_4$ the bulk tetragonality decreases as temperature is raised and it vanishes at the critical temperature 360°C. The tetragonality also decreases by mixing chromium or by quenching, both of which causes the increase of the fraction of cupric ions in 8a site to the critical value $x=0.25$.

Here it can be concluded that for $CuFe_2O_4$ 760°C is not any specific temperature but the one at which the ionic distribution $x=0.25$ (which is the critical value of tetragonal deformation) is realized.

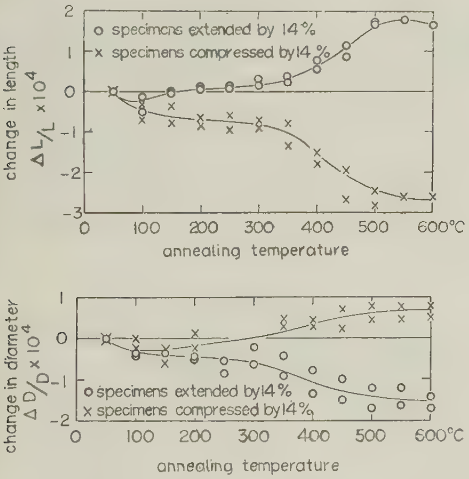
Grain Boundary Migration and Dimensional Change of Low Carbon Steel

By Minoru OKADA
Department of Welding Engineering, Osaka University
and Toichi WATANABE
Department of Mechanical Engineering, Osaka City University

(Received November 14, 1958)

It has been reported by previous investigators[1),2)] that a dimensional change occurs in the same direction to that of cold-working, provided that a low carbon steel is subjected to the low-temperature annealing after the cold-working. The purpose of this note is to propose a mechanism of this phenomenon.

Steel rods containing 0.2%C, 32 mm in diameter, were prepared for the experiment and they were extended or compressed by about 14%. After the deformation, each specimen was annealed for a half hour at different temperatures and the measurements of the change in length or diameter were made, as illustrated in Figs. 1 and 2.



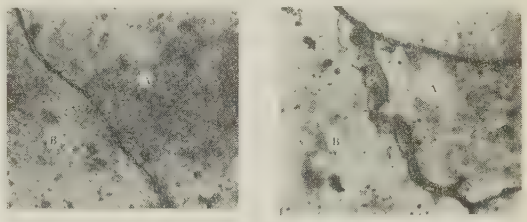
Figs. 1 and 2. The dimensional change of steel rods due to the annealing subsequent to the cold-working.

The main points are as follows:

(1) At anneals below 100°C, the volume contraction was observed in both extended and compressed specimens.

(2) At anneals above 100°C, an increase and a decrease in the length of specimen and vice versa in the diameter were observed, respectively for extended and compressed specimens. Such dimensional changes occurred distinctly in the range of annealing temperatures 350 to 500°C, while the volume of the specimen remained nearly constant during the anneals, as understood from Figs. 1 and 2.

The dimensional changes observed for anneals above 100°C may be related to the grain boundary migration owing to piled-up dislocations[3)]; dislocations piled-up against a grain boundary would tend to migrate in such a direction that their stress concentration may be released. If the affinity between a dislocation and its atmosphere is sufficiently strong enough to impede the backward motion of piled-up dislocations in a slip plane, the grain boundary would migrate at elevated temperatures in such a way of releasing the high stress concentrations. This is the case for low carbon steel where dislocations are strongly anchored by the Cottrell atmosphere; some evidences for the migration of grain boundary were obtained, as clearly shown in Fig. 3. As can be seen in the figures, grain A has grown into grain B and the slip lines exist in the grain A (remarkable in (a)).



(a) (b)

Fig. 3. The migration of grain boundary. The steel specimen containing 0.045%C and 0.005%N was compressed by about 5% at room temperature after etching with 1.5% Nital subsequent to polishing and annealed in vacuum at 500°C for a half hour, and then slightly etched with 1.5% Nital. ×370.

As the results, cold-worked mild steels would change their length in the same direction to that of cold-working without any noticeable volume change.

On the other hand, the volume contraction found at anneals below 100°C is considered to be mainly attributable to the disappearance of excess point defects[4)] introduced by cold-working.

The authors wish to express their hearty thanks to Professor J. Takamura of Kyoto University for his valuable discussions.

Electron Spin Resonance of Mn-activated Phosphors

By On Matumura

Department of Physics, Faculty of Science, Kyusyu University

(Received October 29, 1958)

The electron spin resonance of Mn^{++} in various powder salts has been measured at 3 cm wave length at room temperature. The crystal structure of these salts are rutil, fluorite, rock salt, zinc blende, and wurtzite type respectively, and Mn^{++} are believed to be in cubic or nearly cubic crystalline field surrounded by 4, 6, or 8 negative ions in these phosphors.

Table I.

Phosphors	g	A $10^{-4}\,cm^{-1}$	Number of surrounding negative ions
MgF_2	2.001	90.6	8
CdF_2	2.001	90.6	8
CaF_2	2.003	92	
SrF_2	2.002	93	
BaF_2	2.004	91	
MgO	2.001	81.2	6
CdO	2.001	87.3	
CaO	1.999	87.7	
MgS	2.001	71.9	
CaS	2.001	75.7	
SrS	2.000	75.0	
MgSe	2.004	71.2	
CaSe	2.004	72.9	
CaTe	2.003	67.2	
ZnO		79	4
CdS	2.002	64.8	
CdSe	2.003	61.5	
MgTe	2.013	58.1	
ZnS	2.001	63.8	4
ZnSe	2.01	60	
CdTe		56.9	
ZnTe		56	

The results are interpreted in terms of the following spin Hamiltonian, with $S=5/2$ and $I=5/2$;

$$\mathscr{H}=g\beta \boldsymbol{H}\cdot\boldsymbol{S}+A\boldsymbol{I}\cdot\boldsymbol{S}+\text{higher order terms.}$$

The obtained values of g and A are summarized in the Table I.

From the electro-negativity of Mn^{++} and negative ions and the numbers of the surrounding negative ions, the amount of the ionic character can be calculated after Pauling[1]. As seen in Fig. 1, an almost linear relation exists between the coupling constant A of h. f. splitting and the ionicity[2].

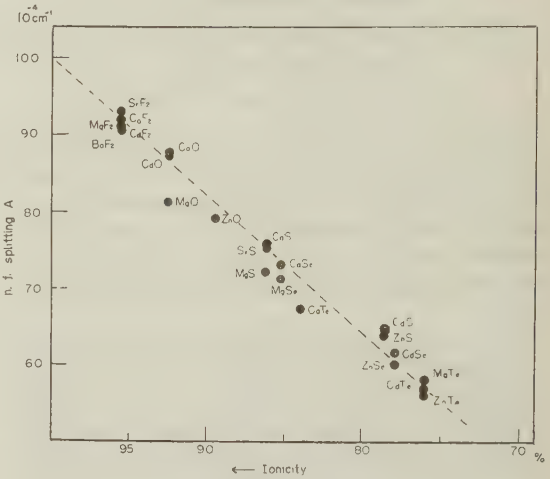

Fig. 1.

Further discussions on the g-values[3], the luminescence wave length, and other properties will be given in the near future. The author is indebted to Prof. Z. Miduno for his discussions and to Mr. K. Hôrai for many details of the experiments. This research is partially supported by the Grant for Promotion of Science from the Ministry of Education.

Some Ferroelectrical Properties of Triglycine Sulfate

By Hiroo TOYODA, Shigeru WAKU,
Hiroyuki SHIBATA and Yoichi TANAKA
*Electrical Communication Laboratory,
Nippon Telegraph and
Telephone Public Corporation, Tokyo*

(Received November 14, 1958)

We have measured some ferroelectrical properties of triglycine sulfate single crystals at room temperature, 0°C, and −73°C. The crystals were prepared by cooling or evaporation methods[1]. They were cut perpendicularly to the b-axis, and polished by fine sand paper or etched in water, their thickness ranging from 0.015 to 0.11 cm. The electrical contacts were made by silver conducting paste or by platinum wire spring, in both cases gold electrodes being evaporated directly on the crystal.

Coercive fields, obtained from the hysteresis loops at 50 c/s, remarkably increase with the amplitude of applied field. A relation $E_c=aE_{\max}{}^b$ holds in a good approximation, where $b=0.5$ for 20°C ($E_{\max}=0.35\sim15$ kv/cm corresponds to $E_c=0.2\sim1.35$ kv/cm), and $b=0.4$ for −73°C ($E_{\max}=5.5\sim22$ kv/cm corresponds to $E_c=4.0\sim6.8$ kv/cm) ($d=0.039$ cm). The results also suggested that the coercive field would increase with frequency of applied field, as Domansky[2] has reported, but a preliminary measurement failed owing to disturbance by hysteresis loss. The spontaneous polarization remains constant in this field region, but we have obtained the values, 3.1~3.3 coul/cm² at 20°C and 4.5~4.8μ coul/cm² at −73°C, which were considerably larger than those ever reported[3], except the one by Husimi[4]. The coercive field has a tendency to decrease with increasing thickness.

Temperature °C	α kv/cm		Mobility calculated from the high field linearity; cm²/volt·sec.
	Low field	High field	
23	1.8~2.2	6	4~5
0	5.5	9.4	1.1~1.5
−73	—	—	1.5~2.0×10⁻²

Polarization reversal was measured by applying repeated pulses, duration of which was 1 to 100μ sec. Figs. 1 and 2 give the typical results for 100μ sec and various pulse heights ($d=0.02$ cm). Stadler and Meitzler[5] have reported that the piezoelectric output of barium titanate was not proportional to the average polarization, but that the relation between these two properties had a hysteresis loop. We have used the ultrasonic method, developed by Husimi[6], and ascertained that in the case of T.G.S. the relation was almost linear.

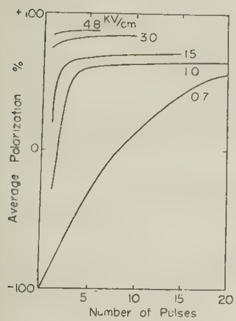

Fig. 1. Polarization reversal under successive Pulses of 100μ sec. at 30°C.

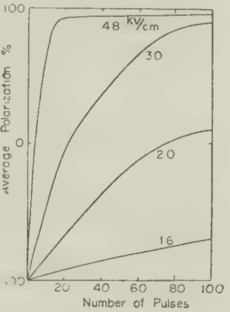

Fig. 2. Polarization reversal under successive pulses of 100μ sec. at −73°C.

We have also measured the switching current. Fig. 3 shows the maximum current density per unit crystal area at three different temperatures ($d=0.023$ cm). All curves look quite alike and can be divided into two parts, namely the high field region and the low field region[7]. It is known that the former is nearly proportional to the field strength, while the latter changes with field strength as $\exp(-\alpha/E)$. The higher field region, however, may be rather better represented in the same exponential form, though the constant α differs from the one for lower field.

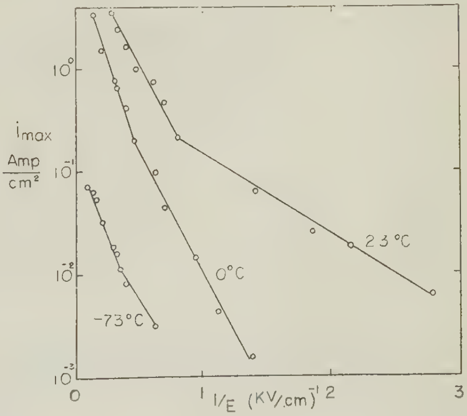

Fig. 3. Maximum of switching current at three different temperatures.

The Far Infrared Reflectivity of NaCl, KCl and KBr Crystals

By Akiyoshi MITSUISHI, Hiroshi YOSHINAGA and Shigeru FUJITA

Department of Applied Physics, Faculty of Engineering, Osaka University, Osaka, Japan

(Received November 19, 1958)

The far infrared reflectivity of NaCl, KCl and KBr crystals was remeasured with the vacuum grating spectrograph[1] of much high resolving power as compared with the measurements in 1930's. The measurements were made in the spectral region from 30 to 200μ at two incident angles, 12° and 52°, assuming the reflectivity of an Al coated mirror as 100%.

Fig. 1 shows the reflection curves obtained in the vicinity of reflection peaks. Very strong and broad peaks centered at 53μ (NaCl), 63μ (KCl) and 79μ (KBr) respectively have been well known as the Reststrahlen peaks. The sub-maxima placed at 38μ (NaCl), 46μ (KCl) and 58μ (KBr) respectively (at 12° incidence) were first found by Czerny in 1930[2].

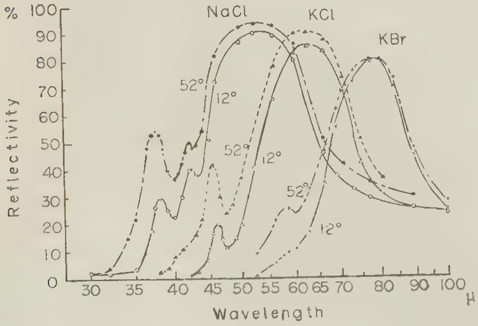

Fig. 1. The far infrared reflection curves of NaCl, KCl and KBr at two incident angles, 12° and 52°.

For NaCl a new weak but definite sub-maximum was found at 42.5μ (at 12° incidence) in the present investigation. No reflection peak was observed beyond 100μ.

In the transmission measurements of NaCl Barnes and Czerny found two weak minima at 40.5μ and 51μ besides the main band at 61.1μ[3]. The three reflection peaks in the present investigation may correspond to these three absorption bands.

Recently Rosenstock studied the problem of infrared absorption by rocksalt lattice[4]. According to his calculation there are five infrared active modes of lattice vibration. Among these one produces the strongest absorption, the other two the next strongest and the remaining two the next strongest. This agrees qualitatively with the experimental results which showed one strong band and two weak bands in both the reflection and transmission measurements, but the calculated wavelengths do not agree.

The reflectivity increases and reflection peaks shifts slightly to the shorter wavelength side as the incident angle increases. From the reflectivities at 12° and 52° incidence the optical constants could be derived graphycally as was done by Simon in the prism infrared region[5], but as the polarization of radiation in the spectrograph has not yet been measured no such attempt was made at present.

At the temperature of liquid air the two sub-maxima of NaCl are clearly observed and the reflectivity increases and reflection curve shifts as a whole slightly to the shorter wavelength side. These results will be reported later.

Diffusion of Manganese in Single Crystals of Copper

By Akira IKUSHIMA
Department of Physics, University of Tokyo

(Received November 6, 1958)

The experimental study on the diffusion of transition elements in noble metals seems to be one of the procedures to elucidate the anomalous behaviors of the transition impurities dissolved dilutely in noble metals. Moreover, there is a merit in the case of the tracer experiment of diffusion that the state of transition impurities in extremely small concentration is investigated.

The diffusion experiments of iron[1),3)], cobalt[2),3)] and nickel[3)] in copper have been carried out by the present author and other investigators. And, here the diffusion experiment of Mn^{54} in single crystals of 99.99% copper is reported.

The experimental procedures were the same as previously reported[1)]. It is, however, to be noted that the following plating bath seemed to be practical: $Mn^{54}Cl_2$ in aqueous solution (Mn^{54} was obtained in this form from the Radiochemical Centre in England); NH_4Cl, 30 gramme per one litre of water; with a carbon anode.

The penetration curves are shown in Fig. 1, and the diffusion coefficients calculated from these plots are given in Table I. Fig. 2 shows the data plotted as log D versus the inverse of the absolute temperature. The straight line fitted by the least square calculation is expressed as $D=D_0 \exp(-Q/RT)$ cm²/sec. with

$$\log_{10} D_0 = 7.00 \pm 0.32 \ (D_0 \text{ in cm}^2/\text{sec.}),$$

$$Q = 91400 \pm 1600 \text{ cal/mole.}$$

The last figures in these equations are the probable errors. Mackliet[3)] measured the diffusion coefficient of this system at 1069°C and his data is consistent with the present work. But, the values of D_0 and Q estimated by Mackliet differ radically from the present results. Mackliet's data is shown in Fig. 2.

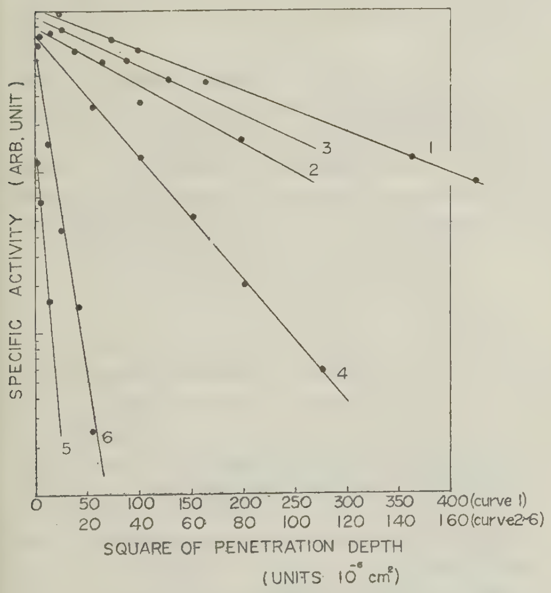

Fig. 1. Penetration curves.

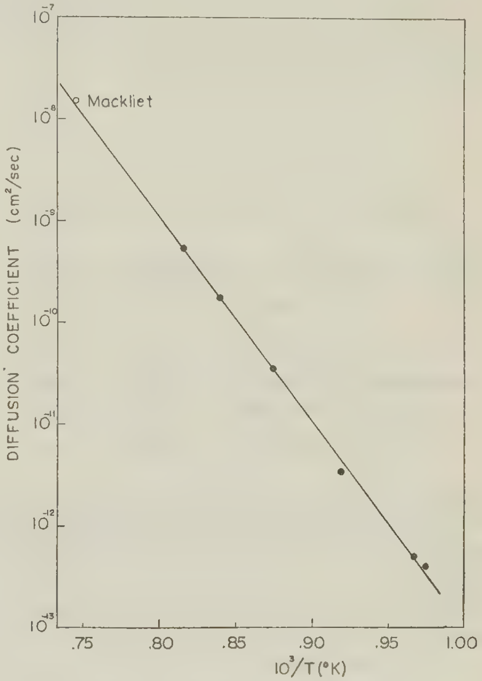

Fig. 2. Plot of log D *vs* 1/T.

Table I. Diffusion coefficients of Mn^{54} in Cu.

No.	Temperature (°C)	Time (sec.)	D (cm²/sec.)
1	950±1	6.85×10^4	4.82×10^{-10}
2	918±1	5.29×10^4	1.79×10^{-10}
3	871±1	3.97×10^5	3.59×10^{-11}
4	817±1	1.75×10^6	3.32×10^{-12}
5	761±1	1.34×10^6	5.07×10^{-13}
6	754±2	2.67×10^6	4.09×10^{-13}

D_0 and Q of the present results are fairly larger than those of Cu^{64} in Cu[4)], Co^{60} in Cu[2),3)] and Ni^{63} in Cu[3)]. The existing theories of diffusion cannot easily account for the large value of Q and especially that of D_0. The latter may be attributed to the deformation of incomplete d-shell of the manganese atom at the saddle point of diffusion, from which the reduction of vibrational frequency results.

The author wishes to thank Professor Y. Tomono for many valuable advices and continuous encour-

agement. This work is partly supported by the Scientific Research Expenditure from the Ministry of Education.

The Variation of Superstructure in Iron Selenide Fe_7Se_8

By Atsushi OKAZAKI

Department of Physics, Faculty of Science, Kyusyu University, Fukuoka Japan

(Received Nov. 17, 1958)

X-ray diffraction studies of single crystal specimens of iron selenide (Fe_7Se_8) have shown that this compound can exist in structural forms distinct from the hexagonal superstructure reported by Okazaki and Hirakawa[1]. The second structure (the triclinic superstructure) is obtained by slow cooling after annealing the hexagonal superstructure at 290°C. The fundamental lattice of this superstructure is of a pseudo NiAs type.

The structure analysis of this superstructure has been made at room temperature by single crystal X-ray work with oscillation, rotation and Weissenberg photographies, the preliminary results of which are as follows:

Laue symmetry: triclinic,

Lattice constants: $A=\sqrt{3}B=12.53$, $B=2a=7.23_6$ and $C=4c=23.5_4$ Å, $\alpha=89.8°$, $\beta=89.4°$ and $\gamma=90.0°$,

where the capital and small letters designate the unit cell dimensions of the super and fundamental lattices, respectively.

The observed extinction rule indicates that the arrangement of iron vacancies is as shown in Fig. 1 (a). This is identical with that in Fe_7S_8, reported by Bertaut[2], although the sulphide is monoclinic. In Fig. 1 (b) the unit cell of the hexagonal superstructure is shown for comparison. In both superstructures the arrangements of the iron vacancies in the AB planes are identical. Only the stacking sequence of these planes along the C axis and hence the C axis length are characteristic to each structure.

The transition between the triclinic superstructure ($C=4c$) and the hexagonal one ($C=3c$) has been observed with oscillation and rotation photographs obtained by using a single crystal high-temperature camera having a cylindrical Ni-foil heater (Dent and Taylor[3]). The accuracy of temperature measurement is within ±2°C and the stability during the exposure time (about 30 min.) is ±0.5°C over the whole temperature range of this experiment.

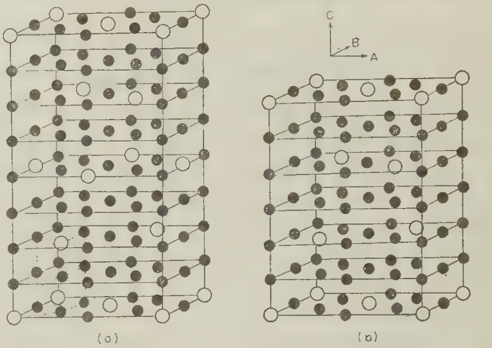

Fig. 1. Unit cells of Fe_7Se_8 superstructures. (a): triclinic ($C=4c$), (b): hexagonal ($C=3c$). Open and solid circles represent vacancies and Fe atoms, respectively. Se atoms are omitted for clarity. Broken lines indicate the fundamental unit cell.

The transition begins at about 240°C and proceeds gradually and is complete at 298°C. During this transition the diffraction pattern of the '$4c$ structure' in the oscillation photograph is replaced gradually by that of the '$3c$ structure' as shown schematically in Fig. 2. That the triclinic deformation of the unit cell decreases gradually is also seen in the complete rotation photographs.

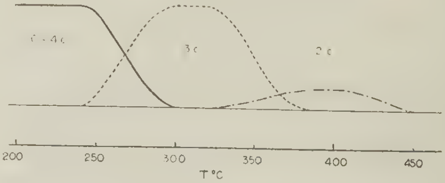

Fig. 2. The diffraction intensity of each type lattice as a function of temperature (schematic).

The third superstructure ($C=2c$) appears at 320°C. The transition from the hexagonal structure is similar to that between the triclinic and hexagonal one and is complete at 388°C. The diffraction intensities of this crystallographic phase are of the order of 1/5 compared with those of the others (also shown in Fig. 2) and the observed extinction rule cannot be explained from the arrangement of the iron vacancies alone. It seems that the arrangement of these vacancies are somewhat disorder. This superstructure disappears at about 450°C, but the remaining (0001) and (0003) reflexions referred to the fundamental NiAs type lattice suggest the partial ordered state in which the iron vacancies remain within the alternative *AB* planes but distributed at random in these planes. Such a situation has been reported by Jellinek on $Cr_7S_8$⁴⁾. At about 460°C the distribution of vacancies becomes completely random.

A slight deviation of chemical composition from Fe_7Se_8 may cause not only the change of the transition temperatures but also the transition process. With specimens prepared earlier the third structure was not observed. The transition process and temperature reported here are those with specimens having reliable stoichiometric composition. The full paper will be published in the near future.

Effects of Deuteron Bombardment on CdS Single Crystals

By Shoji TANAKA and Toshio TANAKA
Department of Applied Physics, University of Tokyo, Tokyo, Japan

(Received November 15, 1958)

Concerning the lattice defects in CdS crystals many investigations have been carried out. The identity of those defects, however, is not yet clarified completely.

We have studied the effects resulting from bombardment of CdS single crystals with deuterons to clarify the nature of defects in this material. The present article describes some results obtained up to now.

The samples used in this experiment are flake-shaped pure CdS single crystal having high dark resistivity, grown by the Frerichs' technique. Deuteron bombardments are performed in air at room temperature by the cyclotron at the Institute of Physical and Chemical Research and the total number of deuterons is about 10^{16} per cm² and their energies about 2 Mev.

The resistivity of the crystals is reduced by these bombardments from about 10^{10} ohm-cm to about 10^4 ohm-cm. Plotting the resistivity logarithmically as a function of reciprocal temperature, one obtains straight lines with slope about 0.4 ev (Fig. 1). It may be considered that the deuteron bombardments produce probably not only donors but also acceptors (compensation defects). Therefore, the donor levels seem to lie about 0.4 ev below the conduction band.

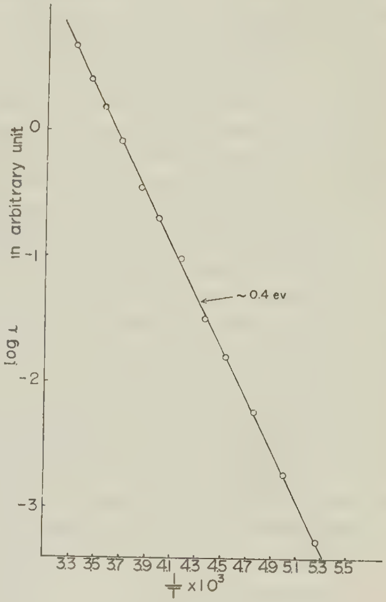

Fig. 1. Temperature-dependency of dark-current for a crystal after deuteron-bombardment.

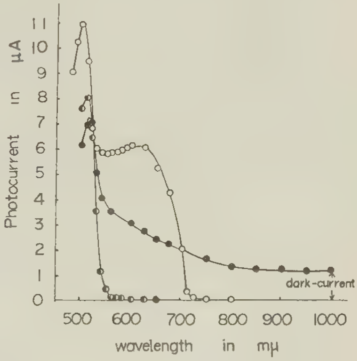

Fig. 2. Spectral distribution of photocurrent.

Before bombardment
(measured at room temperature) ...... ◐
After bombardment
(measured at room temperature) ...... ●
(measured at low temperature) ...... ○

Lambe, Klick¹⁾, Bube²⁾, Broser, Broser-Warminsky³⁾ and other investigators have observed trapping levels lying as deep as the donor levels in the bombarded samples. So it might be resonable that the donor levels are attributed to sulfur vacancies or interstitial cadmium ions. Recently, Melamed[4) also proposed from luminesence experiments that sulfur vacancies are the origin of the donor centers.

Beside, such deuteron bombardment causes the considerable increase of photosensitivity of the crystals and its spectral distribution becomes to show new response to the long wavelength side of the fundamental absorption edge (Fig. 2). This long wavelength response is obscure at room temperature but becomes more predominant at low temperatures, and it increases with bombardment. It may be interpreted as giving the energy corresponding to transition* from lattice defect levels to the conduction band. The defect levels are therefore considered to be about 2.0 ev below the conduction band. These centers exist also in some unbombarded crystals and moreover seem to be produced by some heat treatments.**

The other effects than those above mentioned are also produced. That is, the rise and decay of photocurrent become slow after the bombardment, where the decay consists of a fast component and a slow component which increases with bombardment. The decay time of the slow component is sensitive to temperature, that is to say, it amounts to even more than an hour at low temperatures but decreases abruptly above approximately $-100°$C. Furthermore, the thermally stimulated current and the steady-state photocurrent also show sharp falls at the same temperature. These results might be due to the formation of hole traps by the deuteron bombardment.

---

* More accurately speaking it seems that this transition is made through the shallow excited state of the defect, as considered from the shape of spectral distribution curve of photocurrent.

** Further investigations on the heat treatments are in progress.

Yields and Angular Distributions of Protons from $F^{19}(d, p)F^{20}$ and $F^{19}(d, p)F^{20*}$

By Kazuo ÔNO, Junji SHIMADA, Keiichi KURODA,
Osamu TANAKA, Hiromichi KAMITSUBO, Atsuko ITO,
Shigeya TANAKA and Minoru IMAIZUMI

Institute for the Solid State Physics, University of Tokyo

(Received October 3, 1958)

The reactions $F^{19}(d, p)F^{20}$ and $F^{19}(d, p)^{20*}$ have been studied with deuteron bombarding energy of 1.3 Mev to 2.0 Mev. Angular distributions of protons leaving F^{20} in 0.65 Mev excited state show a pronounced peak at about 60° over the entire deuteron energy range. On the other hand, those leaving F^{20} in the ground state vary with the deuteron bombarding energy and most of them show no peak in the forward direction and a large peak in the backward direction. The absolute yields of the reactions have been measured at $\theta_{cm}=54°$ and $\theta_{cm}=104°$ as functions of the bombarding energy. A marked difference in the energy dependence of the yields for the two reactions is noted. The yield for the reaction $F^{19}(d, p)F^{20}$ at $\theta_{cm}=104°$ shows a broad maximum centered at about 1.70 Mev deuteron energy, on the other hand that from the $F^{19}(d, p)F^{20*}$ reaction at $\theta_{cm}=54°$ shows a slow increase with increasing deuteron energy. These results at our bombarding energies show that the reaction $F^{19}(d, p)F^{20}$ seems to proceed mostly by compound nucleus formation and the reaction $F^{19}(d, p)F^{20*}$ (0.65 Mev) seems to be caused by the stripping process of *d* neutrons.

§ 1. Introduction

The angular distributions of the proton groups from the reactions $F^{19}(d, p)F^{20}$ and $F^{19}(d, p)F^{20*}$ (0.65 Mev level) have been investigated by many authors. The $F^{19}(d, p)F^{20}$ reaction is of particular interest because of the possibility of determining the spin of the ground state of F^{20}. Bromley et al[1] at Rochester University measured the angular distributions of the protons from the reactions using 3.6 Mev deuterons. From the results they concluded that the proton group leaving F^{20} in the ground state could be interpreted as a mixture of $l_n=0$ and $l_n=2$ stripping. The results fix the spin of F^{20} definitely as 1 which would be in disagreement with data from β decay.[2],[3] However, their statistical error was rather large and angular distributions in the backward direction ($\theta_{cm}>100°$) were not measured. After that, the same reaction was also investigated by Takemoto et al[4] with 0.75–1.45 Mev deuterons and by Black[5] with 14.3 Mev deuterons. These two results can not determine whether F^{20} in the ground state is formed by capturing *s*-neutron or not, because in Takemoto's experiment the proton angular distributions are nearly isotropic, and in the other the angular distribution has been measured from 20 to 100 degrees, which indicates only the existence of captured *d* neutrons. Subsequently, El Bedewi[6] observed the angular distributions from 21 excited states of F^{20} using 8.9 Mev deuterons but could not observe that of the ground state because of low intensity.

Recently, two experiments have been made by Ôno et al[7] with 2.03 and 1.92 Mev deuterons and Seward et al[8] with 4.52, 3.82 and 3.52 Mev deuterons, in order to probe the angular distribution characterized by two l_n values, which were obtained by Bromley et al. These results showed no peak near 0° and a large peak in the backward direction. According to their results, the reaction may proceed by compound-nucleus formation and the interpretation of the results of the earlier experiments in terms of Butler-type simple stripping reaction may be unjustified.

The present investigation extends our previous measurements to the lower deuteron energy of 1.3 Mev. Six angular distributions were obtained in the range of deuteron bombarding energy from 1.3 Mev to 2.1 Mev. In order to confirm the compound nucleus formation in the reaction, excitation curves at $\theta_{cm}=54^\circ$ and $\theta_{cm}=104^\circ$ were also obtained in this deuteron energy range.

The angular distributions of protons from the reaction $F^{19}(d,p)F^{20}$ (0.65 Mev) have also been reported by many authors.[1),4),5),6),8)] These results were in good agreement with each other and showed the typical Butler-type stripping peak corresponding to the capture of *d* neutrons. Our present results both from the angular distributions and the excitation curves in $F^{19}(d,p)F^{20*}$ confirm also that the stripping process is dominant in the reaction at our bombarding energies.

§ 2. Appratus

The deuteron beam of the present work was supplied from the 16 inches variable energy cyclotron reported elsewhere[9)]. Analyzed beam currents in excess of 0.1 microamperes are focused at the center of the reaction chamber through a 3 mm second slit, at a distance of about four meters from the cyclotron. The focused beam has an energy spread of about 0.4% (calculated but not yet measured). The absolute errors in the deuteron energies are considered to be ±50 kev and the relative ones are estimated to be within ±10 kev.

The target was prepared by evaporation of PbF_2 onto a thin gold foil. The thickness of the target is 30 kev for 5.3 Mev P_0 alpha particles. Ag absorbers of 15 mg/cm² thickness were employed to prevent any deuterons from reaching to the detector. The current collected in the absorber was measured by a direct current amplifier and recorder which has an accuracy better than 5%. The protons emitted, after passing through the absorbers of Ag, were detected in 50 micron Sakura nuclear plate.

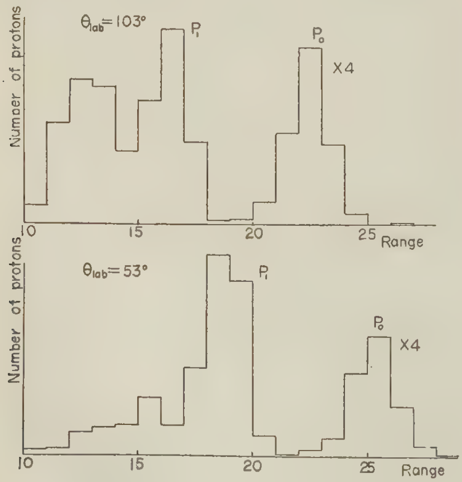

Fig. 1. The spectra of proton emergence at $\theta_{lab}=53^\circ$ and $\theta_{lab}=103^\circ$ for deuteron energy of 1.85 Mev. P_0 and P_1 correspond to protons leaving F^{20} in the ground state and in 0.65 Mev excited state respectively.

§ 3. Results and Discussions

Data on the angular distributions were ob-

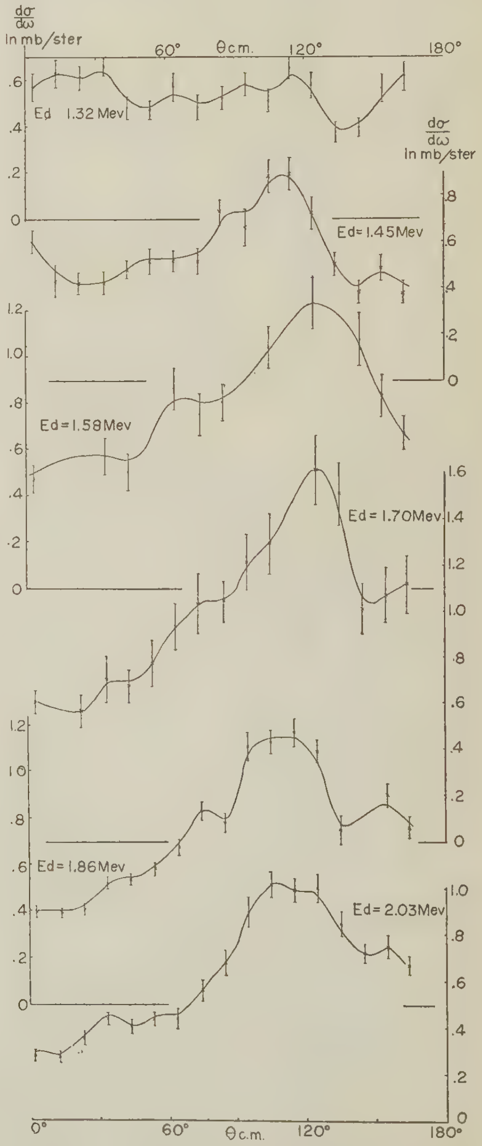

Fig. 2. Angular distributions of the proton from $F^{19}(d,p)F^{20}$ for various bombarding energies in the C.M. system.

tained in 10-degree intervals from −10 to 160 degrees. The spectra of proton emerging at $\theta_{lab}=53°$ and $\theta_{lab}=103°$ for deuteron energy of 1.85 Mev are shown in Fig. 1. Proton groups of P_0 corresponding to the first excited state were fairly well resolved.

$F^{19}(d, p)F^{20}$—The angular distributions of P_0 at laboratory deuteron energies of 1.32, 1.45, 1.58, 1.70, 1.86 and 2.03 Mev are shown in Fig. 2.

The expected stripping maximum at zero degree is not observed. A small peak at about 60 degrees for deuteron energies of 1.45, 1.58, 1.70 and 1.86 Mev may perphaps bear significance of the stripping process of *d* neutrons, which have been observed by Black at $E_d=14.3$ Mev. Here, the most striking aspect of the curves is a large and broad peak in the backward direction and a strong energy dependency of their shapes. Although the low energy angular distributions measured by Takemoto et al at bombarding energies of 1.45, 1.20, 1.00 and 0.65 Mev show rather flat curves and do not show a backward maximum, their results continue smoothly to our curve obtained at $E_d=1.36$ Mev. A broad backward peak and a strong energy dependency of the shape in the angular distributions have also been found at the bombarding energies of 4.13, 3.82 and 3.53 Mev by Seward et al.[8)]

The absolute yields at $\theta_{cm}=54°$ and $\theta_{cm}=104°$ are shown in Fig. 3. The yield at $\theta_{cm}=104°$ shown a broad maximum centered at about 1.7 Mev. It should be noted that protons emitted have maximum intensity near 100°.

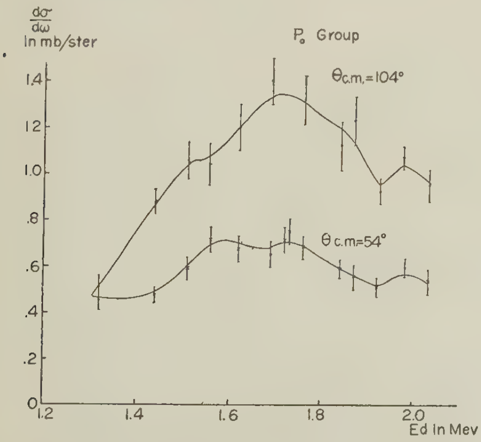

Fig. 3. Absolute yields for $F^{19}(d, p)F^{20}$ for protons emitted at 54° and 104° with respect to the incident deuteron direction.

These results show that the stripping process can not account for these distributions and yields, but compound nucleus formation plays a strong role. This may be due to a small overlapping between the states of F^{19} and F^{20}.

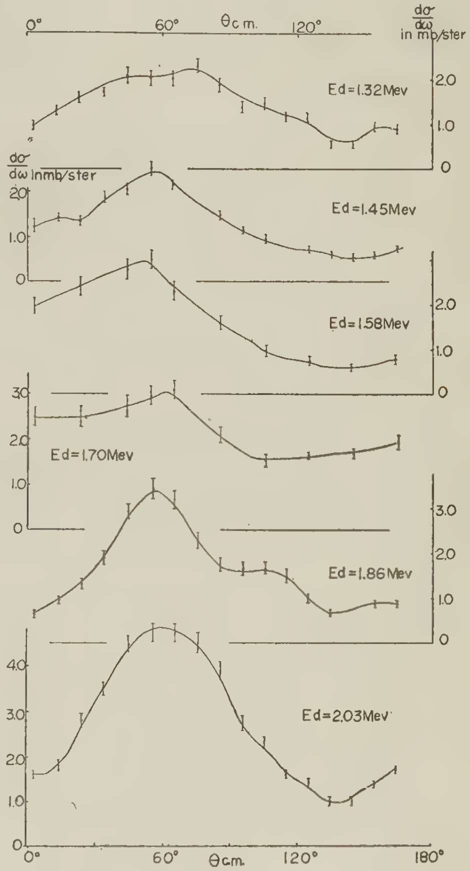

Fig. 4. Angular distributions of proton from $F^{19}(d, p)F^{20*}$ (0.65 Mev) for various bombarding energies in the C.M. system.

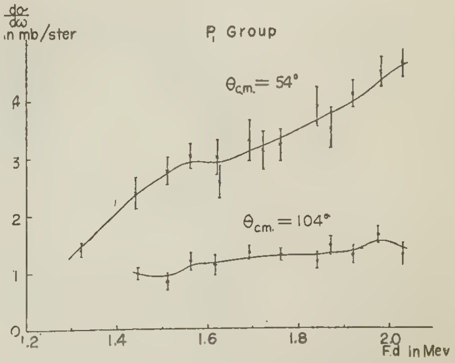

Fig. 5. Absolute yields for $F^{19}(d, p)F^{20*}$ (0.65 Mev) for protons emitted at 54° and 104° to the incident deuteron direction.

From the results obtained by us and by Seward et al, the spin of the ground state F^{20} is not necessarily 1 and the earlier interpretation in terms of stripping is unjustified.

$F^{19}(d, p)F^{20*}$ (0.65 Mev)—The angular distributions and the absolute yields of the reaction are shown in Fig. 4 and Fig. 5 respectively. All of the distributions show similarly a large peak at about 60° and the forward peak becomes more remarkable with increasing deuteron energy. This indicates that most of the cross section is due to stripping, in agreement with the results obtained hitherto by many authors.1),4) The yield at $\theta_{cm}=54°$, corresponding to the stripping peak, shows a slow increase with increasing the bombarding energy. This circumstances can be also interpreted that the reaction proceeds mostly by stripping process. Small peaks in the yield curve and some difference in shape between the six angular distributions may be due to some contribution from compound nucleus formation.

Acknowledgements

The authors are indepted to Professor T. Muto and Professor H. Kumagai for valuable discussions. We also thank to Mr. Y. Wakabayashi of Konishiroku Photo Manufacturing Co. for supplying nuclear plates for us.

Elastic and Inelastic Scattering of 14.1-MeV Protons by Medium Weight Nuclei

By Ken KIKUCHI*, Shinsaku KOBAYASHI and Kazuhisa MATSUDA

Institute for Nuclear Study, University of Tokyo,
Tanashi-Machi, Tokyo

(Received November 1, 1958)

The absolute differential cross sections for the elastic scattering and the inelastic scattering (proceeding to the 1st excited state) of 14.1 Mev protons have been measured for Ni, Fe, Cr and Ti with a five-degree (or less) interval ranging from 20 to 165 degrees. The scattered protons were detected by NaI (Tl) scintillation counter whose energy resolution was about 2.3%. Even at small angles the protons inelastically scattered could be discriminated from those elastically scattered. The angular distributions of inelastic protons agree to that expressed by $|j_2(qR)|^2$ which one would expect from the theoretical prediction based upon the Born approximation.

§ 1. Introduction

Recently theoretical investigations on the inelastic scattering of nucleons by complex nuclei have been made by many authors on the basis of the direct interaction between the incident nucleon and the target nucleus. It is generally considered that the contribution of the direct interaction is most remarkable when the residual nucleus is left at low-lying excited states. In fact a number of measurements[1,2,3] on the angular distribution of protons inelastically scattered by light nuclei have resulted in giving marked forward peaks in contrary to that proposed by the statistical assumption of nuclear reaction. However, most of these experimental results are not in agreement with the simple calculation of the direct process on the assumption of the Born approximation. Moreover, some of these in the low energy region[5] show strong resonance behaviour depending on a small change of the incident energy. Therefore it may be suggested that the theoretical prediction based on the Born approximation has better validity when the incident energy becomes so large that any explicit resonance phenomena does not take place. It is the case when medium weight nuclei are bombarded by nucleons of moderate energy, for which few measurements have been made. One of these works is that made with 17 Mev porton beam at Princeton,[4] in which the angular distribution of proton group corresponding to the 1st excited state of iron nucleus is observed. From this measurement, however, one may not obtain the conclusion on the validity of the Born approximation, because large errors are contained in the measurements at extreme forward angles where the yield from the Rutherford scattering dominates over the inelastic protons concerned. There large errors come mainly from the rather small magnitude of the Q-value for the process, which makes it very difficult to discriminate the protons inelastically scattered from those elastically scattered. Therefore it seems to be worth while to investigate this point employing other target nuclei such as titanium, cromium or nickel, which have larger negative Q-values and have the ground and the excited states of the some nuclear spin 0^+ and

2^+ respectively as those of Fe^{56}. On the other hand, we have tried to make the resolution of the detecting system so high as to discriminate the inelastic protons in the forward angles.

§ 2. Apparatus and Design of the Experiment

The general feature of the experimental arrangement is shown schematically in Fig. 1. Fig. 2 shows the scattering chamber, together with the collimation system, and the detecting system.

1. *Production of the proton beam*

The proton beam is deflected by an A. C. deflector from I. N. S. cyclotron* and, passing through the magnetic shielding channel leaves the cyclotron chamber. Then it is focused by a pair of quadrupole magnets and is deflected by a sector magnet. The combined lens action of the quadrupole magnets and the sector magnet produces a beam spot about 5 mm wide and 10 mm high, whose intensity can be changed stably from 1 μ A to 0.01 μ A or less, before the collimator slits. The beam then passes through the collimator which has two defining apertures of graphite, 5 mm diameter and spaced 80 cm apart. To removed slit scattered protons from the beam, five graphite baffles each 7.5 mm in diameter are arranged as shown in Fig. 1. This collimator limits the beam size within 9 mm in diameter at the target position.

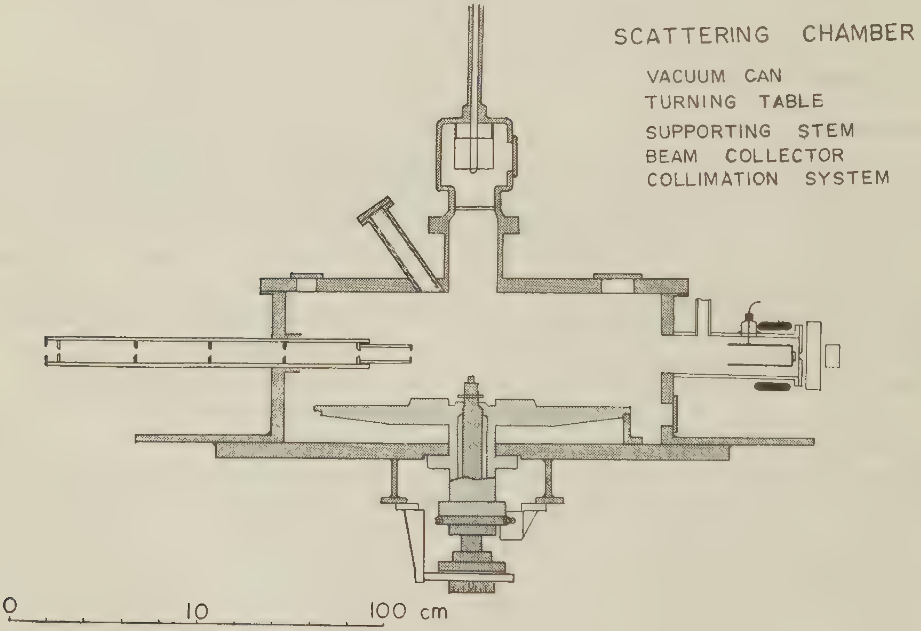

Fig. 2. Scattering chamber.

2. *Scattering chamber*

Details of the scattering chamber will be described elsewhere, so will mention here only the outline of it. It consists of a turning table on which the main detector is mounted, the target assembly and a vacuum can containing them. The turning table can be easily rotated around a fixed centre shaft which also supports the target assembly. The accuracy of the mechanical construction of the table system is such that the precision of the scattering angle is about 0.01 degree. The target can be supplied through an air lock from the center of the lid without breaking the chamber vacuum. The vacuum can has an inner diameter of nearly 100 cm and a height of 40 cm, whose side wall has 32 windows and entrance and exit holes. These windows allow us each 5 degree observations, but we used two of them for the monitor counters. The degrees of misalignment might be less than 0.3 mm per 100 cm.

---

* The construction report of this I.N.S. cyclotron will be published in this Journal in near future.

3. *Beam collector*

The unscattered beam is collected in the Faraday cup. In order to reduce the effects of secondary electrons, the collector cup is equipped with a couple of magnets which produce magnetic fields of about 300 gausses in vertical and horizontal directions. At the bottom of the cup an aperture, 3 mm in diameter, is equipped through which a part of the unscattered beam can be extracted from the vaccum and supplied into an ionization-chamber for the beam energy measurement which placed behind the cup. This aperture is closed with a small piece of permanent magnet during the cross-section measurement and can be opened by changing the polarity of the Faraday cup magnet.

4. *Energy of the incident beam*

The energy of cyclotron beam was maintained at 14.1 MeV, though our cyclotron, with its wide range magnet and variable frequency oscillator system, can offer proton beams of energies from 7.5 MeV up to 15 MeV to the scattering chamber without much intensity change.

The energy of the incident beam was determined by the measurement of, range in aluminium. The unscattered proton beam enters into an argon-filled shallow parallel-plate ionization chamber, after passing through the small aperture prepared at the bottom of the Faraday cup mentioned above. By changing the thickness of aluminium-absorbers placed in front of the ionization-chamber, one can measure the Bragg[6] curve, which determines the mean range of the incident beam.

The energy spread of the incident proton is estimated to be 0.5% or less from the spatial spread of the beam spot in front of the collimator after the deflecting magnet. The time variation of the energy is very difficult to be estimated but it may be less than 0.5% because the stability of the magnet is very high and the resonance condition of the cyclotron for the Faraday cup current is very sharp,—half width of the resonance is about 1.5 kilo cycles per sec. in part of 10 mega cycles per sec.

5. *Detector and electronics*

The scattered protons were detected by a NaI (Tl) crystal of dimension of about 18×18×1.4 mm, which was slightly thickner than the range of the protons. With this size of the crystal, the γ-ray back ground was generally negligible for protons of this energy range. But, when the detector was set at large scattering angles, a rather intense γ-ray back ground was observed because of the proximity to the beam collimator. However this back-ground was not so serions as to disturb the detection of protons concerned because γ-rays yield only small[7] pulses in such thin crystal. The detector slit was 5 mm in diameter, had a 7.5 mm baffle slit before it and was about 20 cm apart from the target.

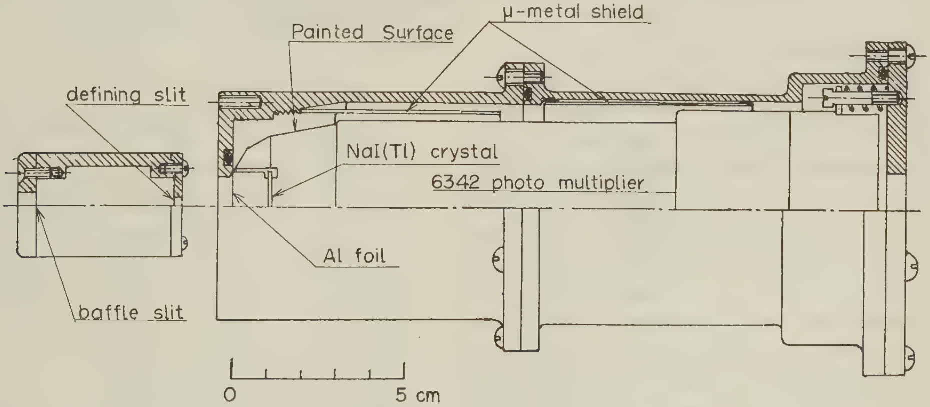

Fig. 3. Detector.

As can be seen from Fig. 3*, the crystal was supported by wires and placed inside an air-tight housing having a thin aluminium window for penetration of the protons. This housing, containing the photo-multiplier together, was filled with dry air at atmospheric pressure. The inner surface of the housing facing to the crystal was painted with titanium oxide paint for reflection of light.

---

* We owe this design to Professor A. Isoya.

The signal pulses, after passing through a cathod follower attached to the turning table in the scattering chamber, were sent to the counting room about 50 m apart from the measuring room. And after amplified by a linear amplifier the pulses were fed to a Jhonston type 10 channel pulse height analyser. All the electronic equipments were constructed in the electronics devision of our laboratory.

6. *Target*

With the exception of Cr foils, the target foils were obtained from commercial sources. Rolled foils of iron and titanium—about 5 μ thick—were considered to be quite uniform. The Cr foils were prepared by electroplating following the method of P. Kafalas et al.[6] The Cr foils had a contamination of oxygen but the others were fairly clear. The thickness of the nickel foil was about 1 mg/cm² and that of the cromium foil was about 0.5 mg/cm².

The areas of the foils used were measured to less than 1 per cent by direct measurement with a comparator. The weights were determined to 1 percent with a microbalance.

7. *Experimental procedure*

At each scattering angle where cross section was measured, the followings were recorded: the pulse height spectrum in the desired proton group, the number of elastically scattered protons observed in the 90° monitor counter and the charge collected in the Faraday cup during the time required for the spectral measurement. The counting time for each measurement was adjusted so that the statistical errors in the number of counts should be much less than the errors originating in the subtraction of back-ground. The counting rate was adjusted by controlling the beam intensity so that the counting loss may be much less than 1%. The target foils were fixed at 45° to the incident beam and the forward and the backward cross sections were measured without changing their inclinations. All the relative differential cross sections were determined with regard to the counts of the monitor counter and the absolute values were determined from the reading of the integrator.

Probable errors of the differential cross sections of elastic scattering were not more than 5%, which was mainly due to the inaccuracy of the integrator, the non-uniformity of target foils and some effects of the slit edge scattering.

Most errors of the inelastic cross section come from the back-ground subtraction especially in forward angles. Our procedure was as follows: we extended the rather constant back-ground at the lower energy side of the inelastic peak and, on the other hand, we also extended the lower energy tail of the elastic peak. Joining smoothly of these two curves, we obtained the back-ground spectrum to the inelastic peak when the yield and shape of the elastic peak played as some guide to the procedure. Then we estimated the possible upper and lower limit of these back ground and determined the probable errors of the inelastic cross sections.

§ 3. Results and Disscussions

1. *Elastic scattering*

To exhibit some of the regularities in the data, smooth curves fitted to the experimental points have been plotted in Figs. 4 through 7.

For elastic scattering in this energy region there are some data[7,8] by other investigators, one of which is also shown in Fig. 4 in comparison with ours. The behavior of both

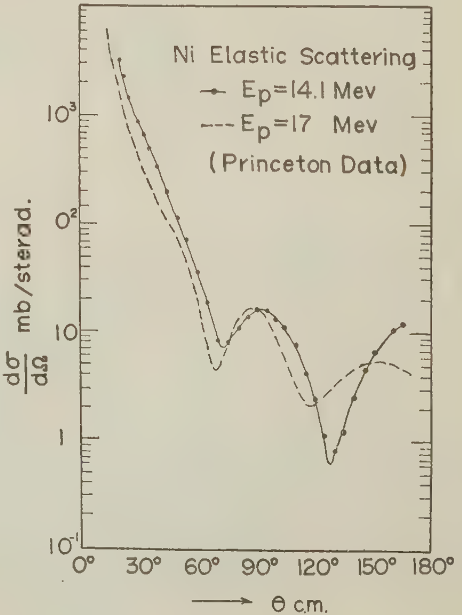

Fig. 4. The angular distribution of protons elastically scattered from Ni measured at E_p= 14.1 Mev.

curves is very similar and seems to agree with what one would expect from the picture of a incident wave scattered by a optical potential. Since the calculation based upon the five-parameters optical potential is very tedious and, as the matter of fact, can not be accomplished without using an electronic computer, has not been done. For iron, the angular distribution of 7.4 MeV protons was also observed in order to see the energy dependence of the elastic scattering phenomena. As can be easily seen from Fig. 5,

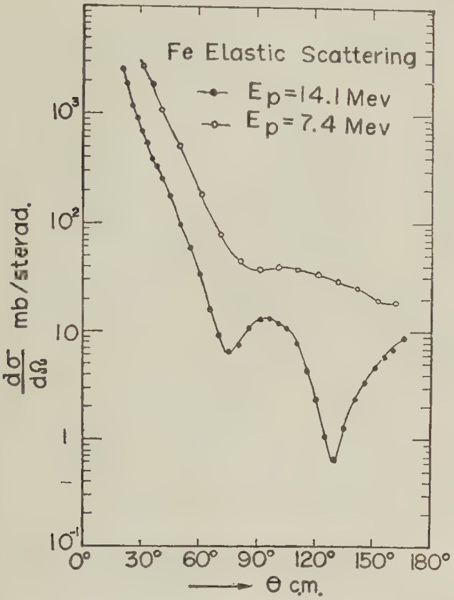

Fig. 5. The angular distributions of protons elastically scattered from Fe measured at $E_p=$ 14.1 Mev and 7.4 Mev.

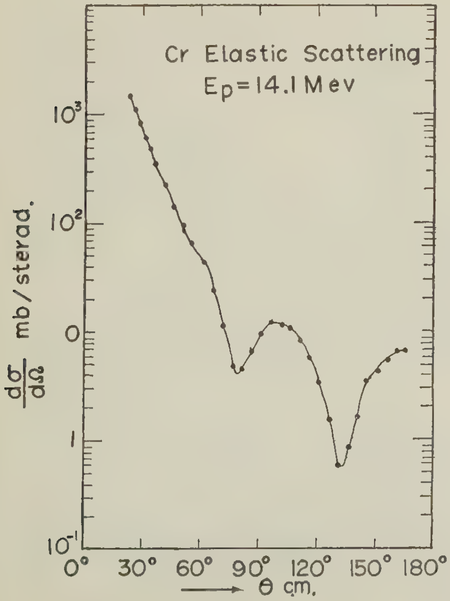

Fig. 6. The angular distribution of protons elastically scattered from Cr measured at $E_p=$ 14.1 Mev.

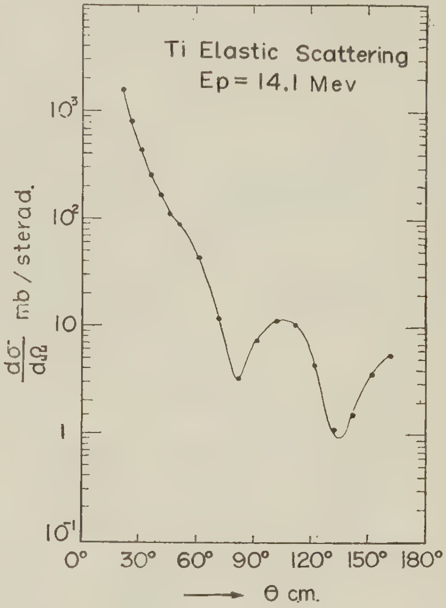

Fig. 7. The angular distribution of protons elastically scattered from Ti measured at $E_p=$ 14.1 Mev.

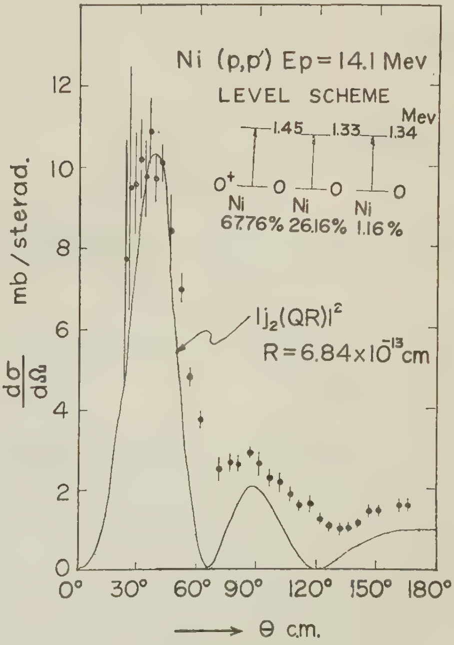

Fig. 8. The angular distribution of protons inelastically scattered from Ni ($Q \sim -1.4$ Mev) at $E_p=14.1$ Mev.

the energy dependence is remarkable but is a reasonable from the point of view that the incident beam is scattered by an optical potential with a Coulomb force. For energies between 7.4 MeV and 14 MeV further measurements are to be made.

2. *Inelastic scattering proceeding to the 1st excited state*

Because natural elements were used as targets, in some cases the observed proton groups included those corresponding to the 1st excited states of different isotopes. However, almost all of these levels have the same spin and parity 2^+, so the protons due to these levels are considered to give not very different angular distributions. In fact one can see from Figs. 8, 10 and 11 that the observed angular distributions are in fair agreement with those expected from the simple calculation based upon the Born approximation. If one adopts the Born approximation and assumes surface interaction as the base of the theoretical calculation, the angular distribution of protons in the $0^+ \rightarrow 2^+$ excitation can be fitted by the expression $|j_2(QR)|^2$ independent of the type of interaction.[9] Kajikawa, Sasakawa and Watari[10] calculated the angular distribution at 17 MeV for iron with distorted wave. Their results show no dip in forward direction, but our results can be fitted with the more simple approximation. Our procedure of back-ground substraction have some ambiguity and the experimental results do not

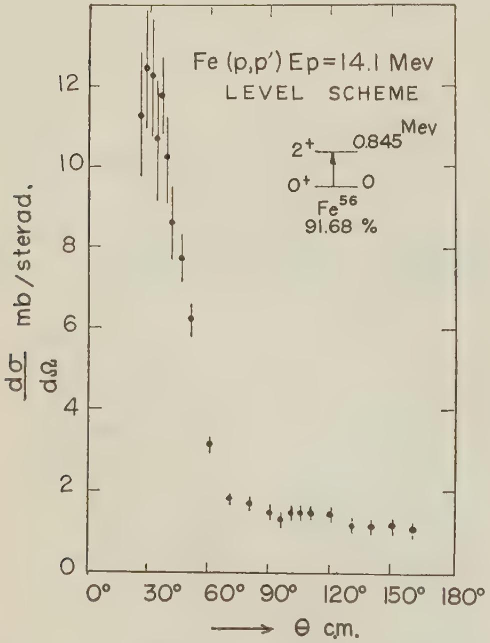

Fig. 9. The angular distribution of protons inelastically scattered from Fe ($Q = -0.845$ Mev) at $E_p = 14.1$ Mev.

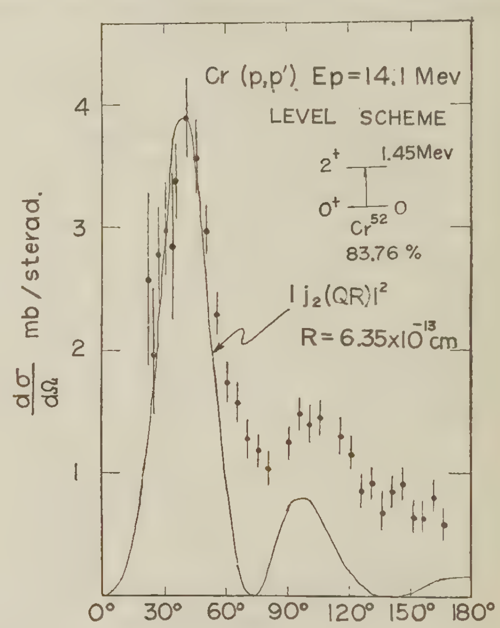

Fig. 10. The angular distribution of protons inelastically scattered from Cr ($Q = -1.45$ Mev) at $E_p = 14.1$ Mev.

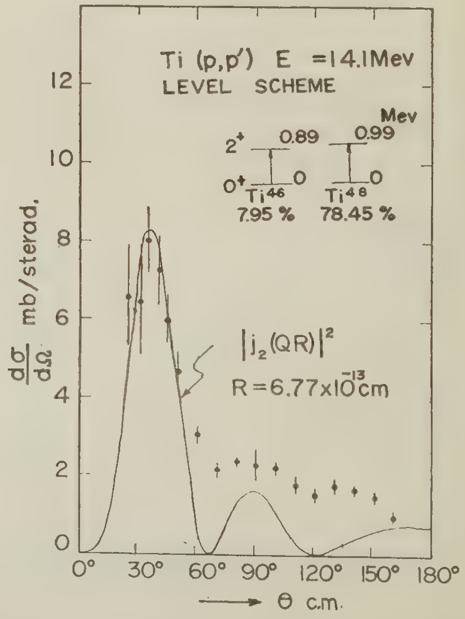

Fig. 11. The angular distribution of protons inelastically scattered from Ti ($Q \sim -1$ Mev) at $E_p = 14.1$ Mev.

completely exclude the possibility of monotonic increase of differential cross section as decreasing angle. But such case is considered to have very small probability to occur throughout these mass range and at this incident energy as can be seen from the figures. In order to obtain more accurate data at forward directions, we must look forward to the magnetic reaction-particle analyser which we are now preparing.

Moreover, we must mention the rather large differences of forward cross section between these nuclei. The peak cross section of cromium is less than half of the that of iron or nickel in spite of rather same elastic cross section at these small angle. We do not want however to deduce, a premature conclusion from this experimental results, but the neutron shell of Cr^{52} may play some part in this point. Backward structures of angular distributions are specific to each element. But, this may not be attributed to the effects of target contamination by light nuclei, because the positions are different from those calculated by kinematics.

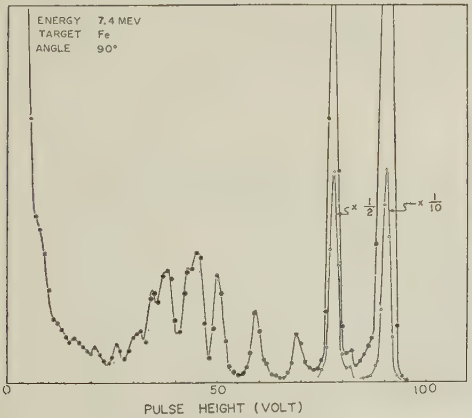

Fig. 12. Pulse-height distribution from scattering from Fe at the laboratory angle of 90° (E_p= 7.4 Mev).

3. *Other results*

We measured the emitted spectra of inelastic protons from iron at E_p=14.1 MeV and 7.4 MeV. The results are shown Figs. 12 and 13. We measured the spectrum of emitted protons at several angles when the incident energy was 14.1 MeV. There were no remarkable differences between the spectra at 60°, 90°, 120° and 150° except at low excitation energy and at γ-ray back-ground. We searched an anomalous inelastic scattering peak suggested by B. L. Cohen.$^{10)}$ We did not find any peak corresponding to the excitation of about 3 MeV region, but at about $Q=-4.5$ MeV we found rather large yield of inelastic scattering throughout all angular range. From the peak shape it seems to correspond to a few single levels. The differential cross section for this

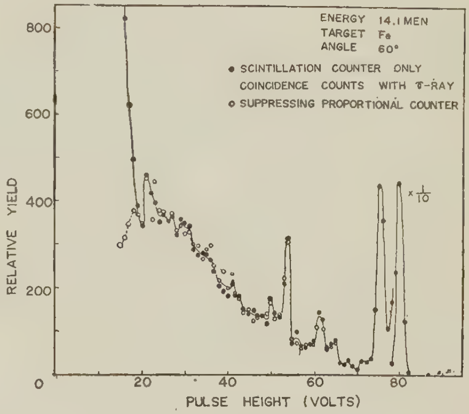

Fig. 13. Pulse-height distribution from scattering from Fe at the laboratory angle 60° (E_p=14.1 Mev).

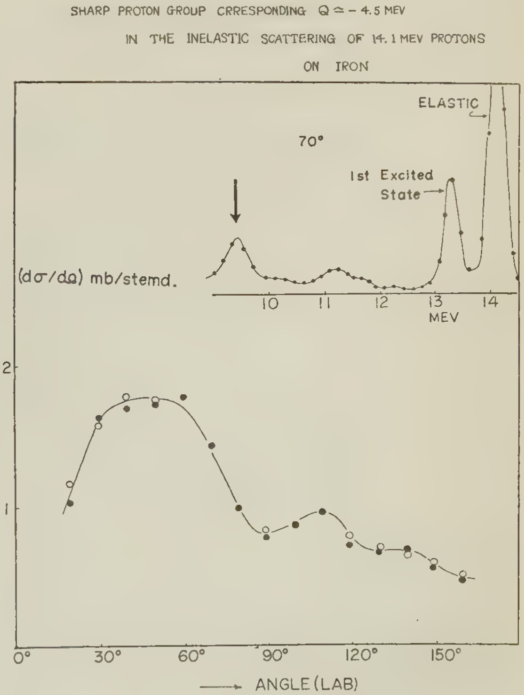

Fig. 14. Sharp proton group corresponding Q≃ −4.5 Mev in the inelastic scattering of 14.1 Mev protons on iron.

peak was measured and is shown in Fig. 14. Its angular distribution shows remarkable forwardness as the semi-classical calculation suggests.[11]

Acknowledgment

This work was performed as one of the test experiments of I.N.S. cyclotron and parts of the work were done by the temporal visiting physicists from other universities; Drs. K. Hisatake (Tokyo Institute of Technology) J. Muto (Kyoto University) I. Kumabe (Kyoto University) N. Ryu (Hiroshima University) and S. Yamabe (Osaka University) and Mrs. K. Takeshita (Kyushu University) Ito (Kyoto University) and Okano (Kyoto University). The authors wish to thank Professors S. Kikuchi and I. Nonaka for their constant encouragements; to Mr. S. Tanaka for advice on Cr foil Preparation.

They are also ought to say thanks to Mrs. T. Karasawa, A. Suzuki and H. Ogawa and other operating crew of the cyclotron.

Journal of the Physical Society of Japan Vol. 12 No. 2, February, 1959

Thermodynamic Foundation of the Theory of Plasma

By Taro Kihara

Department of Physics, Faculty of Science, University of Tokyo

(Received October 30, 1958)

Thermodynamics of irreversible processes is applied to dense plasmas in a weak magnetic field. Basic equations of "magneto-thermo-hydrodynamics" are derived together with relations between transport coefficients. Extremely dilute plasmas and plasmas at the Debye-Hückel limit are discussed as particular cases.

§ 1. Introduction

In a previous article[1] entitled "Macroscopic Foundation of Plasma Dynamics" the author assumed, at the beginning, the Euler equation of motion for each plasma component. In this equation a role was played by the partial pressure whose existence was tacitly supposed. The treatment was also restricted to the case where the plasma temperature was uniform. Under these assumption and restriction the aim of that article was to consolidate, in an elementary way, the foundation for the plasma dynamics.

The present article is a thermodynamic approach to foundation of plasma theory or basis of so to speak magneto-thermo-hydrodynamics;

it will supplement the previous one.

The thermodynamics of irreversible processes, which has been developed since Onsager's reciprocity theorem, will be applied in the following to the phenomenological theory of plasma. Such a treatment does not seem to have existed up till now.

In the present article neither the existence of partial pressures nor the uniformity of the temperature is supposed. But we assume instead the following: (i) the plasma is nearly in thermal equilibrium; (ii) the magnetic field in the plasma is weak. Just as in the preceding article we consider a plasma composed of several species of charged and neutral particles in which neither ionization nor recombination occurs and no temperature difference exists between plasma components. For simplicity we assume this time that the viscosity is negligible.

§ 2. Equation of Motion for Plasma

Let n_j and $\boldsymbol{v}_j$ be, respectively, the number density and the flow velocity of jth component. Then the equation of continuity for the component is

$$\partial n_j/\partial t+\operatorname{div}(n_j\boldsymbol{v}_j)=0\,. \qquad (2.1)$$

Denoting by n_jm_j and n_je_j the mass and the charge densities of the jth component, respectively, we adopt the equation of motion

$$\sum n_jm_j\left(\frac{\partial}{\partial t}+\boldsymbol{v}\cdot\operatorname{grad}\right)\boldsymbol{v}$$
$$=\sum n_j[e_j(\boldsymbol{E}+c^{-1}\boldsymbol{v}_j\times\boldsymbol{B})+m_j\boldsymbol{g}]-\operatorname{grad}P$$

for the plasma as a whole. Here $\boldsymbol{v}$ is the average flow

$$\boldsymbol{v}=\sum n_jm_j\boldsymbol{v}_j/\sum n_jm_j \quad (\sum\equiv\sum_j \text{ throughout})\,,$$

$\boldsymbol{E}$ is the electric field, $\boldsymbol{B}$ is the magnetic flux density, $\boldsymbol{g}$ is the gravitaional acceleration, and P is the pressure. (The Gauss system of units is used, $c=3\times10^{10}$ cm/sec.)

By virtue of the assumptions (i) and (ii) in the preceding section, both $|\boldsymbol{v}_j-\boldsymbol{v}|^2$ and $(\boldsymbol{v}_j-\boldsymbol{v})\times\boldsymbol{B}$ are negligible. Hence the equation of motion can be rewritten in the form

$$\sum n_j\boldsymbol{F}_j-\operatorname{grad}P=0\,, \qquad (2.2)$$

where

$$\boldsymbol{F}_j\equiv e_j(\boldsymbol{E}+c^{-1}\boldsymbol{v}\times\boldsymbol{B})+m_j\left[\boldsymbol{g}-\left(\frac{\partial}{\partial t}+\boldsymbol{v}\cdot\operatorname{grad}\right)\boldsymbol{v}\right], \qquad (2.3)$$

and $\boldsymbol{E}+c^{-1}\boldsymbol{v}\times\boldsymbol{B}$ is the electric field in the coordinate system moving with the velocity $\boldsymbol{v}$.

One of our objectives is to "decompose" (2.2) and derive the equation of motion for each component. For this purpose we first transform, following Prigogine[3)], the term of grad P.

Let us start from two thermodynamic relations for the Gibbs function G for a system composed of N_j particles of jth species at the temperature T and the pressure P:

$$dG=-SdT+VdP+\sum\mu_jdN_j\,,$$
$$G=\sum N_j\mu_j\,.$$

Here V and S are, respectively, the volume and the entropy of the system; μ_j is the chemical potential per particle for jth species. From these two relations follows

$$\sum N_jd\mu_j=-SdT+VdP$$

or, per unit volume ($n_j=N_j/V$),

$$\sum n_j(d\mu_j+s_jdT)=dP\,. \qquad (2.4)$$

Here s_j is the entropy per particle,

$$s_j=-\left(\frac{\partial\mu_j}{\partial T}\right)_{P,\,\text{composition}}, \qquad (2.5)$$

the subscript "composition" indicating the derivative at constant relative concentrations, i.e. at constant $(\sum n_j)^{-1}n_i$'s. Hence,

$$\sum n_j\left[d\mu_j-\left(\frac{\partial\mu_j}{\partial T}\right)_{P,\,\text{composition}}dT\right]=dP\,. \qquad (2.6)$$

When the plasma is nearly in thermal equilibrium, we have therefore

$$\sum n_j(\operatorname{grad}\mu_j)_T=\operatorname{grad}P\,, \qquad (2.7)$$

where, in general,

$$(\operatorname{grad}\psi)_T=\operatorname{grad}\psi-\left(\frac{\partial\psi}{\partial T}\right)_{P,\,\text{composition}}\operatorname{gard}T\,. \qquad (2.8)$$

The equation of motion (2.2) has thus been transformed into

$$\sum n_j[\boldsymbol{F}_j-(\operatorname{grad}\mu_j)_T]=0\,. \qquad (2.9)$$

Its decomposition is equivalent to finding $\boldsymbol{R}_j$ $(\sum\boldsymbol{R}_j=0)$ in

$$n_j[\boldsymbol{F}_j-(\operatorname{grad}\mu_j)_T]+\boldsymbol{R}_j=0\,. \qquad (2.10)$$

§ 3. Entropy Production

The thermodynamics of irreversible processes is based on the Gibbs relation

$$TdS=dU+PdV-\sum\mu_jdN_j$$

for each small region of a system. Here dS, dU, dV and dN_j are, respectively, increments of the entropy, internal energy, volume, and number of particles of jth species in the small region. By use of the local time derivatives of the entropy density, s, and the density of the internal energy, u, the Gibbs relation can be transformed into a simple form

$$T\frac{\partial s}{\partial t}=\frac{\partial u}{\partial t}-\sum\mu_j\frac{\partial n_j}{\partial t}\,.$$

Now, $\partial u/\partial t$ is equal to the inflow of heat plus work done by electromagnetic, gravitational and inertia forces. Hence the time rate of increase of the entropy density s is given by

$$T\frac{\partial s}{\partial t}=-\mathrm{div}\,\boldsymbol{q}^*+\sum n_j\boldsymbol{v}_j\cdot\boldsymbol{F}_j-\sum\mu_j\frac{\partial n_j}{\partial t} \tag{3.1}$$

with the (absolute) heat flow $\boldsymbol{q}^*$, $\boldsymbol{F}_j$ being given by (2.3).

By virtue of (2.1) we get

$$\begin{aligned}&T^{-1}(-\mathrm{div}\,\boldsymbol{q}^*-\sum\mu_j\partial n_j/\partial t)\\&=T^{-1}[-\mathrm{div}\,\boldsymbol{q}^*+\sum\mu_j\,\mathrm{div}\,(n_j\boldsymbol{v}_j)]\\&=-\mathrm{div}\,T^{-1}(\boldsymbol{q}^*-\sum\mu_jn_j\boldsymbol{v}_j)-T^{-1}\boldsymbol{q}^*\cdot\mathrm{grad}\ln T\\&\quad-\sum n_j\boldsymbol{v}_j\cdot\mathrm{grad}\,(\mu_j/T)\,.\end{aligned}$$

Introducing the heat function per particle

$$h_j=\mu_j+Ts_j\,,$$

we have

$$T\,\mathrm{grad}\,(\mu_j/T)=(\mathrm{grad}\,\mu_j)_T-h_j\,\mathrm{grad}\ln T\,.$$

Thus (3.1) is transformed into

$$\frac{\partial s}{\partial t}=-\mathrm{div}\left(\frac{\boldsymbol{q}}{T}+\sum s_jn_j\boldsymbol{v}_j\right)+\left(\frac{\partial s}{\partial t}\right)_{\mathrm{irr}}, \tag{3.2}$$

$$\begin{aligned}T\left(\frac{\partial s}{\partial t}\right)_{\mathrm{irr}}&=-\boldsymbol{q}\cdot\mathrm{grad}\ln T\\&\quad+\sum n_j\boldsymbol{v}_j\cdot[\boldsymbol{F}_j-(\mathrm{grad}\,\mu_j)_T]\,,\end{aligned} \tag{3.3}$$

where

$$\boldsymbol{q}=\boldsymbol{q}^*-\sum h_jn_j\boldsymbol{v}_j$$

is the "reduced heat flow" due to conduction. Since $\boldsymbol{q}/T+\sum s_jn_j\boldsymbol{v}_j$ in (3.2) is the entropy flow, $(\partial s/\partial t)_{\mathrm{irr}}$ indicates the rate of entropy production due to irreversible processes. Eq. (3.3) holds when both factors of each summand are small in absolute values.

§ 4. Linear Relations

(a) *Equations of motion for components*

The linear relation between forces

$$-\mathrm{grad}\ln T\,,\quad n_j[\boldsymbol{F}_j-(\mathrm{grad}\,\mu_j)_T]$$

and fluxes

$$\boldsymbol{q}\,,\quad \boldsymbol{v}_j$$

can be expressed in the "mixed" form

$$\left.\begin{aligned}\boldsymbol{q}&=-K_{00}\,\mathrm{grad}\ln T+\sum_i K_{0i}\boldsymbol{v}_i\,,\\ n_j[\boldsymbol{F}_j-(\mathrm{grad}\,\mu_j)_T]&=-K_{j0}\,\mathrm{grad}\ln T+\sum_i K_{ji}\boldsymbol{v}_i\,.\end{aligned}\right\} \tag{4.1}$$

Here the phenomenological coefficients are scalars independent of forces or fluxes. It is to be noted that the magnetic field is included through $\boldsymbol{F}_j$, although it does not contribute to the work in (3.1) or (3.3). If it had not been included, the phenomenological coefficients would be tensors depending on the magnetic field.

Since the entropy production is always positive, the quadratic form for the coefficients is positive definite, in particular

$$K_{00}>0 \text{ and } K_{jj}>0 \text{ for any } j\,, \tag{4.2}$$

the thermal conductivity $\lambda\equiv K_{00}/T$ being positive. Onsager's reciprocity is, in the present case[4)],

$$K_{0j}=-K_{j0}\,,\quad K_{ji}=K_{ij}\,. \tag{4.3}$$

Taking the equation of motion (2.9) into account we know that

$$\sum K_{0i}=\sum K_{i0}=0\,,\quad \sum_i K_{ji}=\sum_i K_{ij}=0\,. \tag{4.4}$$

The second set of equations (4.1) gives the equation of motion of each component. The term $\boldsymbol{R}_j$ in (2.10) has thus been determined to be

$$\boldsymbol{R}_j=K_{j0}\,\mathrm{grad}\ln T-\sum_i K_{ji}\boldsymbol{v}_i\,,$$

or, by vertue of (4.4),

$$\boldsymbol{R}_j=K_{j0}\,\mathrm{grad}\ln T+\sum_i(-K_{ji})(\boldsymbol{v}_i-\boldsymbol{v}_j)\,. \tag{4.5}$$

This is an inner force composed of thermal diffusion and friction due to relative motion. The symmetry $K_{ji}=K_{ij}$ indicates Newton's law of reaction. For two-component plasmas the coefficient of friction $-K_{12}$ is always positive; but for many-component plasmas it is possible for some friction coefficients to be negative.

(b) *Electric and thermal conductivities*

When

$$\boldsymbol{g}-\left(\frac{\partial}{\partial t}+\boldsymbol{v}\cdot\mathrm{grad}\right)\boldsymbol{v}=0\,,$$

and

$$(\mathrm{grad}\,\mu_j)_T=0 \text{ for all } j\,,$$

(3.3) reduces to

$$T\left(\frac{\partial s}{\partial t}\right)_{\mathrm{irr}}=-\boldsymbol{q}\cdot\mathrm{grad}\ln T+\boldsymbol{J}\cdot\left(\boldsymbol{E}+\frac{\boldsymbol{v}}{c}\times\boldsymbol{B}\right)$$

with the electric current density $\boldsymbol{J}=\sum n_je_j\boldsymbol{v}_j$. The linear relation between forces ($-\mathrm{grad}\ln T$, $\boldsymbol{E}+c^{-1}\boldsymbol{v}\times\boldsymbol{B}$) and fluxes ($\boldsymbol{q}$, $\boldsymbol{J}$) can be expressed in the form

$$\left.\begin{aligned} \boldsymbol{q}&=-T\lambda\,\mathrm{grad}\ln T+\alpha\boldsymbol{J}\,,\\ \boldsymbol{E}+c^{-1}\boldsymbol{v}\times\boldsymbol{B}&=\alpha\,\mathrm{grad}\ln T+\sigma^{-1}\boldsymbol{J}\,.\end{aligned}\right\}\quad(4.6)$$

Here the phenomenological coefficients are scalars; and Onsager's reciprocity has been taken into account. The λ is the thermal conductivity, σ the electric conductivity; they are both positive. (When the plasma is a gas composed of electrons and positive ions, the sign of α is negative.)

In case T is uniform, the second equation of (4.6) reduces to the Ohm's law

$$\boldsymbol{E}+c^{-1}\boldsymbol{v}\times\boldsymbol{B}=\sigma^{-1}\boldsymbol{J}\,,\qquad(4.7)$$

which is one of the basic equations assumed in the *conventional* magnetohydrodynamics[5]. Essential contents of the magnetohydrodynamics, however, do not explicitly depend on the Ohm's law, but rather

$$\mathrm{rot}\,(\boldsymbol{E}+c^{-1}\boldsymbol{v}\times\boldsymbol{B}-\sigma^{-1}\boldsymbol{J})=0\,,\qquad(4.8)$$

which follows from (4.6) under much weaker restriction, namely if

$$\mathrm{rot}\,(\alpha\,\mathrm{grad}\ln T)\equiv\mathrm{grad}\,\alpha\times\mathrm{grad}\ln T=0$$

(cf. the following).

(c) *Induction equation in the magnetohydrodynamics*

When a neutral plasma is composed of electrons and several heavier species and all the heavier species have equal mean velocities (which are therefore close to $\boldsymbol{v}$), then (3.3) reduces to

$$T\left(\frac{\partial s}{\partial t}\right)_{\mathrm{irr}}=-\boldsymbol{q}\cdot\mathrm{grad}\ln T+n_e(\boldsymbol{v}_e-\boldsymbol{v})\cdot[\boldsymbol{F}_e-(\mathrm{grad}\,\mu_e)_T]\,,$$

where the subscript e refers to electrons and (2.9) has been used. The electric current is expressed by $\boldsymbol{J}=-en_e(\boldsymbol{v}_e-\boldsymbol{v})$ in which $-e$ is the electron charge. Neglecting the gravitational and inertia forces for electrons we obtain therefore

$$T\left(\frac{\partial s}{\partial t}\right)_{\mathrm{irr}}=-\boldsymbol{q}\cdot\mathrm{grad}\ln T+\boldsymbol{J}\cdot\left[\boldsymbol{E}+\frac{\boldsymbol{v}}{c}\times\boldsymbol{B}+\frac{1}{e}(\mathrm{grad}\,\mu_e)_T\right].$$

The corresponding linear relation is

$$\left.\begin{aligned}&\boldsymbol{q}=-T\lambda\,\mathrm{grad}\ln T+\alpha\boldsymbol{J}\,,\\ &\boldsymbol{E}+c^{-1}\boldsymbol{v}\times\boldsymbol{B}+e^{-1}(\mathrm{grad}\,\mu_e)_T\\ &\quad=\alpha\,\mathrm{grad}\ln T+\sigma^{-1}\boldsymbol{J}\,.\end{aligned}\right\}\quad(4.9)$$

Since the displacement current is negligible near the thermal equilibrium, the current density $\boldsymbol{J}$ is equal to $(c/4\pi)\,\mathrm{rot}\,\boldsymbol{H}$, $\boldsymbol{H}$ being the magnetic field. Then, the induction equation

$$\frac{\partial\boldsymbol{B}}{\partial t}=-c\,\mathrm{rot}\,\boldsymbol{E}$$

becomes

$$\frac{\partial\boldsymbol{B}}{\partial t}=\mathrm{rot}\,(\boldsymbol{v}\times\boldsymbol{B})-\frac{c^2}{4\pi}\,\mathrm{rot}\,(\sigma^{-1}\,\mathrm{rot}\,\boldsymbol{H})+\boldsymbol{a}\,,\qquad(4.10)$$

in which

$$\begin{aligned}\boldsymbol{a}&=\mathrm{rot}\,[e^{-1}(\mathrm{grad}\,\mu_e)_T-\alpha\,\mathrm{grad}\ln T]\\ &=\mathrm{rot}\,[(e^{-1}Ts_e-\alpha)\,\mathrm{grad}\ln T]\\ &=\mathrm{grad}\,(e^{-1}Ts_e-\alpha)\times\mathrm{grad}\ln T\,.\end{aligned}$$

Here s_e is the entropy per electron defined by (2.5); and (2.8) has been used. When and only when $\boldsymbol{a}$ vanishes, (4.10) takes the usual form of induction equation which plays an essential role in the magnetohydrodynamics. It is important to note that here no use has been made of the too-restrictive Ohm's law (4.7).

(d) *Ordinary and thermal diffusions*

When a neutral two-component plasma is under uniform pressure, and if

$$\frac{\boldsymbol{v}}{c}\times\boldsymbol{B}=0,\quad \boldsymbol{g}-\left(\frac{\partial}{\partial t}+\boldsymbol{v}\cdot\mathrm{grad}\right)\boldsymbol{v}=0\,,$$

then (3.3) reduces to

$$\begin{aligned}T(\partial s/\partial t)_{\mathrm{irr}}&=-\boldsymbol{q}\cdot\mathrm{grad}\ln T+\sum_{j=1,2}n_j\boldsymbol{v}_j\cdot[e_j\boldsymbol{E}-(\mathrm{grad}\,\mu_j)_T]\\ &=-\boldsymbol{q}\cdot\mathrm{grad}\ln T+\boldsymbol{J}\cdot[\boldsymbol{E}-e_1^{-1}(\mathrm{grad}\,\mu_1)_T]\,.\end{aligned}$$

The corresponding linear relation is again

$$\left.\begin{aligned}&\boldsymbol{q}=-T\lambda\,\mathrm{grad}\ln T+\alpha\boldsymbol{J}\,,\\ &\boldsymbol{E}-e_1^{-1}(\mathrm{grad}\,\mu_1)_T=\alpha\,\mathrm{grad}\ln T+\sigma^{-1}\boldsymbol{J}\,.\end{aligned}\right\}\quad(4.11)$$

The term $e_1^{-1}(\mathrm{grad}\,\mu_1)_T$ can be transformed into a symmetric form. From our assumptions

$$n_1e_1+n_2e_2=0\,,$$

$$n_1(\mathrm{grad}\,\mu_1)_T+n_2(\mathrm{grad}\,\mu_2)_T=0\,,$$

(the latter being the Gibbs-Duhem relation), follows

$$e_2(\mathrm{grad}\,\mu_1)_T=e_1(\mathrm{grad}\,\mu_2)_T\,,$$

and we obtain in fact

$$e_1^{-1}(\mathrm{grad}\,\mu_1)_T=(e_1-e_2)^{-1}[(\mathrm{grad}\,\mu_1)_T-(\mathrm{grad}\,\mu_2)_T]\,.$$

For $\boldsymbol{E}=0$, we have the equation of diffusion

$$\begin{aligned}\boldsymbol{v}_1-\boldsymbol{v}_2&=\boldsymbol{J}/n_1e_1\\ &=-\frac{\sigma}{n_1e_1^2+n_2e_2^2}[(\mathrm{grad}\,\mu_1)_T-(\mathrm{grad}\,\mu_2)_T]\\ &\quad-\frac{\alpha\sigma}{n_1e_1}\,\mathrm{grad}\ln T\,.\end{aligned}$$

Introducing the "modified" diffusion coefficient D^* and the thermal diffusion ratio k_T by

$$v_1-v_2=-D^*\left[\frac{1}{kT}\{(\mathrm{grad}\,\mu_1)_T-(\mathrm{grad}\,\mu_2)_T\}+\frac{(n_1+n_2)^2}{n_1n_2}k_T\,\mathrm{grad}\ln T\right], \qquad (4.12)$$

with the Boltzmann constant k, we obtain finally

$$D^*/kT=\sigma/(n_1e_1^2+n_2e_2^2), \qquad (4.13)$$

$$\frac{(n_1+n_2)^2}{n_1n_2}k_T=\frac{n_1e_1^2+n_2e_2^2}{n_1e_1}\frac{\alpha}{kT}. \qquad (4.14)$$

The former is a relation between the electric conductivity and the diffusion coefficient; such a relation is called the Einstein relation in general.

§ 5. Ideal-Gas Plasma

It is sometimes convenient to introduce the fugacity p_j^* which is related to the chemical potential μ_j by

$$\mu_j=\mu_j^+(T)+kT\ln p_j^*,$$

where $\mu_j^+(T)$ is a function of the temperature only. Then, by use of the definition (2.8), we have

$$n_j(\mathrm{grad}\,\mu_j)_T=(n_jkT/p_j^*)(\mathrm{grad}\,p_j^*)_T. \qquad (5.1)$$

For an extremely dilute plasma approximated by an ideal gas, the ratio p_j^*/n_jkT, which is called activity coefficient, is unity, and hence

$$(n_jkT/p_j^*)(\mathrm{grad}\,p_j^*)_T=(\mathrm{grad}\,P_j)_T=\mathrm{grad}\,P_j, \qquad (5.2)$$

where $P_j\equiv n_jkT$ is the partial pressure for jth component ($\sum P_j=P$). The term $\boldsymbol{a}$ in (4.10) is then calculated to be

$$\boldsymbol{a}=\mathrm{grad}\ln T\times\mathrm{grad}\,(e^{-1}kT\ln n_e+\alpha).$$

For ideal-gas plasmas holds a similarity law as stated in the previous article.

The modified diffusion coefficient D^* coincides, in the present case, with the conventional diffusion coefficient D defined by

$$v_1-v_2=-D(n_1^{-1}\,\mathrm{grad}\,n_1-n_2^{-1}\,\mathrm{grad}\,n_2), \qquad (5.3)$$

and (4.13) becomes

$$D/kT=\sigma/(n_1e_1^2+n_2e_2^2). \qquad (5.4)$$

An ideal-gas plasma at uniform temperature can be treated, as in the previous article, without assumptions (i) and (ii) made in § 1. Even the assumption that no temperature difference exists between plasma components can partially be removed. When the relaxation between temperatures of components is sufficiently slow, the partial pressure P_j, which is equal to the fugacity p_j^*, is given by n_jkT_j, T_j being the component temperature. If we define, instead of the diffusion coefficient D in (5.3), the coefficient δ by

$$v_1-v_2=-\delta[(kT_1/n_1)\,\mathrm{grad}\,n_1-(kT_2/n_2)\,\mathrm{grad}\,n_2],$$

then δ is related to the electric conductivity σ as

$$\sigma=(n_1e_1^2+n_2e_2^2)\delta,$$

which, in case $T_1=T_2=T$, reduces to (5.4) since $kT\delta=D$.

§ 6. Debye-Hückel Plasma

When a plasma is not far from an ideal gas, it can be treated in a similar way as in the Debye-Hückel[6)] theory of electrolytic solutions. Under the assumption that the constituent particles have no internal structure, the pressure P and the internal energy u per unit volume are given by the Debye-Hückel limiting law

$$P=kT\left(\sum n_j-\frac{1}{6}\frac{\kappa^3}{4\pi}\right),$$

$$u=kT\left(\frac{3}{2}\sum n_j-\frac{1}{2}\frac{\kappa^3}{4\pi}\right),$$

where κ is Debye characteristic constant defined by

$$\kappa^2=4\pi\sum n_je_j^2/kT. \qquad (6.1)$$

The condition for these relations to hold is that the Debye shielding length κ^{-1} is much larger than the mean distance $(\sum n_j)^{-1/3}$ between constituent particles. The fugacity p_j^* is calculated to be

$$p_j^*=n_jkT-\frac{1}{2}n_je_j^2\kappa, \qquad (6.2)$$

the activity coefficient for the jth component being $1-e_j^2\kappa/2kT$.

Debye-Hückel's elementary but ingenious theory on electrolytic solutions has been confirmed by Kramers[7)], Kirkwood[8)], and Mayer[9)] so far as the Debye-Hückel limiting law is concerned. One might however doubt the validity of the Debye-Hückel theory in the case of gaseous plasmas, because the plasma oscillation with the thermal energy is not explicitly considered. For treatment of thermodynamic properties, however, it is not necessary to separate a particular type of collective modes of motion. It is true, as Pines and Bohm[10)] have shown, that the motion of electrons can be divided, by use of the so-called random phase approximation, into collective motion known as plasma oscillation on one hand and individual particle motion with a type of shielded interparticle potential on the other. This shielding, however, is different from the Debye-Hückel shielding. It is also to be noted that the Debye-Hückel limiting law will not be derived from the random phase approximation, which may hold only for random motion of electrons.

The partial pressure P_j satisfying (5.2) does not exist in general for the Debye-Hückel plasma. In fact

$$\frac{n_j kT}{p_j^*}(\mathrm{grad}\, p_j^*)_T = \mathrm{grad}\,(n_j kT) - \frac{n_j e_j^2}{2T}\,\mathrm{grad}\,(\kappa T) + \frac{1}{3}\frac{n_j}{\sum n_j}\sum n_j e_j^2 \frac{\kappa}{T}\,\mathrm{gard}\, T\,.$$

No similarity law exists in general, too.

Let us finally consider a neutral two-component Debye-Hückel plasma at uniform temperature and pressure in order to find a relation between the modified diffusion coefficient D^* defined by

$$\boldsymbol{v}_1 - \boldsymbol{v}_2 = -(D^*/kT)[(\mathrm{grad}\,\mu_1)_T - (\mathrm{grad}\,\mu_2)_T]\,, \tag{6.3}$$

and the conventional D defined by (5.3). The chemical potential μ_1 is then a function of n_1 only, and

$$\left(\frac{\partial\mu_1}{\partial n_1}\right)_{T,P} = \frac{\partial\mu_1(n_1, n_2)}{\partial n_1} - \frac{\partial\mu_1(n_1, n_2)}{\partial n_2}\frac{\partial P(n_1, n_2)}{\partial n_1}\bigg/\frac{\partial P(n_1, n_2)}{\partial n_2}\,,$$

$\mu_1(n_1, n_2)$, $\mu_2(n_1, n_2)$ and $P(n_1, n_2)$ being the chemical potentials and the pressure, respectively, at that temperature. Since

$$\frac{\partial\mu_1(n_1, n_2)}{\partial n_1} = \frac{kT}{n_1} - \frac{\pi e_1^4}{\kappa kT}\,,$$

$$\frac{\partial\mu_1(n_1, n_2)}{\partial n_2} = -\frac{\pi e_1^2 e_2^2}{\kappa kT}\,, \quad \text{etc.,}$$

we have, neglecting the square of a small quantity,

$$\left(\frac{\partial\mu_1}{\partial n_1}\right)_{T,P} = \frac{1}{n_1}\left[kT - \frac{\pi n_1 e_1^2(e_1^2 - e_2^2)}{\kappa kT}\right]$$

or

$$\left(\frac{\partial\mu_1}{\partial n_1}\right)_{T,P} = \frac{1}{n_1}\left[kT - \frac{\kappa}{4}\,\frac{n_1 e_1^2(e_1^2 - e_2^2)}{n_1 e_1^2 + n_2 e_2^2}\right].$$

Taking $n_1 e_1 \approx -n_2 e_2$ into account we obtain

$$\left(\frac{\partial\mu_1}{\partial n_1}\right)_{T,P} = \frac{1}{n_1}\left[kT - \frac{\kappa}{4}e_1(e_1 + e_2)\right],$$

from which follows, at a constant pressure,

$$(\mathrm{grad}\,\mu_1)_T = [kT - \kappa e_1(e_1 + e_2)/4]n_1^{-1}\,\mathrm{grad}\, n_1\,.$$

Similarly

$$(\mathrm{grad}\,\mu_2)_T = [kT - \kappa e_2(e_1 + e_2)/4]n_2^{-1}\,\mathrm{grad}\, n_2\,.$$

From these expressions we obtain

$$(\mathrm{grad}\,\mu_1)_T - (\mathrm{grad}\,\mu_2)_T = [kT - \kappa(e_1 + e_2)^2/4](n_1^{-1}\,\mathrm{grad}\, n_1 - n_2^{-1}\,\mathrm{grad}\, n_2)\,, \tag{6.4}$$

Hence the relation

$$D = D^*[1 - \kappa(e_1 + e_2)^2/4kT] \tag{6.5}$$

holds between two definitions of the diffusion coefficient. These two coincide for $e_1 = -e_2$ i.e. fully ionized gas composed of electrons and one-valued ions.

In terms of the conventional diffusion coefficient D, (4.13) becomes

$$\frac{D}{\sigma} = \frac{kT - \kappa(e_1 + e_2)^2/4}{n_1 e_1^2 + n_2 e_2^2}\,. \tag{6.6}$$

It is interesting to note that the relation

$$(\mathrm{grad}\,\mu_1)_T - (\mathrm{grad}\,\mu_2)_T = kT(n_2^{-1}\,\mathrm{grad}\, n_1 - n_1^{-1}\,\mathrm{grad}\, n_2)$$

holds for the Debye-Hückel plasma, although the right-hand side does not depend on the Debye constant explicitly.

The author wishes to thank Dr. N. Hashitzume for many helpful comments.

Hall Effect in Oxide Cathodes

By Tadaichi Yabumoto

Institute of Electronic Engineering, Shizuoka University, Hamamatsu, Japan

(Received September 6, 1958)

The measurement of Hall effect in oxide cathodes has been carried out in various methods of preparing samples.

The apparent electron mobility in a temperature range, 700°K∼1200°K, was about $10^3 \sim 10^4$ cm²/v. sec.

These values are very high as compared with that for a single crystal. The effect of porosity upon the mobility seems to exist to some extent, the porosity being changed by means of the different preparations and treatments of the cathodes.

From the viewpoint of pore conduction the mean free path of an electron is about $10^{-5} \sim 10^{-3}$ cm which seems to be of the same order with the size of pores existing in the actual oxide cathodes.

§ 1. Introduction

According to the hypothesis of pore conduction which was originally proposed by Loosjes and Vink the electric current in an oxide cathode at high temperatures is predominantly carried by the electron gas emitted into pores of the cathode.

Theories and experiments based on this model have been reported by several authors[1-4].

From this hypothesis the electron mobility is expected to be remarkably larger than that of an electron through the crystal because the mean free path of an electron will be of the same order of magnitude with the mean size of a pore.

As for the Hall effect in oxide cathodes, there have been several reports discussing both on the basis of semiconductor model and on this model[5-7].

In this paper, the Hall effect and conductivity were measured with samples of various porosity prepared by five methods* and some discussions were made.

§ 2. Experimental Procedure

Samples of different porosities were prepared by the following five methods.

(1) Oxide cathodes were treated with H_2O vapour. Oxide cathodes were heated at about 800°K for one hour in water vapour of about 10^{-2} mm Hg which was excluded by flashing the getter after the treatment and the oxide cathodes were then reactivated[8].

(2) Oxide cathodes were heated under low pressures of the air. After activation was accomplished, the oxide cathodes were exposed in the air and heated in its atmosphere of several mm Hg.

(3) Oxide cathodes were prepared by changing the ratio of BaO and SrO. The degree of sintering seems to vary with the composition of BaO and SrO. It has been known that sintering is most remarkable at 100% BaO. Samples with three kinds of composition were tested at molecular ratio of 50 : 50, 90 : 10, and 100 : 0 of BaO and SrO.

(4) $Ba\cdot Sr(CO_3)_2$ or $BaCO_3$ layers were pressed with high pressures in a mould and heated in vaccuum.

(5) Pressed $Ba\cdot Sr(CO_3)_2$ or $BaCO_3$ layers in in case (4) were heated at about 1200°C in the air.

By these processes we could get the oxide cathodes of different degrees of sintering.

The compositions and treatments of the samples are given in Table I.

The porosity of these samples could not be given quantitatively but appears to be larger in the order W 10–3, H 10–4, H 10–5, H 10–7, P 0–1, N 0–1. In the sample No–1 it was sintered visibly to a high degree.

These samples with the size of 2×1×2 mm were mounted between two platinum sleeves and two platinum probes for Hall voltage measurements were also inserted into these $Ba\cdot Sr(CO_3)_2$ coatings.

The structure of a experimental tube is

---

* These results were reported at the spring and the annual meetings of the Physical Society of Japan in 1953.

Table I. Sample's treatments and compositions

No. of samples	Treatments	Compositions
W 10–3	treated with H_2O vapour	$(Ba \cdot Sr)O_2$
H 10–4	exposed in the air and treated at its atmosphere of several mm Hg	$(Ba \cdot Sr)O_2$
H 10–5	treated with the same method as H 10–4	BaO 90% SrO 10%
H 10–7	normally processed	100% BaO contained 2∼3% $Ba(NO_3)_2$
P 0–1	pressed at high pressures at $BaCO_3$	100% BaO
N 0–1	treated in the air at about 1200°C	100% BaO

shown in Fig. 1.

Platinum sleeves and platinum probes were used to aboid the interface effect in the conductivity and Hall voltage meausements.

$Ba \cdot Sr(CO_3)_2$ was pressed by springs not to make cracks in the coating at the processing of oxide cathodes.

The cathode was heated by tungsten heaters inserted into the platinum sleeves.

High input impedance tube was necessary to measure the Hall voltage because the resistance between probes is above several megohms. For this purpose, tube 954 was used at a low plate voltage and the input voltage was applied to the third grid of that tube. The measuring circuit is shown in Fig. 2.

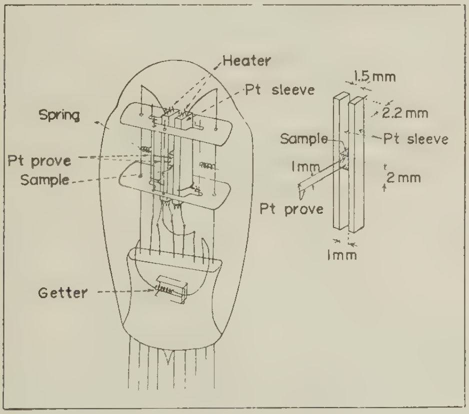

Fig. 1. The structure of experimental tube.

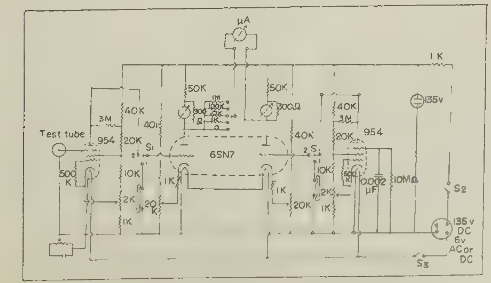

Fig. 2. Measuring circuit for Hall voltage.

In this circuit the input impedance was above 10 megohms. Hall voltage was amplified and measured by balancing method as shown in this figure.

The voltage across a sample was applied within a range where Ohm's law is valid.

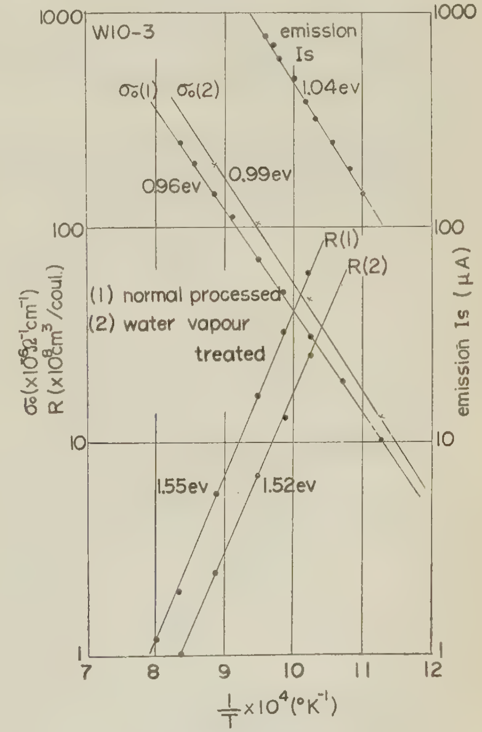

Fig. 3a. Temperature dependency of electrical conductivity σ_0 and Hall coefficient R.

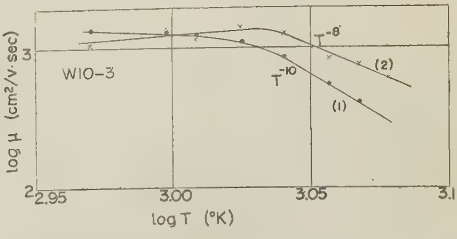

Fig. 3b. Temperature dependency of electron mobility.

The magnetic field up to 400 gauss was supplied by a solenoid and the higher field was by an electromagnet with iron core. Maximum field used was 1500 gauss.

Hall voltage and conductivity were measured in a temperature range of 700°K~1250°K. At the lower temperatures we could not measure the Hall voltage by this instrument because of the high resistance and noise from samples.

§ 3. Experimental Results

1. *Conductivity and Hall coefficient*

Hall coefficient was calculated by the equation

$$V_H = R\left(\frac{H\cdot I}{d}\right),$$

where V_H denotes the Hall voltage, H the applied magnetic field strength, I the electric current and d the thickness of the sample respectively.

The value of the Hall coefficient was obtained from the linear region of V_H/I vs. H curves. In these measurements the sign of Hall coefficient was always negative and mobility was obtained from $\mu = R\sigma_0$, where μ is the apparent mobility and σ_0 is the conductivity without magnetic field.

As an example σ_0, R and μ for W 10-3 were illustrated in Fig. 3. In this figure, (1)

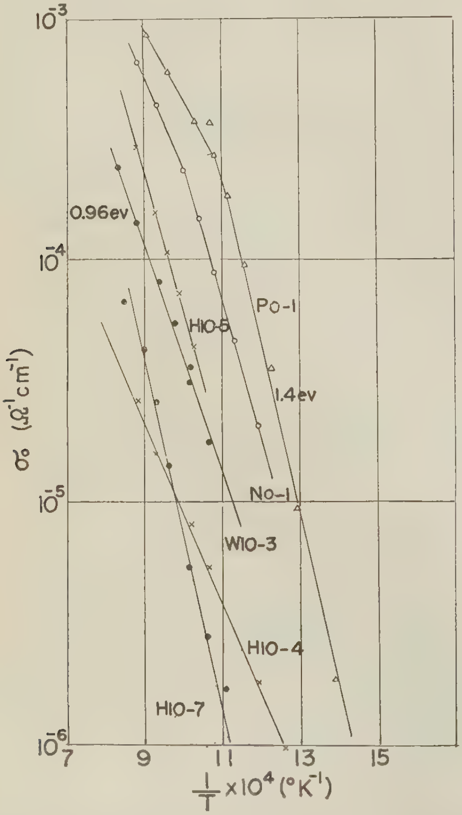

Fig. 4. Temperature dependency of conductivity for various samples.

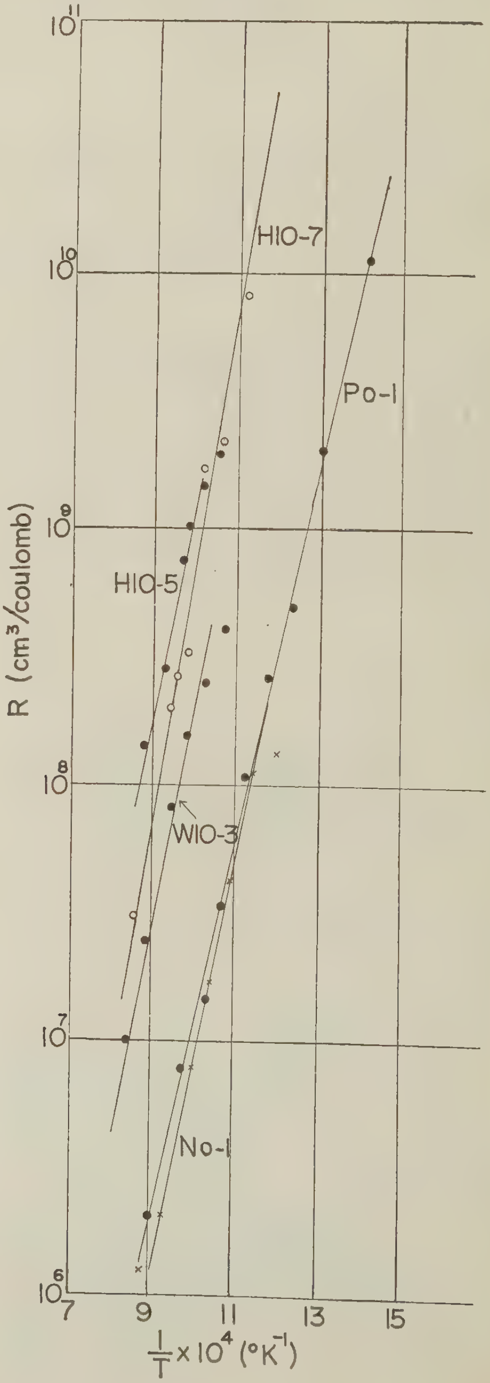

Fig. 5. Temperature dependency of Hall coefficinet for various samples.

is for the oxide cathode prepared by the normal method, (2) is for the one treated with water vapour by above mentioned method after measurement for case (1).

σ_0, R and μ vs. temperature curves for various samples are shown in Fig 4, 5 and 6 respectively.

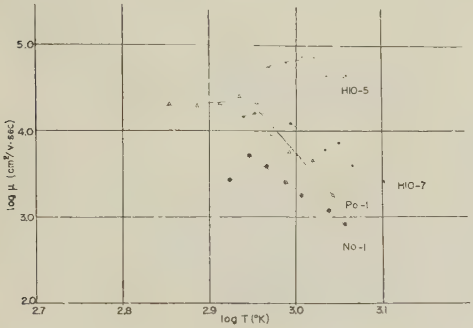

Fig. 6. Temperature dependency of electron mobility for various samples.

The maximum of the Hall coefficient vs. $1/T$ curve as seen by Forman[7)] did not appear as shown in Fig. 5.

The apparent value of μ is $10^3 \sim 10^4$ cm²/V. sec for various samples, which is higher by about three or four decades than that of a single crystal which is $3 \sim 9$ cm²/V. sec[9)].

The value of μ at various temperatures for different samples are given in Table II.

Table II. The apparent value of μ (cm²/V sec for some samples

Temperature (°K)	N 0–1	P 0–1	H 10–7	H 10–5
1123	8.55×10^2	1.77×10^3	4.30×10^3	4.27×10^4
1067	1.07×10^3	4.60×10^3	4.12×10^3	7.02×10^4
972	5.30×10^3	5.48×10^3	$8.8\ \times10^3$	6.13×10^4
932	3.89×10^3	9.12×10^3	6.37×10^3	5.67×10^4
890	5.32×10^3	1.97×10^4	$9.7\ \times10^3$	
824	2.76×10^3	1.83×10^4		

From this table the apparent mobility seems to have some correlations with the method of peparing samples and accordingly to the porosity of samples. For the samples like N 0–1 which is supposed to have a high degree of sintering, the mobility is relatively small. The Hall voltage has linear relations with magnetic field and current, but in some cases, for instance the porous specimen of equimolecular mixture of barium and strontium without treatment, showed an oscillatory behavior as shown in Fig. 7. Its sign is negative at low magnetic field and with increasing field varies alternately from negative to positive and from positive to negative. This fact will be understood on the aspect that electrons in a pore have long mean free paths corresponding to the mean size of pores and make a cyclic motion in the transverse magnetic field.

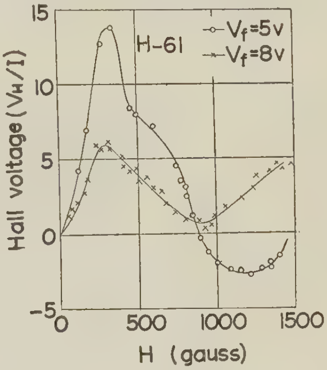

Fig. 7. An extraordinary change of Hall voltage with magnetic field.

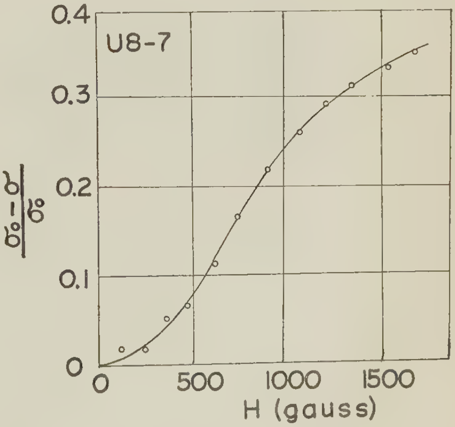

Fig. 8. The curve of magneto-resistive effect.

2. *Magneto-resistive effect*

The change of conductivity with transverse magnetic field is also very large as shown in Fig. 8. This fact has also been observed by other investigators[6–7)].

The relation of $\sqrt{\Delta\sigma/\sigma_0}$ vs. H is shown in Fig. 9 with the heater voltage as a parameter, where $\Delta\sigma=\sigma_H-\sigma_0$, σ_H being the conductivity with magnetic field and σ_0 the conductivity without magnetic field. This effect is more remarkable at high temperatures as shown in the figure.

This phenomenon is also explained by the pore conduction model for which the mean free path of an electron is large compared with that of an electron through the crystal and the temperature effect is explained by an idea that if the temperature was raised, the ratio of the conduction in a pore to the conduction in a bulk crystal will be increased and electrons will be more influenced by magnetic field.

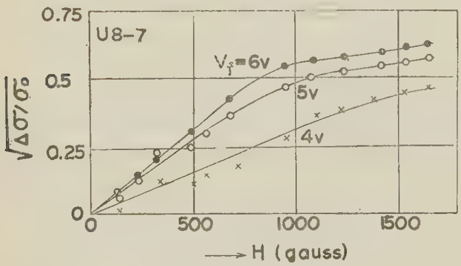

Fig. 9. The curve of $\sqrt{\Delta\sigma/\sigma_0}$ *vs. H.*

§ 4. Discussion

This remarkably large value of apparent mobility in oxide cathods compared with that of a single crystal can be considered reasonably from the pore conduction hypothesis. Instead, such a large mobility cannot be interpreted as the behavior of the electron in bulk of the polycrystalline. The effect of crystal boundary will be expected to lower the value of electron mobility through the crystal.

If we take the oxide grain to be a giant molecule which scatter isotropically the free thermal electrons in the pore, the conductivity, Hall coefficient and mobility are given by,

$$R=(3\pi/8)\cdot(1/ne)\ ,$$

$$\sigma=ne\mu,\ \ \mu=4el/3\sqrt{2\pi mkT}$$

where n is the number of electrons/cm³, and l is the meam free path which is of the order of the mean size of the pore. The number of electrons calculated from the Hall coefficient by this relation at various temperatures are given in Table III.

The number of electrons per cm³ are about $10^{11}\sim10^{12}$ at 1100°K and these values are similar to that of Ishikawa et al.[6]. The calculated values of the mean free path are given in Table IV.

These values of l are $10^{-5}\sim10^{-3}$ cm at 1000°K, varying with samples and estimated to be about the same as the size of a pore existing in the actual oxide cathodes.

In the sample N 0-1 it is especially small corresponding to the high degree of sintering.

Table III. The mean number of electrons per cm³ in the pores for some samples

Temperature (°K)	N 0-1	P 0-1	H 10-7	H 10-5
1125	5.1×10^{12}	3.09×10^{12}	6.24×10^{10}	4.4×10^{10}
1065	3.04×10^{12}	8.29×10^{11}	3.84×10^{10}	2.24×10^{10}
972	3.68×10^{11}	4.33×10^{11}	3.81×10^{9}	4.36×10^{9}

972	1.19×10^{-5}	3.51×10^{-4}	6.31×10^{-5}	3.95×10^{-4}
890	1.62×10^{-5}	1.27×10^{-3}	6.66×10^{-5}	
824	1.64×10^{-5}	1.12×10^{-3}		

§ 5. Conclusion and Acknowledgements

From the measurements of Hall coefficient and conductivity in a temperature range, 700K~1200°K, the apparent electron mobility in an oxide cathode is very large compared with that of a single crystal and the magnetoresistive effect is also large.

The difference of the preparation of samples, accordingly the difference of porosity seems to show some effects on the mobility. These facts can be reasonably explained by the pore conduction hypothesis and make this model more valid.

This work has been carried out at the Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation during his tenature of office.

The author wishes his sincere thanks to Mr. Yukio Kamiya for technical assistance and also his thanks to the members of electron physics of the E. C. L. for the corporation.

Transformation des Reseaux Metalliques sous l'Influence des Elements d'Insertion: Transformation du Nickel sous l'Influence de l'Azote

par Nobuzo TERAO et Aurel BERGHEZAN

European Research Associates, 95, rue Gatti de Gamond,
Uccle-Bruxelles/Belgium

(Received October 8, 1958)

A detailed study has been undertaken on the transformation of nickel lattices under the influence of nitrogen as an "insertion" impurity. For this study, thin polycrystalline and monocrystalline layers of evaporated nickel have been heated in an atmosphere of ammonia. This nitriding process has been followed kinetically by electron diffraction. Using these techniques, it has been shown that the "insertion" of nitrogen atoms takes place in successive steps. First, a considerable expansion of the initial f.c.c. lattice of nickel (from $a=3{,}52$ to $a=3{,}72$ Å) is observed with the formation of Ni_4N. Then, if the nitriding is continued, this f.c.c. lattice of expanded nickel (Ni_4N) is transformed into a hexagonal lattice of Ni_3N.

The exact structure of these nitrides has been determined and a mechanism of the transformation from the expanded cubic nickel lattice (Ni_4N) to the hexagonal nickel lattice (Ni_3N) has been proposed. This mechanism consists, in part, of a series of microslips on the (111) plane and in the $[11\bar{2}]$ direction of nickel atoms, similar to those produced in the martensitic transformation of cobalt, which transforms the stacking order of the {111} planes of the f.c.c. lattice into the stacking order of the {0001} planes of the hexagonal lattice. In addition, the diffusion of nitrogen results in another stacking transformation from the cubic $\{1\bar{1}0\}$ planes into the $\{1\bar{2}10\}$ planes of the hexagonal variety.

§ 1. Introduction

Il a été rapporté dans la littérature que, comme certains autres métaux, le nickel et le chrome, présentent également des transformations allotropiques. Ces nouvelles formes allotropiques sont actuellement de plus en plus considérées comme correspondant à de fausses transformations. C'est pourquoi, notre attention s'est portée sur cette question et c'est le nickel qui sera traité ici.

Normalement ce métal se présente sous la forme cubique à faces centrées, mais certains auteurs ont signalé une variété hexagonale compacte qui n'est plus ferromagnétique[1)~4)]. A l'intérêt théorique de cette transformation, un intérêt pratique a été associé, à savoir des propriétés catalytiques très différentes des deux variétés. Cependant, ces dernières années, la variété hexagonale a été de plus en plus mise en doute et il semble maintenant qu'elle soit en réalité une fausse transformation due à l'insertion dans le réseau du nickel d'atomes de carbone, d'azote et même d'hydrogène5)~12).

Ainsi, Le Clerc et Michel8) et Jacobson et Westgren7) ont montré par rayons X que l'insertion des atomes de carbone dans le réseau du nickel conduit à l'obtention d'une variété hexagonale, qui n'est autre que le carbure: Ni_3C. De son côte Nagakura14) a examiné plus en détail la formation et la décomposition du carbure de nickel et proposé un mécanisme pour cette transformation.

De même, K. H. Jack11) a montré par rayons X que l'insertion des atomes d'azote dans la maille du nickel conduit á une forme hexagonale compacte. Il a trouvé, en outre, quelques réflexions de sur-structure et conclu que la structure de Ni_3N est isomorphe avec celle de ε-Fe_3N et ε-$Fe_3(C, N)$, confirmant ainsi une conclusion antérieure de Sachsze et Juza9) basée sur l'observation d'une seule raie de sur-structure. Plus récemment, J. J. Trillat et ses collaborateurs13),16) ont étudié par diffraction électronique l'action de l'azote sur le nickel en utilisant deux méthodes, á savoir d'une part l'action directe de l'azote et d'autre part l'action d'ions provenant de l'air et produits par un canon à ions. Leurs résultats montrent que les atomes d'azote s'insèrent d'abord dans le réseau cubique à faces centrées du nickel et le dilatent considérablement, puis le transforment en un réseau hexagonal correspondant au nitrure: Ni_3N. En chauffant ce nitrure Ni_3N dans le vide, il redonne le nickel ordinaire de départ.

Dans le but d'apporter une contribution plus importante à ce problème de la transformation du nickel sous l'influence d'atomes d'azote, nous avons essayé dans ce travail de déterminer la structure exacte de la forme hexagonale finale: Ni_3N, celle de la forme intermédiaire dilatée signalée par Trillat et enfin, le mécanisme de cette fausse transformation allotropique sous l'influence d'atomes d'insertion.

§ 2. Méthode Expérimentale

L'action de l'azote sur le nickel a été effectuée en adoptant le procédé utilisé antérieurement par J. J. Trillat et l'un de nous13), par passage de gaz ammoniac séché sur des couches minces de nickel, polycristallines ou monocristallines, chauffées à des temperatures variables (150–300°C). Les couches minces de nickel ont été préparées par vaporisation sous vide sur support de sel gemme et leur épaisseur était d'environ 200–400 Å. La durée de la nitruration était comprise entre une et sept heures. Après refroidissement complet en atmosphère de NH_3, les préparations sont retirées du four et examinées par diffraction électronique par transmission.

§ 3. Résultats

I. Nitruration des couches minces de nickel polycristallin

1°) *Structure de la forme finale de nitruration*: Ni_3N

Comme dans les travaux précédents13),16) il a été trouvé que le nickel cubique se transforme par nitruration en une variété hexagonale qui n'est autre que le nitrure de nickel: Ni_3N. La cinétique de cette transformation a été suivie par de nombreux essais, qui ont montré que le degré de nitruration est assez variable avec les conditions expérimentales.

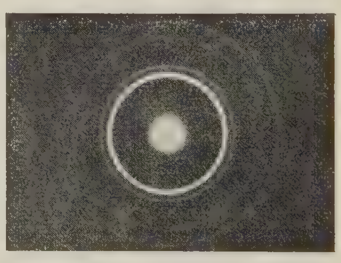

Fig. 1. Diagramme de diffraction électronique du nickel polycristallin.

Avant la nitruration, la couche mince de nickel est formée en général de très petits cristaux donnant des diagrammes de diffraction électronique aux anneaux continus assez élargis. La Fig. 1 montre un exemple de ces diagrammes. Ce nickel, c.f.c. de maille $a=3{,}52$ Å, se dilate fortement par nitruration jusqu'à atteindre la maille $a=3{,}72$ Å. Ensuite, en continuant la nitruration cette forme cubique dilatée se transforme en une variété hexagonale. Simultanément à cette dernière transformation, les anneaux de diffraction électronique deviennent fins et ponctués indiquant un grossissement important des cristaux. Les deux ou trois variétés peuvent coexister, mais, au fur et à mesure que la nitruration se

* Données par R. Bernier (1951)—Réf. (10).

poursuit, les variétés cubiques disparaissent pour ne laisser apparaître en fin de compte que la variété hexagonale comme on peut le voir sur la Fig. 2 reproduisant le diagramme de diffraction du nickel après une heure de nitruration à 230°C. L'interprétation de ce diagramme sera notre premier objectif. Le Tableau I résume les mesures des 32 premiéres raies classées en trois groupes de réflexions. P=raies principales, *s*=raies de sur-structure et *i*=raies interdites. Au delà de ces 32 raies on ne mentionne dans le tableau que les raies principales. Les raies principales, toujours assez fortes, sont attribuées à la structure hexagonale compacte de paramètres:

$$a = 2.66_0 \text{ Å} ; \qquad c = 4.30_4 \text{ Å}$$

$$c/a = 1.618 .$$

Les réflexions "*i*" sont attribuées à la même maille bien qu'elles soient interdites pour la maille hexagonale compacte. Par contre, les raies "*s*" très faibles ne peuvent être attribuées à cette maille, mais à une maille supérieure toujours hexagonale de paramètres:

$$a_s = \sqrt{3}\, a = 4.60_7 \text{ Å} , \qquad c_s = c = 4.30_4 \text{ Å} .$$

Cette maille supérieure semble bien être une maille de sur-structure, dans laquelle les atomes de nickel et d'azote sont arrangés, comme indiqué dans la Fig. 3. Les grands cercles montrent l'arrangement des atomes de nickel qui forment la maille hexagonale compacte et les petits cercles la position des atomes d'azote. Les traits de lignes représentent la maille hexagonale compacte supposée dans certains travaux anterieurs[10),15)]. Cet arrangement en sur-structure des atomes de nickel et d'azote dans la maille du Ni_3N est en accord avec les travaux par rayons X de Jack[11)], mais diffère de la structure proposée par Nagakura[14)] pour le carbure de nickel: Ni_3C.

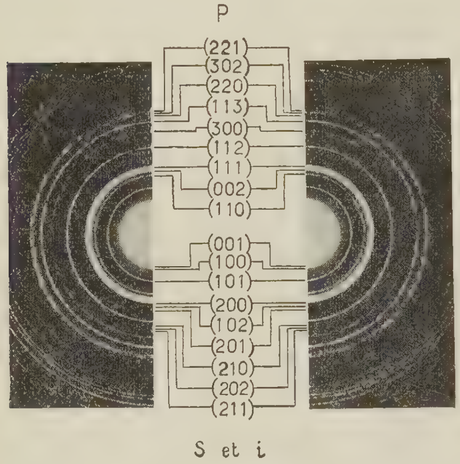

Fig. 2. Diagramme de diffraction électronique du Ni_3N.

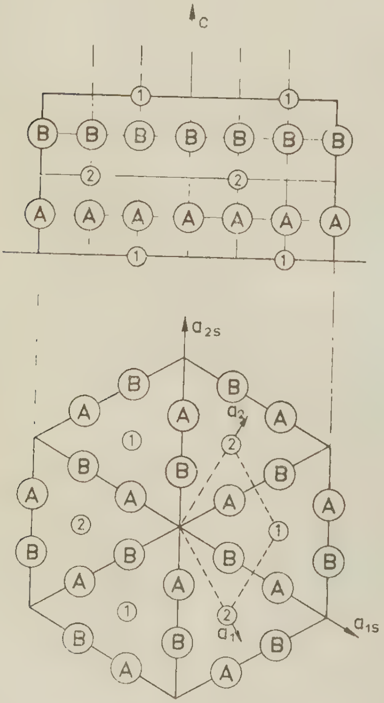

Fig. 3. Structure de Ni_3N.

2°) *Structure de la forme intermédiaire dilatée*

Comme montré précédemment, la transformation du nickel sous l'influence des atomes d'azote a lieu suivant le schéma:

$$Ni_{c.f.c.} \rightarrow Ni_{c.f.c.} \text{ dilaté} \rightarrow Ni_3N$$
(hexagonal compacte).

Les diagrammes de diffraction électronique du nickel dilaté montrent que la forme cubique à faces centrées se conserve, bien qu'on observe, en outre, certains anneaux supplémen-

taires, toujours faibles et très diffus. Les mesures faites sur plusieurs diagrammes et sur des échantillons différents sont résumées dans le Tableau II. On y remarque que la raie de diffraction 3,3 Å est très faible et diffuse. C'est probablement pourquoi elle n'est que rarement visible.

La Fig. 4 montre le diagramme de diffraction du nickel dilaté coexistant avec le nickel ordinaire initial et la Fig. 5 montre le diagramme du nickel dilaté seul. Comme les raies (100), (110), (210), (211)··· sont interdites pour le cristal cubique à faces centrées formé d'une seule sorte d'atomes, nous avons attribué ces réflexions à un réseau de sur-structure, toujours cubique à faces centrées contenant en plus des atomes de nickel un atome d'azote.

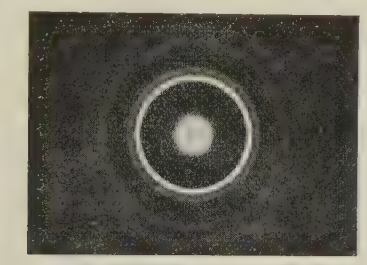

Fig. 4. Diagramme de diffraction électronique de (Ni+Ni dilaté).

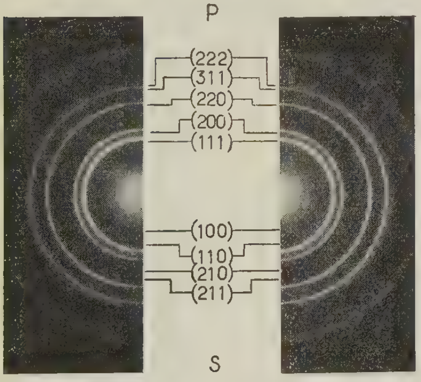

Fig. 5. Diagramme de diffraction électronique du nickel dilaté.

La position la plus probable de cet atome d'azote dans la maille de sur-structure est: (1/2, 1/2, 1/2) car l'autre position probable (1/4, 1/4, 1/4) est exclue par les dimensions respectives des atomes de nickel et d'azote. Cela conduit à admettre l'existence d'une nouvelle forme de nitrure de nickel: Ni_4N dont les positions exactes des deux sortes d'atomes sont:

$$\text{Ni}\begin{cases}(0,\ 0,\ 0);\quad (1/2,\ 1/2,\ 0)\\(0,\ 1/2,\ 1/2);\quad (1/2,\ 0,\ 1/2)\end{cases}$$

$$\text{N}\quad (1/2,\ 1/2,\ 1/2)\,.$$

II. Nitruration des couches minces de nickel monocristallin

Lorsque l'évaporation du nickel se fait sur une face (001) de NaCl chauffé à 400–450°C, la couche mince de nickel est monocristalline à l'exception de quelques macles qui donnent lieu à des taches de diffraction satellites. Les diagrammes de diffraction électronique indiquent que la couche a l'orientation suivante:

$$(001)_{\text{Ni}}//(001)_{\text{NaCl}}$$

$$[100]_{\text{Ni}}//[100]_{\text{NaCl}}$$

La nitruration a été conduite de la même façon que sur le nickel polycristallin. Les couches monocristallines ont l'avantage de mieux montrer certaines réflexions qui sont trop faibles et trop diffuses et de permettre de déterminer la relation d'orientation entre le nickel initial et le nickel nitruré.

Au cours de la nitruration la maille cubique à faces centrées du nickel monocristallin se dilate d'abord comme dans le cas du nickel polycristallin de $a=3.52$ Å à 3,72 Å. Les diagrammes de diffraction électronique sont formés de taches individuelles tout comme le nickel de départ, montrant ainsi que l'orientation monocristalline est conservée. Toutefois, les taches du nickel dilaté sont toujours diffuses. Par contre, dès l'apparition de la forme hexagonale (Ni_3N), on observe sur les diagrammes de diffraction l'apparition d'anneaux fins et ponctués. Cela permet de distinguer facilement les diffractions de la forme cubique (Ni+Ni dilaté) de celles de la forme hexagonale (Ni_3N) surtout lorsque ces formes coexistent dans le même échantillon.

La Fig. 6 montre le diagramme du nickel monocristallin de départ dont la face (001) est perpendiculaire au faisceau d'électrons. Après

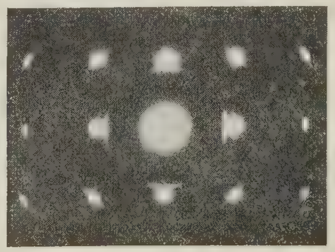

Fig. 6. Diagramme de diffraction électronique du nickel monocristallin.

nitruration d'une heure à 230°C on obtient le diagramme représenté dans la Fig. 7(a) où on observe encore les taches du nickel initial à côté des taches correspondant au nickel dilaté, toujours c.f.c. de maille $a = 3.72$ Å. On remarque en outre sur ce diagramme, qu'il contient en plus des taches normales du cristal c.f.c., des taches de sur-structure (100), (110), (210)··· comme on le voit schématisé sur la Fig. 7(b).

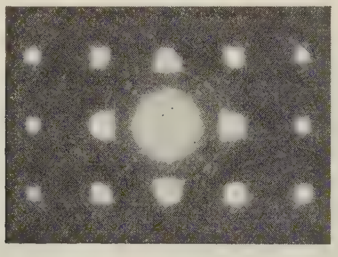

Fig. 7 (a). Diagramme de diffraction électronique de ($Ni+Ni_4N$).

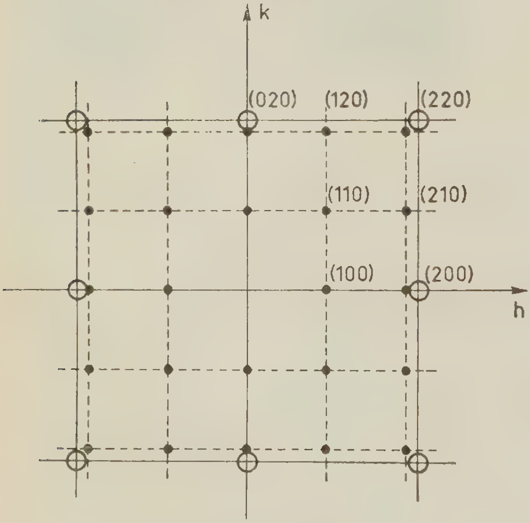

Fig. 7 (b). Schéma correspondant à la fig. 7 (a).
○ Ni
• Ni_4N

La Fig. 8(a) montre le diagramme de diffraction d'une nitruration plus poussée, sur lequel on voit la coexistence des trois formes: nickel initial, nickel dilaté (Ni_4N) et les anneaux du nickel hexagonal (Ni_3N) renforcés sélectivement par endroits à cause de l'orientation privilégiée d'ensemble du nickel initial.

Le Tableau III résume les résultats des mesures faites sur plusieurs diagrammes analogues à celui de la Fig. 8(a) où les trois formes coexistent dans le même échantillon. On a toutefois éliminé de ce tableau les données de la forme hexagonale (Ni_3N) car elles sont exactement les mêmes que celles obtenues par la nitruration du nickel polycristallin et

Tableau III. Mesures faites sur les diagrammes du type Fig. 8(a) (couches monocristallines).

Ni d(Å)	Indice h k l	Ni dilaté		
		Intensité	d_{obs}(Å)	d_{cal}(Å); $a=3.72$Å
	100	F	3.63	3.72
	1½0	M	3.33	3.33
	110	tf	2.64	2.63
1.76	200	F	1.87	1.86
	210	f	1.66	1.66
1.25	220	M	1.31	1.32
0.88	400	M	0.93	0.93
0.79	420	M	0.83	0.84
0.62	440	M	0.65	0.66

rapportées dans le Tableau I. Sur le Tableau III on remarque que la valeur 3,63 Å de la tache (100) est beaucoup plus petite que la valeur 3,72 Å mesurée sur le diagramme de la Fig. 7(a) et sur le nickel polycristallin: cette différence dépasse largement l'erreur expérimentale.

La Fig. 8(b) montre le diagramme schématique de la partie centrale de la Fig. 8(a) où les diffractions de la forme cubique (100), (1, 1/2, 0), (110) et (210) sont nettement visibles. On n'a pas trouvé de traces de diffraction telles que (1/2, 1/2, 0), (1/2, 0, 0) etc.; toutes les raies précédentes ont été dessinées dans la Fig. 8(b). On ne sait pas encore à quoi attribuer ce diagramme, mais nous supposons qu'il correspond à un stade intermédiaire entre le nickel dilaté (Ni_4N) et le nickel hexagonal (Ni_3N). Pour le préciser il nous faudrait plus de mesures sur plusieurs diagrammes pris sur échantillons différents, mais en pratique il est très difficile d'arrêter la nitruration exactement à ce stade assez fugace.

En continuant la nitruration, toutes les taches du nickel ordinaire de départ et du nickel dilaté (Ni_4N) disparaissent et on n'obtient en fin de compte (3 heures à 230°C) que la forme hexagonale. En poursuivant encore la nitruration, il se produit une coalescence de petits cristaux issus de la transformation $Ni_4N \rightarrow Ni_3N$, ayant comme conséquence l'augmentation de leur désorientation relative et la disparition de l'orientation initiale privilégiée.

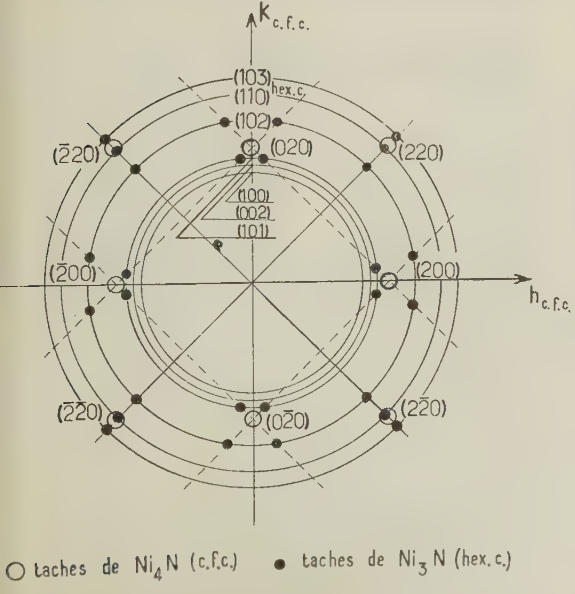

Fig. 9. Relation d'orientation entre Ni_4N et Ni_3N.

Les diagrammes de diffraction électronique des couches monocristallines permettent en outre, de déterminer la relation d'orientation entre le nickel dilaté (Ni_4N) et le Ni_3N. Celle-ci est montrée dans la Fig. 9* et elle peut s'écrire:

$$\left.\begin{array}{l}(111)_{Ni_4N}//(0001)_{Ni_3N}\\ [10\bar{1}]_{Ni_4N}//[2\bar{1}\bar{1}0]_{Ni_3N}\end{array}\right\} Ni_3N\ ;$$

indice d'hexagonal compacte.

III. Mécanisme de la transformation de la forme cubique dilatée (Ni_4N) en la forme hexagonale (Ni_3N)

La relation d'orientation établie au chapitre précédent montre que les rangées les plus compactes d'atomes des deux systèmes cristallins (cubique et hexagonale) sont parallèles. Cette donnée expérimentale est importante car elle indique que le mécanisme de la transformation du nickel dilaté (Ni_4N) cubique en nickel hexagonal (Ni_3N) se fait par des microglissements sur les plans {111}, semblables à

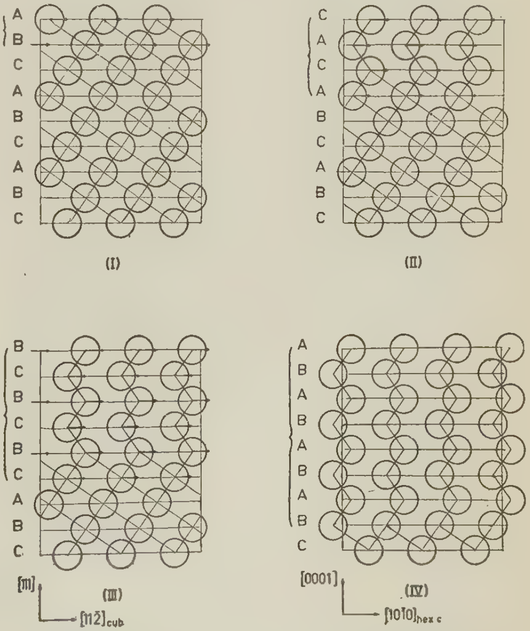

Fig. 10. Transformation du réseau c.f.c en hexagonal par microglissements dans le plan (111) direction [112].

---

* Dans la Fig. 9, on n'a indiqué que les diffractions les plus importantes et les indices des anneaux du Ni_3N ont été donnés d'après la maille hexagonale compacte.

ceux qui provoquent la transformation martensitique du cobalt. C'est-à-dire que chaque glissement est produit par le déplacement d'une dislocation partielle dans la direction $[11\bar{2}]$[17].

Si ce mécanisme ressemble au mécanisme de la transformation martensitique du cobalt, les phénomènes qui le régissent sont différents; alors que dans le cas du cobalt, le glissement est provoqué par les changements de volume dus aux chocs thermiques; dans le cas de la transformation du nickel dilaté (Ni_4N) en (Ni_3N) le glissement semble être provoqué par les tensions internes résultant de la diffusion des atomes d'azote dans le réseau cristallin du nickel. Ces microglissements qui affectent les atomes de nickel ont comme conséquence le changement de l'ordre d'empilement des plans $\{111\}_{\text{cubique}}$, en un empilement des plans $\{0001\}_{\text{hexagonal}}$ (Fig. 10). En plus, la diffusion d'atomes d'azote supplémentaires dans le réseau du Ni_4N (cubique) provoque un autre changement d'empilement: Lesplans $\{1\bar{1}0\}_{\text{cubique}}$ deviennent après la transformation les plans $\{1\bar{2}10\}$ de la variété hexagonale.

Voyons ce mécanisme plus en détail:

Considérons d'abord l'arrangement des atomes dans les mailles, initiale du (Ni_4N) et finale du (Ni_3N). La maille cubique à faces centrées du Ni_4N a en plus de l'ordre d'empilement ABCABC··· des plans $\{111\}$, l'ordre d'empilement $\alpha\beta\alpha\beta'\alpha\beta\alpha\beta'\cdots$ des plans $\{1\bar{1}0\}$ comme on le voit sur la Fig. 11(a). En ne considérant que les atomes de nickel, les plans β et β' sont les mêmes; ils ne se distinguent que par la position des atomes d'azote. D'autre part, la maille du Ni_3N est hexagonale compacte et elle a donc l'ordre d'empilement ABAB··· des plans $\{0001\}$. Cependant, pour bien définir cette maille, il est nécessaire en outre de considérer l'empilement des atomes dans le plan $(1\bar{2}10)$. L'ordre est comme suit: $123, 1'2'3', 123, 1'2'3'\cdots$ et il est indiqué dans la Fig. 11(b) en projection plane. Si on considère dans cet ordre d'empilement la distribution relative des atomes, les planes: 1–1′, 2–2, et 3–3′ sont équivalents; ils se distinguent par la position exacte de chaque atome qui se déplace parallèlement de la distance $(\sqrt{3}/2)a$ $[10\bar{1}0]$ hexagonal compacte.

Le mécanisme de la transformation du Ni_4N (cubique) en Ni_3N (hexagonal) peut être séparé

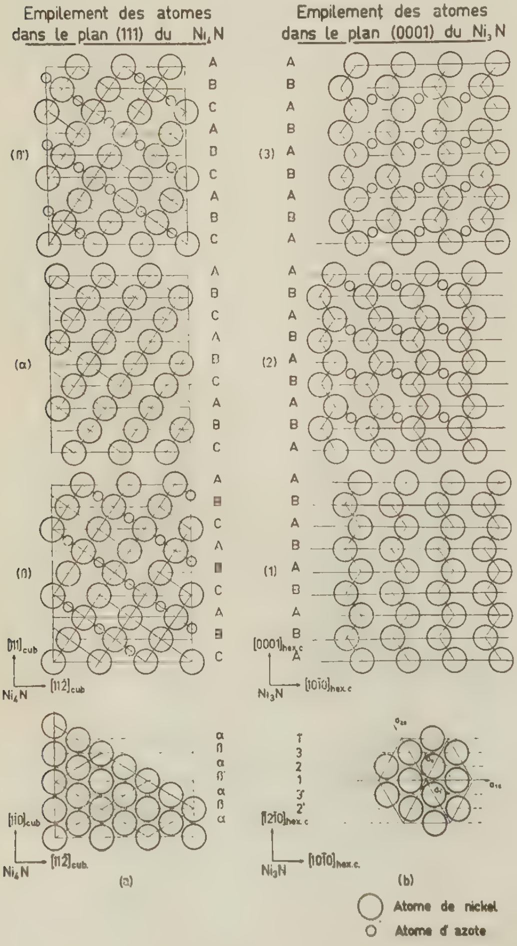

Fig. 11.

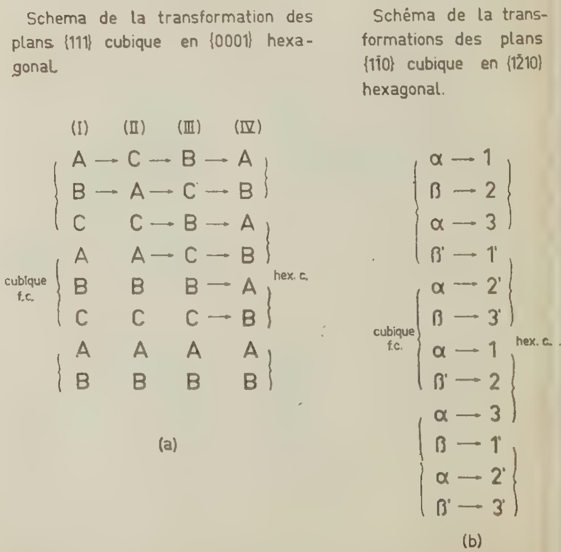

Fig. 12.

en deux transformations élémentaires bien qu'interdépendantes: microglissements dans les plans {111} provoquant la transformation du réseau cubique faces centrées en hexagonal et ceci en 4 mouvements visibles dans le schéma de la Fig. 12(a), et diffusion d'atomes d'azote provoquant le changement dans l'ordre d'empilement des plans $\{1\bar{1}0\}_{\text{cubique}}$ en $\{1\bar{2}10\}_{\text{hexagonal}}$ visible dans le schéma de la Fig. 12(b).

Pour certains détails il est encore nécessaire de considérer les dimensions respectives des atomes de nickel et d'azote dans les réseaux des deux nitrures. On voit alors qu'un des mécanismes probables de la transformation $\alpha \rightarrow 1$ et $\beta \rightarrow 2$ serait comme indiqué respectivement dans les Figs. 10 et 13. En outre, les transfsrmations $\beta \rightarrow 3'$, $\beta' \rightarrow 2$ et $\beta' \rightarrow 3'$ doivent être identiques à la transformation $\beta \rightarrow 2$.

Suivant ces mécanismes "types" indiqués plus haut, les atomes d'azote diffusent seulement dans le plan $(1\bar{1}0)$, mais la diffusion peut se produire dans un plan perpendiculaire et elle est nécessaire pour réaliser les transformations $\alpha \rightarrow 3$, $\beta' \rightarrow 1'$, $\alpha \rightarrow 2'$ et $\beta \rightarrow 1'$. Par exemple, prenons trois plans voisins superposés:

$$\begin{cases} \alpha \longrightarrow 3 \\ \beta' \longrightarrow 1' \\ \alpha \longrightarrow 2' . \end{cases}$$

La transformation $\beta' \rightarrow 1'$ s'effectue si les atomes d'azote du plan β' diffusent vers les deux plans α voisins. Si des atomes d'azote supplémentaires sont fournis de l'extérieur aux plans α, les transformations $\alpha \rightarrow 3$ et $\alpha \rightarrow 2'$ se produisent à leur tour. Un mécanisme pareil à celui-ci est possible dans le cas d'autres plans voisins superposés:

$$\begin{cases} \alpha \longrightarrow 3 \\ \beta \longrightarrow 1' \\ \alpha \longrightarrow 2' . \end{cases}$$

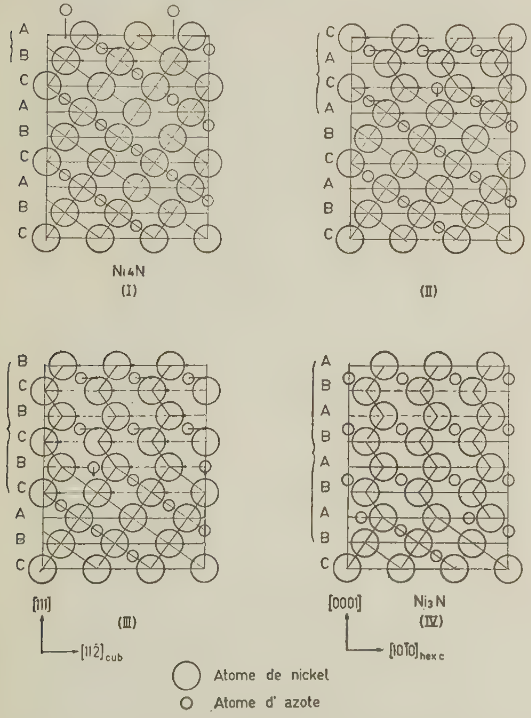

Fig. 13. Mécanisme de transformation du Ni_4N (c.f.c) en Ni_3N (hexagonal) par des microglissements successifs dans le plan (111) et diffusion simultanée d' azote dans le réseau.

Il semble cependant que le mouvement réel de l'atome d'azote est encore plus compliqué et plus irrégulier que le modèle idéalisé décrit plus haut. Ceci est indiqué par le fait que si l'on fait subir la nitruration à un monocristal de nickel, il conserve son orientation monocristalline seulement jusqu'au stade du Ni_4N, mais au fur et à mesure que la nitruration avance vers le Ni_3N, l'orientation monocristalline se détruit au profit d'un agrégat polycristallin. Si le mécanisme idéal que nous avons schématisé était le vrai, le monocristal devrait se conserver jusqu'au stade final du Ni_3N. Comme l'expérience montre l'inverse, cela indique que le mécanisme est plus compliqué encore; surtout la diffusion d'atomes d'azote dans les plans perpendiculaires aux plans $\{1\bar{1}0\}$ doit se faire le long des imperfections de structure à l'échelle atomique. A travers ces voies des imperfections de structure, les atomes d'azote peuvent pénétrer de l'extérieur dans la maille directement dans les plans de type β et β', et non seulement dans les plans de type α comme indiqué dans le schéma.

En conclusion, le processus de nitruration des couches minces de nickel, polycristallines et monocristallines, étudié par diffraction électronique, montre que la diffusion de l'azote dans le nickel conduit, suivant le degré de nitruration, à la formation de différents nitrures. D'abord, l'insertion des atomes d'azote provoque une dilatation considérable de la maille du nickel initial (de $a=3.52$ Å à 3.72 Å) par la formation du Ni_4N. Ensuite, si la nitruration est poursuivie, cette maille c.f.c.

dilatée se transforme en une maille hexagonale compacte correspondant au Ni_3N. Les structures exactes de ces nitrures ont été déterminées et un mécanisme détaillé de la transformation de la forme cubique dilatée (Ni_4N) en la forme hexagonale (Ni_3N) a été proposé.

Ce mécanisme comprend d'une part, le changement de l'ordre d'empilement des plans $\{111\}_{\text{cubique}}$ en un empilement des planes $\{0001\}_{\text{hexagonal}}$: ce changement se produit par des microglissements sur les plans $\{111\}$ qui affectent seulement les atomes de nickel. D'autre part, la diffusion d'atomes d'azote dans le réseau du Ni_4N (cubique) provoquent un autre changement d'empilement: les $\{1\bar{1}0\}_{\text{cubique}}$ deviennent après la transformation les plans $\{1\bar{2}10\}$ de la variété hexagonale. Il est très difficile de savoir lequel de ces deux changements se produit le premier, la diffusion d'atomes d'azote provoquant le glissement qui affecte les atomes de nickel ou le glissement des atomes de nickel qui permet ensuite la diffusion de l'azote, car expérimentalement les deux apparaissent simultanement.

Ce mécanisme un peu idéalisé ne correspond pas tout à fait au mécanisme réel plus compliqué. De ce fait on doit admettre que la diffusion à l'intérieur d'un cristal des atomes de petits diamètres, comme celui d'azote qui est un atome essentiellement d'insertion, ne se fait pas exclusivement par des voies de cheminement interstitielles.

Remerciements

Ce travail fait partie d'un projet plus ample supporté matériellement par l'Union Carbide Corporation, New York et il nous est très agréable de la remercier ici et de lui exprimer notre reconnaissance pour ce soutien. Nous sommes également reconnaissants au Dr. R. H. Gillette pour son encouragement constant et l'intérêt qu'il a mis dans ce travail.

Stress-Ordering Effect on Thermal Expansion of CuAu Single Crystals

By Makoto HIRABAYASHI

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai

(Received October 14, 1958)

Linear thermal expansion of CuAu single crystals was measured. When a bar-formed specimen was slowly cooled from above the transition temperature under compressive stress along its longitudinal direction, it was confirmed that the *c*-axes of the ordered phase were predominantly lined up in one of the cubic axes nearest to the stress direction. Furthermore a linear relationship was established to hold between the compressive stress previously applied and the amount of the dilatometric change due to the order-disorder transition. However, even when some of the crystals were initially annealed free from external stress, the tetragonal *c*-axes were not distributed statistically along the three original cubic axes.

§ 1. Introduction

As well known, the copper-gold alloy with the equi-atomic composition forms a face-centered tetragonal ordered phase CuAu I below 380°C, whereas above this temperature an orthorhombic ordered phase CuAu II is formed up to 410°C[1]. The lattice constants of CuAu I and CuAu II are considerably different from those of the disordered cubic phase existing stably above 410°C, as given in Table I. Namely, compared with the disordered cell, the *a*-direction of CuAu I expands by about 2.3%, while the *c*-direction contracts by about 5.3%. Therefore, if the ordering treatment for single crystal is performed under compressive stress along one of the cubic axes, the tetragonal *c*-axis of the ordered phase may preferentially be lined up in this direction. In order to confirm this expectation, we measured linear thermal expansion of single crystals of CuAu, and found the stress-ordering effect on the dilatometric change.

Table I. Lattice constants of CuAu in kX unit[1].

	Ordered phase		Disordered phase
	CuAu I	CuAu II*	
a	3.952	3.954	3.865
b	—	39.66	—
c	3.662	3.652	—

* CuAu II is thought of as formed from CuAu I by step shifts which occur at every fifth unit cell along its *b*-direction.

§ 2. Experimental

Three single crystals were grown by the Tammann-Bridgman method in vacuum. They had rod shape of 15~30 mm in length and 2~4 mm in diameter. Chemical analysis of the alloy showed the composition to be 49.8 atomic per cent gold. Crystallographical directions of the rods, along which linear expansion was measured, were determined by

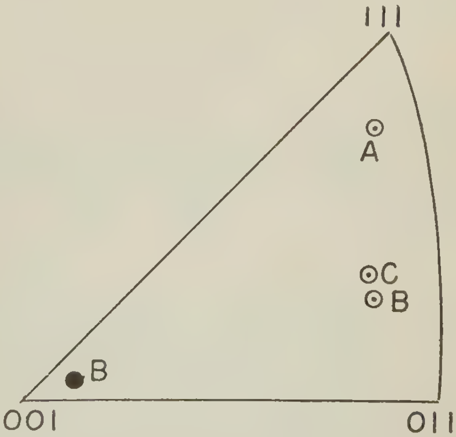

Fig. 1. Stereographic representation of the crystallographical directions of three single crystals of CuAu. Open circles correspond to the longitudinal directions. The closed circle represents the lateral direction of crystal B, along which thermal expansion was measured.

X-ray back reflection Laue method in the disordered state. The result is shown in Fig. 1. Thermal expansion was measured by a simple vertical dilatometer, which had also been used in the study of the polycrystalline specimens of CuAu[2].

Figs. 2 and 3 show thermal expansion curves in the longitudinal direction of the crystal A. Rates of heating and cooling are about 2 deg/min. Before the measurements for each curve in Fig. 2, the crystal was heat-treated as follows: for curve *a* the crystal was annealed for 8 hr at about 350°C, for 5 hr at about 300°C and then slowly cooled to room temperature, and for curve *c* it was quenched from 500°C into water. Curve *b* shows a cooling run from 500°C. These treatments were carried out without any external stress. It should be noted in this figure that the transition from order to disorder accompanies the linear contraction of about 1.4%.

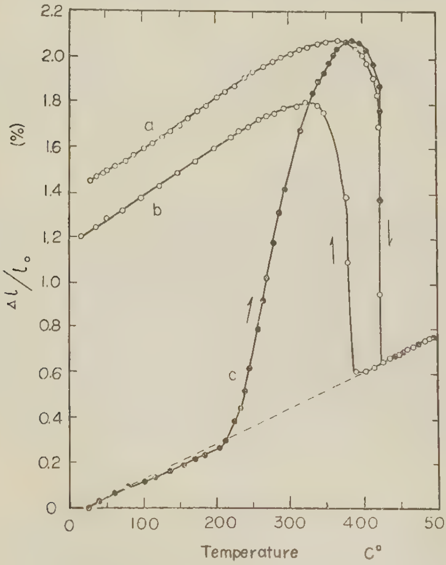

Fig. 2. Thermal linear expansion along the longitudinal direction of the crystal A. Curves *a* and *c* correspond to heating of ordered and disordered states, respectively. Curve *b* is a cooling one.

On the other hand, when the same initial ordering treatment as described above was carried out under compression along the longitudinal direction of this crystal, the disordering by reheating accompanied the expansion instead of the contraction along this direction, as shown in Fig. 3. This figure shows that the expansion increases with the compressive stress, and, hence, that the *c*-axis of the ordered phase tends to be parallel with the cubic axis, which is nearest to the stress direction. Similar behaviour was also observed on dilatometric measurements of the longitudinal direction of the crystal B. Thus, the expectation described before was confirmed.

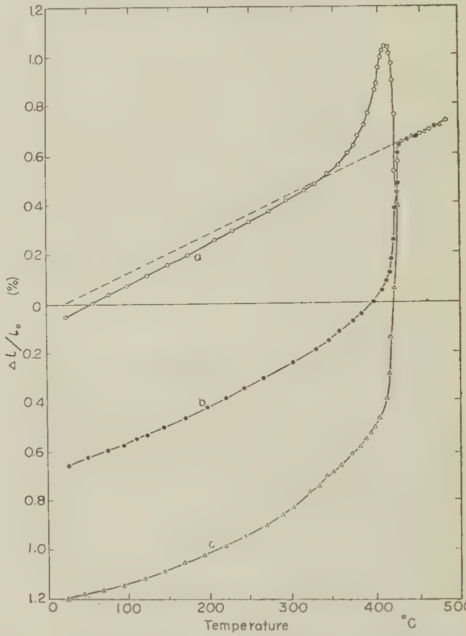

Fig. 3. Thermal linear expansion curves of the crystal A on reheating from the states cooled slowly under compression. Curves *a*, *b* and *c* correspond to the compressive stresses 273, 417 and 522 gr/mm², respectively.

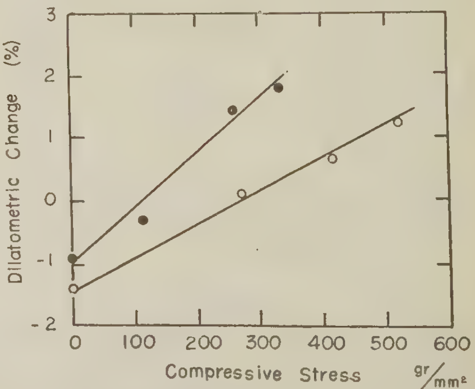

Fig. 4. Longitudinal dilatometric changes due to disordering as a function of compressive stress applied previously. Open and closed circles correspond to the crystals A and B, respectively. Positive sign of the ordinate means expansion on dis-ordering.

Moreover, the linear relationship was found to hold between the change in thermal expansion due to disordering by reheating and the compressive stress applied during the previous ordering process. Fig. 4 gives the results for the crystals A and B.

The linear thermal expansion coefficient shows clearly two-step changes at about 400° and 420°C corresponding to the transitions from CuAu I to CuAu II and from CuAu II to disorder, respectively. Fig. 5 gives some examples for the crystal A. These curves show similar temperature dependence to the expansion coefficient curves of the polycrystalline specimens[2].

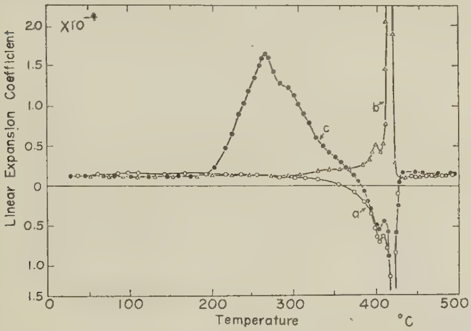

Fig. 5. Linear expansion coefficient in the longitudinal direction of the crystal A. Curves *a* and *c* correspond to curves *a* and *c* in Fig. 2 respectively, and curve *b* corresponds to curve *b* in Fig. 3.

§ 3. Discussion

It must be remarked that even when the crystals A and B are initially annealed without external stress, the tetragonal *c*-axes are not distributed statistically along the three original cubic axes. Because, if the *c*-axes were equally distributed along the three cubic axes, these specimens would have to expand on disordering by reheating along the directions measured. However, the contraction actually took place as seen in Fig. 2, so the tetragonal *c*-axes of the ordered crystal A should mostly be located along a cubic axis near the lateral direction. Also this was confirmed in the case of the crystal B as follows. As shown in Fig. 6, the crystal expands along the longitudinal direction, while it contracts along the lateral direction on ordering under no external stress. The latter direction is located closely to the cubic axis as given in Fig. 1. Therefore it can be concluded that, for the crystal B as well as the crystal A, the tetragonal *c*-axes line up predominantly along the original cubic axis nearly perpendicular to the grown axis. However, such circumstances do not generally hold for all crystals prepared. In fact, the crystal C annealed under no external stress expands along the longitudinal direction, which is located near that of the crystal B as given in Fig. 1, by about 0.86% on the transition from order to disorder, just as expected from the statistical distribution of the tetragonal axis.

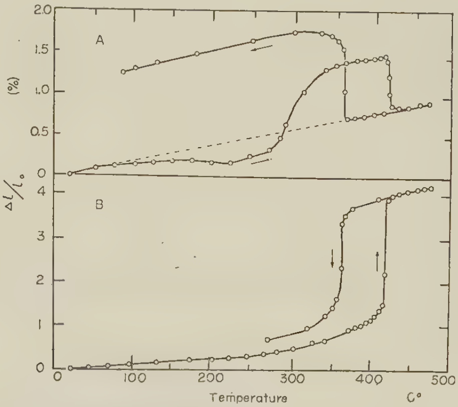

Fig. 6. Thermal expansion curves of the crystal B on heating and cooling at the rate of about 2 deg/min. Upper curves (A) correspond to the measurement along the longitudinal direction of the crystal initially disordered. Lower curves (B) correspond to the lateral direction of the ordered crystal.

In the early stage of ordering in the CuAu crystal, it is reasonably expected that the ordered nuclei have their axes nearly, not precisely, parallel to those of the disordered phase, because they form coherently on {110} planes of the disordered structure[3]. The later stage of ordering is accompanied by the formation of twins with the {110} habit planes[4]. Such a twin formation can easily be understood on the basis of the minimum strain energy, but it makes difficult to interpret quantitatively the present results. If it is simply assumed, however, that the tetragonal *c*-axis directs parallel with the three original cubic axes, the fraction of *c*-axis distributed along each of them may be estimated from the measurements of dilatometric changes along two different directions of the crystal. From Fig. 6 for the crystal B, it was roughly estimated that the fraction of the ordered region, whose c-axis was assumed to direct along the cubic axis closest to the longitudinal direction, was only about two per cent of the total volume. The reason for such highly unequal distribution of the c-axis* is not yet clear, but the twin formation and such an internal stress as induced in the process of crystal growth from the melt may play an important role. This is probably supported by the present result that the external stress applied during the superlattice formation forces to change the c-axis distribution in the ordered crystal.

The author wishes to express his sincere thanks to Professor S. Ogawa for his kind advices and discussions. This work was supported in part by the fund of the Ministry of Education in Aid of Scientific Researches.

Selenium Rectifiers with Artificial Layers of Selenides of Cadmium, Tin, Bismuth and Lead*

By Yoshiro MORIGUCHI

Nippon Electric Co., Ltd., Kawasaki-shi, Japan

(Received October 30, 1958)

Artificial layers of selenides of Cd, Sn, Bi and Pb are made between the bulk Se and the counter electrode of selenium rectifiers with the method of vacuum evaporation. The d.c. and a.c. characteristics of these rectifiers are observed in order to get some informations about the actions of the barrier layer in usual selenium rectifiers. The results suggest that the roles of SnSe layer should never be neglected in the rectifying action in selenium rectifiers as well as those of CdSe layer, and the selenides of Bi and Pb seem to be undesirable materials.

§ 1. Introduction

In selenium rectifiers, it has been well known that the selenides of the counter-electrode metals exist between the bulk selenium layer and the counter electrode¹⁾, and that among the selenides, CdSe layer, which has the largest resistivity, should play the most important role as the barrier material in selenium rectifiers²⁾. The direct experimental substantiations for the role of CdSe in the rectifying action are, however, not so many at present, and it seems to be desirable to investigate directly the roles of the selenides of cadmium as well as the other counter-electrode metals in selenium rectifiers.

In the present experiment, the selenides of some kinds of metals were prepared by the method of vacuum fusion, and they were evaporated in vacuum to make thin layers between the bulk selenium and the counter electrode. The d.c. and a.c. characteristics of these rectifiers were observed and some informations about the rectifying characteristics of the selenide layers were obtained.

§ 2. Experimental Results

The selenides used in the present experiment were made by heating the stoichiometric amounts of selenium and each metal in an evacuated silica tube. Their bulk properties are listed in Table I. These selenides were evaporated on the surface of selenium of a commercial selenium rectifier (40×40 mm) which had no counter electrode, and then upon the surface of the selenide, counter electrodes of 1 cm² area were sprayed or evaporated as shown in Fig. 1. As counter electrodes, sprayed ternary alloy of Cd, Sn and Bi (melting point 140°C) was mainly used, and the evaporated pure metals were sometimes used. The thickness of the evaporated selenide was estimated from the weight of selenide evaporated on a glass plate which was placed close to the sample during the evaporation, assuming the density of the film as that of the bulk material which is given in Table I, but there may be errors of about 10% in thickness according to the inaccuracy of both weighing and the value of density.

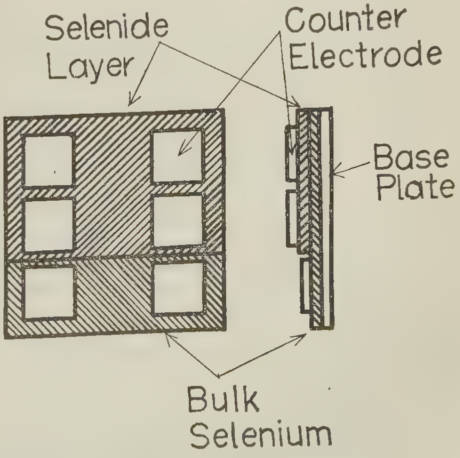

Fig. 1. The construction of the samples.

On the selenium rectifiers prepared in the above-mentioned manner, the d.c. and a.c. measurements were carried out mainly at room temperature, and for a few samples at liquid air temperature. The a.c. characteristics for frequency 1000 c/sec were measured by a substitution method using a usual a.c. bridge, and the impedance of rectifiers were analyzed assuming a parallel circuit of resistance and capacitance. The typical examples of d.c. and a.c. characteristics obtained in the experiment are shown in Figs. 2∼9.

(1) *Rectifiers with CdSe layer*

Some examples of the d.c. characteristics of the rectifiers which have the CdSe layers of different thickness are shown in Fig. 2. As shown in the figure, the resistance of the rectifiers in the forward direction, the threshold voltage which is given by the forward characteristics, and the reverse breakdown voltage seem to increase with increasing thickness of CdSe layer. The threshold voltage V_D and the bulk resistance R_S obtained from the linear part in the forward characteristics are listed in Table II which includes the resistivity of CdSe calculated from the values of R_S and the thickness of the CdSe layer d using the following equation:

$$\rho=\frac{S}{d}(R_S-R_{Se}), \tag{1}$$

where S is the area of the counter electrode, and R_{Se} the resistance of the bulk Se layer. It is difficult to estimate the value of R_{Se} correctly; here the value of the bulk resistance in the forward direction of a rectifier, which was made on a part of the same rectifier disk without any artificial layer and had not been electrically formed at all, were used as the value of R_{Se}. The value obtained here was about 20 Ω/cm². (The bulk resistance was determined below the current density of 3 mA/cm² in this experiment. The value of the bulk resistance of usual selenium rectifiers which is determined for the higher current density is far smaller than the value obtained here, but the value of the resistance obtained at the higher current density seems to be uncorrect on account of the temperature rise in the barrier.)

The characteristics of the sample (3-3) at liquid air temperature is also shown in Fig. 2. As seen in the figure and in Table VII, the values of V_D and R_S increase extremely at low temperature, but the peak back voltage scarcely changes.

The a.c. characteristics obtained for the same samples are shown in Fig. 6. It is obvious from the figure that as the thickness of CdSe layer increases, the barrier capacitance becomes smaller and the bias voltage dependency of the capacitance also decrease; the behaviours seem to be in favour of the Mott barrier. It is also shown in the figure that the capacitance and its bias voltage dependency at low temperature are far smaller than at room temperature. In addition it is seen that in some samples which have the comparatively large impedance in the forward direction, the capacitance decreases as the forward bias voltage increases, as has already been reported by Strosche[3]. It was not able to confirm whether the effect might be observed for all samples, because the exact measurement of the capacitance in the forward direction was difficult on account of the low resistance, especially in low impedance samples. The effect was already observed for usual selenium rectifiers, too[4].

(2) *Rectifiers with SnSe layer*

The d.c. characteristics of a few selenium rectifiers which have SnSe layers of different thickness are shown in Fig. 3. The threshold voltage V_D and the spreading resistance R_S are far smaller in these rectifiers than in the rectifiers with CdSe layers at room temperature, and consequently, these rectifiers have a fairly good rectifying property, although the current in the reverse direction is not so small. The threshold voltage V_D and the spreading resistance R_S at room temperature for all samples are listed in Table III. This table shows that the values of V_D and R_S are scarcely dependent upon the thickness of SnSe layer, and the values of R_S are nearly equal to the resistance of the bulk selenium layer itself, suggesting that the resistance of SnSe layer is negligibly small. It is shown in Fig. 3 and in Table VII, however, that at low temperature the values of both V_D and R_S become remarkably large.

The capacitance-bias voltage relations for the same samples are shown in Fig. 7, denoting that at room temperature, both the capacitance and its bias voltage dependency are not only nearly independent of the thickness of

SnSe layer, but also far larger than in the case of CdSe layer. At low temperature, however, the capacitance as well as its bias voltage dependency becomes so small that the features resemble those for CdSe layer. In addition, the decrease of the capacitance in the forward direction appears at low temperature, although the effect could not be observed at room temperature on account of the very low impedance.

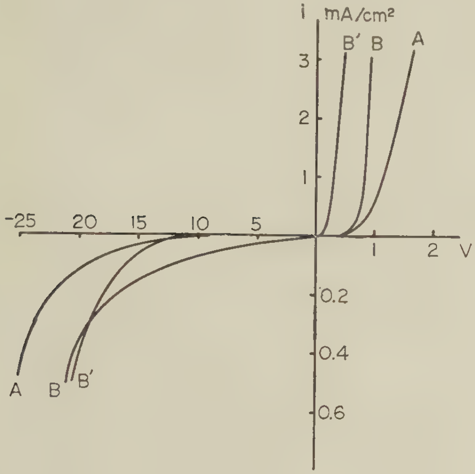

Fig. 2. The d.c. characteristics of typical Se rectifiers with CdSe layer. Curves A and B are for the samples 3–1 and 3–3, respectively, at room temperature, and curve B′ is for the sample 3–3 at liquid air temperature. The abscissa for curve B′ in the forward direction should be read ×10 (Thicknesses of CdSe=0.73μ and 0.50μ for samples 3–1 and 3–3, respectively.)

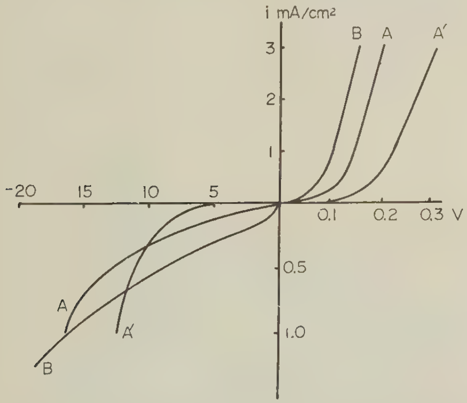

Fig. 3. The d.c. characteristics of the typical Se rectifiers with SnSe layer. Curves A and B are for the samples 10–6 and 14–3, respectively, at room temperature, and curve A′ is for the sample 10–6 at liquid air temperature. The abscissa for the curve A′ in the forward direction should be read ×10. (Thicknesses of SnSe=0.8μ and 1.2μ for samples 10–6 and 14–3, respectively.)

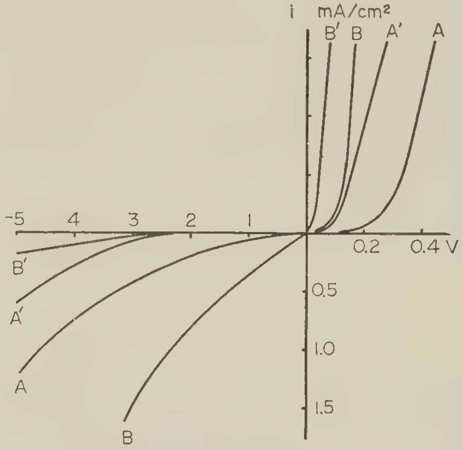

Fig. 4. The d.c. characteristics of the typical Se rectifiers with Bi_2Se_3 and BiSe layers. Curves A and A′ are for the sample 13–5 (Bi_2Se_3) at room temperature and at liquid air temperature respectively, and curves B and B′ for the sample 5–1 (BiSe) at room and liquid air temperatures, respectively. The abscissa for the curves A′ and B′ in the forward direction should be read ×10. (Thicknesses of the selenides=0.45μ and 0.50μ for samples 13–5 and 5–1, respectively.)

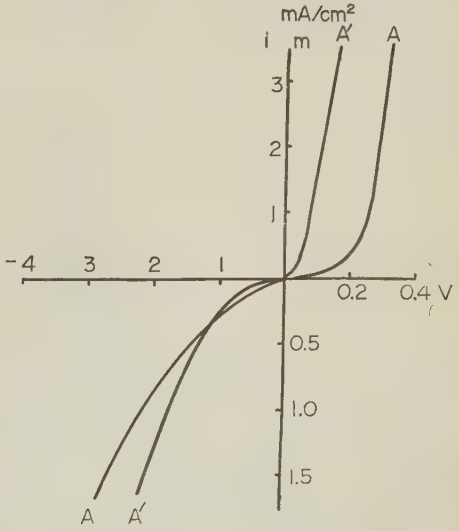

Fig. 5. The d.c. characteristics of the typical Se rectifier with PbSe layer. Curves A and A′ are for the sample 13–1 at room and liquid air temperatures, respectively. The abscissa for the curve A′ in the forward direction should be read ×10. (Thickness of PbSe=1.4μ.)

The selenide of tin, SnSe is also known to exist, but the effects of this material could not be measured, because it decomposed when evaporated in vacuum.

(3) *Rectifiers with Bi_2Se_3 and BiSe layers*

Both Bi_2Se_3 and BiSe are known as the selenides of bismuth. The crystal structures of these two selenides are very similar to each other, and it seems to be difficult to know which is really existing in usual selenium rectifiers.

The d.c. characteristics of some rectifiers with both Bi_2Se_3 and BiSe layers are shown in Fig. 4. As seen in the figure, both threshold voltage V_D and spreading resistance R_S in this case are smaller than in the case of CdSe, but larger than in the case of SnSe, and the breakdown voltage in this case is far smaller than in the cases of both CdSe and SnSe. In this case also, both V_D and R_S increase with decreasing temperature as seen

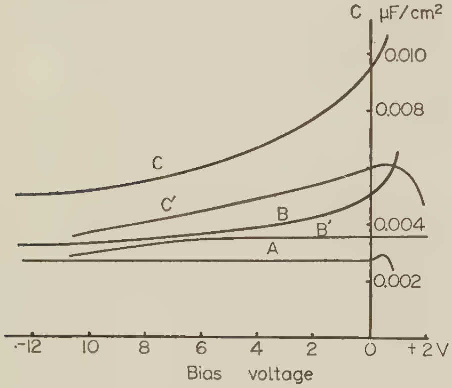

Fig. 6. The capacitance-voltage characteristics of the Se rectifiers with CdSe layer. Curves A, B and C are for the samples 11–6, 3–1 and 3–3, respectively, at room temperature, and curves B′ and C′ are for 3–1 and 3–3, respectively, at liquid air temperature. (Thicknesses of CdSe=1.6μ, 0.73μ and 0.50μ for samples 11–6, 3–1 and 3–3, respectively.)

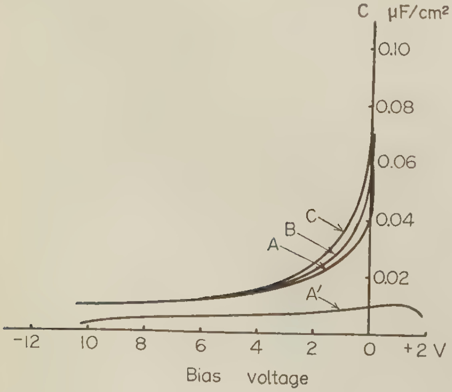

Fig. 7. The capacitance-voltage characteristics of the Se rectifiers with SnSe layer. Curves A, B and C are for the sample 10–6, 14–3 and 14–5, respectively, at room temperature, and curve A′ is for the sample 10–6 at liquid air temperature. (Thicknesses of SnSe=0.8μ, 1.2μ and 0.1μ for samples 10–6, 14–3 and 14–5 respectively.)

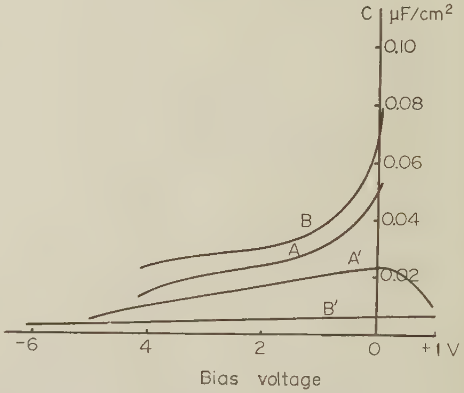

Fig. 8. The capacitance-voltage characteristics of the Se rectifiers with Bi_2Se_3 and BiSe layers. Curves A and A′ are for the sample 13–5 (Bi_2Se_3) at room and liquid air temperatures, respectively, and curves B and B′ are for the sample 5–1 (BiSe) at room and liquid air temperatures, respectively. (Thicknesses of the selenides=0.45μ and 0.50μ for samples 13–5 and 5–1, respectively.)

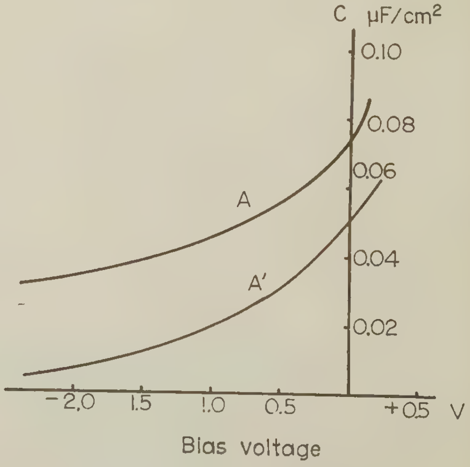

Fig. 9. The capacitance-voltage characteristics of the Se rectifiers with PbSe layer. Curves A and A′ are for the sample 13–1 at room and liquid air temperatures, respectively. (Thickness of PbSe=1.4μ for sample 13–1.)

in the figure and in Table VII.

The a.c. characteristics for these samples are shown in Fig. 8. Both capacitance and its bias voltage dependency of these samples are fairly large at room temperature and become considerably small at low temperature.

It should be noted that there is no essential difference between Bi_2Se_3 and BiSe. There was a noticiable fact, however, that when the thin Cd or Sn layer as the counter electrode is evaporated upon Bi_2Se_3 or BiSe layer, the colour of Bi_2Se_3 or BiSe layer near the Cd or Sn electrode changes into that of CdSe or SnSe, respectively, in a few days. From this fact, it might be doubtful that Bi_2Se_3 or BiSe layer could keep its purity between the selenium layer and the counter electrode metal even in the rectifiers with artificial Bi_2Se_3 or BiSe layer.

(4) *Rectifiers with PbSe layar*

Though the alloy which was used as the counter electrode of the selenium rectifier did not contain Pb, the characteristics of the rectifiers with PbSe layer were also measured in order to compare the results with those mentioned above. The results are shown in Fig. 5, Fig. 9, Table VI and VII. At room temperature, the value of threshold voltage V_D is smaller than in the case of CdSe, and larger than in the case of SnSe, and the spreading resistance R_S, capacitance and its bias voltage dependency are nearly the same as in the case of SnSe. The breakdown voltage is very small and these samples have very poor rectifying characteristics, especially at low temperature.

§ 3. Discussion

(1) *Case of CdSe layer*

Being an *n*-type semiconductor, CdSe seems to make a barrier layer between selenium and CdSe, and another one between CdSe and counter electrode metal. As seen in Table I, the donor density in CdSe is about the order of $10^{13}/cm^3$ and far smaller than the acceptor density in selenium which is about the order of $10^{16}/cm^3$ in usual rectifiers, and the following two cases, therefore, should be considered, as pointed out by Strosche[3].

(a) When the donors in CdSe layer are sufficiently abundant to make the space charge layer near the contact to selenium layer, both space charge layers, i.e., a *p–n* junction between CdSe and selenium, and a Schottky or Mott barrier between CdSe and counter electrode, should effectively act as the rectifying layers, and the characteristics of the rectifier should be analyzed by the double barrier layer theory[5]. The two barrier layers between CdSe and selenium, and between CdSe and counter electrode are named respectively the 1st and 2nd barrier layers for simplicity, and their diffusion potentials are respectively denoted as V_{D1} and V_{D2}. Considering the rectifying direction of this rectifier, the 1st barrier layer is the main barrier and the 2nd the sub-barrier and accordingly,

$$V_{D1} > V_{D2} . \qquad (2)$$

The equivalent circuit for this case is expressed as in Fig. 10 (c) or 10 (d), and when the bias voltage is applied in the forward direction, the sub-barrier layer is subjected to a large voltage in the reverse direction as in Fig. 10 (b). Consequently, if the bias voltage in the forward direction becomes sufficiently large, the sub-barrier layer dies away by breakdown, and the main barrier layer also disappears on account of the large forward bias, and the rectifier shows an ohmic characteristics for the forward voltage greater than a fixed value. This voltage is the so-called threshold voltage V_D, and then the threshold voltage V_D is given by the following equation:

$$V_D = V_{D1} + V_{C2} , \qquad (3)$$

where V_{C2} is the breakdown voltage of the sub-barrier layer. Considering the values of the forbidden gap E_G and the impurity level ΔE for selenium and CdSe, the value of V_{D1} seems to be about 1 volt at room temperature, and then the value of V_D must be greater than 1 volt, even if the value of V_{D2}, and accordingly the value of V_{C2} are sufficiently small. The observed values of V_D listed in Table II are plotted against the thickness of CdSe layers in Fig. 11. In the figure, the value of V_D increases as the thickness of the layer increases, and approaches a constant value (about 1.2 volt) as the thickness of the layer becomes greater than about 1 micron.

Although equation (3) implies that the value of V_D must be independent of the thickness of the layer, the fact that the observed value decreases with the decreasing thickness may be explained by the following reason: (i) the nonuniformity of the thickness of the CdSe layer is relatively great when the layer is thin, and the weak point in the barrier layer are comperatively numerous, (ii) the ions or atoms of tin or bismuth in the counter electrode metal may diffuse to make the selenides of tin or bismuth in the layer of CdSe during the forming process of the rectifier and there may be some bridge across the barrier layer. The explanations seems to be supported by the tendency that the apparent resistivity ρ is smaller in samples with thin layers than in those with thick layers as seen in Table II. If these assumptions may be accepted, the value of V_D for the samples with sufficiently thick layer, about 1.2 volt, may correspond to the value of V_D given by equation (3). Using this value and assuming the value of V_{D1} to be about 1.0 volt as mentioned above, the value of V_{C2} is estimated to be about 0.2 volt. According to the relation between breakdown voltage and diffusion potential given by Billig[6], $V_{C2}\approx 0.2$ volt corresponds to $V_{C2}\approx 0.01$ volt. This relation can also explain qualitatively the great change of the apparent threshold voltage V_D with temperature.

In order to consider the a.c. characteristics of these samples, the equivalent circuit as shown in Fig. 10 (d) may be used, and the impedances of the 1st and 2nd barrier layers, the resistance of CdSe layer between both barrier layers, and the capacitance between the selenium and the counter electrode are denoted as A_1-jB_1, A_2-jB_2, R_L and C_L respectively. When this circuit is substituted by a usual parallel circuit of resistance R and capacitance C, the following relations hold:

$$R=(A_1+A_2+R_L)+\frac{(B_1+B_2)^2}{(A_1+A_2+R_L)}, \qquad (4)$$

$$\omega C=\omega C_L+\frac{B_1+B_2}{(A_1+A_2+R_L)^2+(B_1+B_2)^2} \qquad (5)$$

and

$$\left.\begin{aligned} R_L&=\frac{d}{S}\rho \\ C_L&=\frac{\kappa S}{4\pi d}\,. \end{aligned}\right\} \qquad (6)$$

Here, ω is the angular frequency of the applied ripple voltage, d the thickness of CdSe layer, S the area of the electrode, and ρ and κ are the resistivity and the dielectric constant of CdSe, respectively.

Assuming that

$$A_1+A_2+R_L \gg B_1+B_2\,, \qquad (7)$$

the relation

$$C\approx C_L=\frac{\kappa S}{4\pi d} \qquad (8)$$

is obtained from equation (5) and it suggests that C is apparently independent of the bias voltage and is inversely proportional to the thickness of CdSe layer. The observed capacitance for the sample with thick CdSe layer scarcely depends upon the bias voltage as seen in Fig. 6. The zero bias capacitance C_0 of all samples are plotted against the thickness of CdSe layer in Fig. 12, which shows that the relation (8) is approximately satisfied. From this figure the dielectric constant κ is obtained to be about 6 according to equation (6), and this value does not seem to be an unreasonable one, though it is about twice the value estimated by applying Landsberg's theory[7] for some of these samples[8].

The above discussion is based upon the assumption of the condition (7) which holds for $A_i \gg B_i$, or $R_L \gg B_i$, where the suffix i ($i=1$ or 2) refers to the 1st and 2nd barrier layers respectively. Taking the equivalent circuits of the 1st and 2nd barrier layers to be the parallel circuits of the resistance and capacitance as shown in Fig. 10 (d), the impedance of each barrier is given as follows:

$$A_i=\frac{R_i}{1+R_i^2\omega^2C_i^2}\,, \qquad B_i=\frac{R_i^2\omega C_i}{1+R_i^2\omega^2C_i^2}\,. \qquad (9)$$

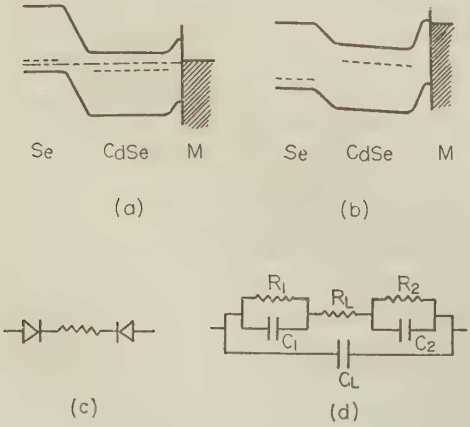

Fig. 10. Barrier model of Se rectifiers with CdSe layer.
(a) Equilibrium state. (b) Bias voltage is applied in the forward direction. (c) and (d) are the equivalent circuits of this rectifier.

(i) For $A_i \gg B_i$, equation (9) gives

$$R_i \omega C_i \ll 1 \,. \tag{10}$$

Though it is impossible to estimate correctly the values of the parameters in equation (10) from the present experiment, R_i must be smaller than $10^4\,\Omega\text{cm}^2$ in order to satisfy the condition (10), assuming the value $C_i \approx 0.1\mu\text{F}/\text{cm}^2$ which does not seem to be unreasonable. If the above values for R_i and C_i are adopted, $B_i \ll A_i \ll 10^4\,\Omega\text{cm}^2$, and from equation (4), R must be smaller than $10^4\,\Omega\text{cm}^2$, while the observed values of R are about $10^4 \sim 10^6\,\Omega\text{cm}^2$.

(ii) For $R_L \gg B_i$, it is required from equation (4) and (7) that $R_L \approx R \approx 10^4 \sim 10^6\,\Omega\text{cm}^2$, and using this value and equation (6), the resistivity of the CdSe, ρ, is obtained to be about $10^{10} \sim 10^{11}\,\Omega\text{cm}$, which is far greater than either the resistivity of bulk CdSe (in Table I), or the one which is obtained from spreading resistance R_S for the same sample (in Table II). But it may be possible that the resistance of CdSe layer, which exists in such a position as shown in Fig. 10 (a), is not necessarily equal to that of bulk CdSe on account of possible recombination and injection of carriers at the boundary between CdSe and selenium.

(b) When the donors in the CdSe layer are not sufficiently abundant to compensate the space charge in the selenium side, the donors in the CdSe layer are all ionized and then the layer acts as a Mott barrier. In this case, the barrier layer is single and, as is well known, the threshold voltage V_D is the difference between the work functions of selenium and counter electrode metal, and does not depend upon the thickness of the layer as in the assumption (a). The experimental dependency of V_D on the thickness of the CdSe layer which is seen in Fig. 11 may be explained as in the assumption (a). However, the observed value of V_D, if it should be the contact potential difference, seems to be rather too large, especially at low temperature.

The equivalent circuit for the barrier layer of this type is given by simple parallel circuit of a resistance and a capacitance, and consequently, the apparent capacitance does not depend upon the bias voltage and is always inversely proportional to the thickness of the CdSe layer. This situation seems to be well satisfied by the experimental results as shown in Figs. 6 and 12.

Further, the appropriateness of the assumption (a) and (b) should be considered in other ways. When a single barrier exists in a metal rectifier, the forward current is expressed as follows.

$$i_f \propto \exp\left[e(V - i_f R_S)/kT\right] \,, \tag{11}$$

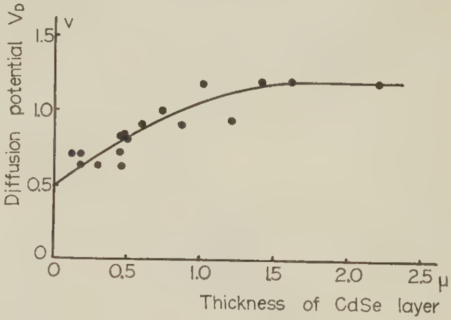

Fig. 11. The variation of the diffusion potential of Se rectifiers with thickness of CdSe layer at room temperature.

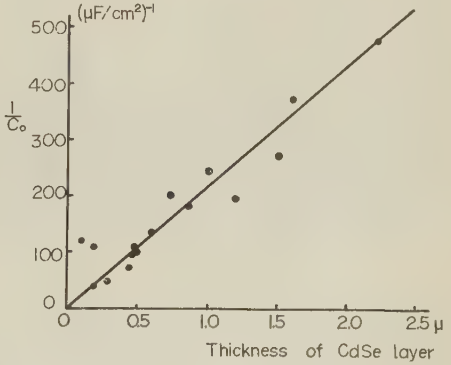

Fig. 12. The variation of zero-bias capacitance of Se rectifiers with thickness of CdSe layer at room temperature.

where, e is the electron charge, V the applied voltage, k the Boltzmann constant, T the absolute temperature. Accordingly, the plot of $\ln i_f$ vs. $V - i_f R_S$ should produce a straight line, and its slope should give a value corresponding to e/kT which is theoretically about $37\,\text{V}^{-1}$ at room temperature. Such a plot is given in Fig. 13 which shows that, though the linearity is nearly satisfied, the slope α is about a half of the theoretical value as seen in Table II. For the explanation for the fact that the experimental slope α is smaller than the theoretical one, the double barrier theory seems possible to be applied as pointed out by Numata[5]. Further, for the experimental fact that the capacitance of the rectifier decreases in the forward direction, the bouble barrier theory seems also applicable, because the reversely biased sub-barrier layer should affect the total capacitance.

Considering the facts mentioned above in addition to the fact that the apparent threshold voltage has a large value at low temperatures, the assumption (a) seems more reasonable than (b), though (a) has some difficulty concerning the value of the resistance of the CdSe layer, R_L.

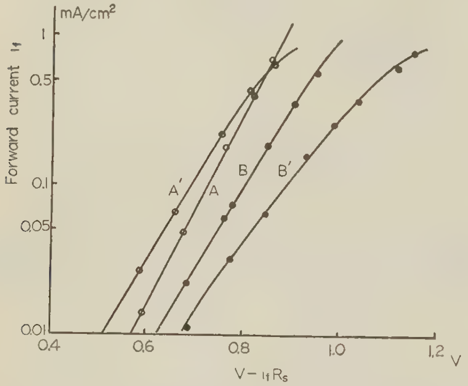

Fig. 13. The relation between the forward current and applied voltage in Se rectifiers with CdSe layer. Curves A and B are respectively for samples 3–1 and 11–6 before electrical forming, and curves A′ and B′ are respectively for samples 3–1 and 11–6 after electrical forming at room temperature.

(2) *Case of SnSe layer*

According to Grimm and Nasledov[9], a rectifying layer may exist between selenium and SnSe when they contact together. This layer and the barrier layer which seems to exist between SnSe and the counter electrode metal should construct a double barrier layer as in the case of the CdSe layer. In this case, however, the SnSe layer should not form a Mott barrier on account of its low resistivity.

The value of the threshold voltage V_D in the case of SnSe seems to be independent of the thickness of the layer, and is far smaller than that in the case of CdSe as seen in Table III. The value of the spreading resistance R_S is also independent of the thickness of the layer and nearly equal to the value of the resistance of the selenium layer itself.

The zero bias capacitance C_0 is plotted against the thickness of the layer in Fig. 14, and the figure shows that the capacitance seems to be also independent of the thickness of the layer neglecting the scattering among the samples, and the value of C_0 is far larger than in the case of the CdSe. These results show that the term ωC_L in equation (5) is sufficiently small compared with the second term and the term R_L is also negligible compared with the term A_l, being compatible with the low resistivity of SnSe.

The experimental relation between the forward current and the voltage across the barrier layer ($V - i_f R_S$) is shown in Fig. 15 which shows that the linearity between $\ln i_f$ and $V - i_f R_S$ is very good and the slope of the straight line is almost equal to the theoretical value 37 V^{-1} for a single barrier layer as seen in Table III. This fact seems to mean that the rectifier of this construction is typical one which is applicable for the usual theory of the rectification assuming a single barrier layer.

The experimental relation between the capacitance C and the bias voltage V is illustrated in Fig. 16, showing that there is the linear relation between $1/C^2$ and the bias voltage, that is, the Schottky capacitance relation[10]. It is reasonable to assume that the barrier layer is single and the Schottky type. Then the density of the impurity centers in the barrier layer and the diffusion potential are given from the straight line in Fig. 16. The density of the impurity centers N and the diffusion potential V_D' obtained thereby are also given in Table III. The value of the density of the impurity centers is in very good agreement with that in Table I which was obtained for bulk SnSe by the measurement of the Hall coefficient. However, the value of V_D' is somewhat larger than that of V_D.

From the above-mentioned facts, in the rectifier with SnSe layer, SnSe seems to build up a single and fairly stable barrier layer with either the selenium or the counter electrode metal at least at room temperature.* At low temperature, however, both V_D and R_S are greater, and both capacitance and its bias voltage dependency are smaller than those at room temperature, respectively, as in the case of CdSe layer. These facts seem to show not only that the bulk resistance of the SnSe layer increases with decreasing temperature, but also that the sub-barrier may come out to play a role in the rectification on account of the movement of the Fermi level resulting from the temperature decrease.

---

* Grimm and Nasledov[9] seem to assume that the rectifying contact is the contact between selenium and SnSe layer.

(3) *Case of Bi_2Se_3 and BiSe layer*

As both Bi_2Se_3 and BiSe are *n*-type, the barrier model and the equivalent circuit of a rectifier with the Bi_2Se_3 or BiSe layer may be illustrated in a manner similar to Fig. 10 for the case of the CdSe layer. As these materials have, however, far smaller resistivity than CdSe, the bulk resistance of the Bi_2Se_3 or the BiSe layer, R_L, as well as the layer capacitance ωC_L may be neglected in equations (4) and (5) as in the case of the SnSe layer. Consequently, the capacitance of the rectifier, C, is supposed to be independent of the thickness of the layer, and it is experimentally shown in Fig. 17.

The relation between $\ln i_f$ and $V-i_fR_S$ is linear as seen in Fig. 19, but the slope α is smaller than the theoretical value. This seems to suggest the existence of a double barrier layer. But in the region of large reverse bias voltage, the sub-barrier layer should disappear and Schottky barrier should be built up, so that $1/C^2$ becomes linearly proportional to the reverse bias voltage as seen in Fig. 18. The density of the impurity center N and the diffusion potential V_D' obtained from this figure are listed in Table IV and V. However, the densities of the impurity centers obtained here are smaller than those of the bulk materials listed in Table I.

At low temperatures, the impedances of both the barrier layer and the Bi_2Se_3 or BiSe layer become large, and the second term in equation (5) becomes smaller than the first term ωC_L. Consequently, the capacitance decreases and tends to be independent of the applied voltage so that the characteristic approaches that of a Mott barrier, as shown in Fig. 8.

As mentioned in § 2 (3), CdSe and SnSe may be produced in the layer of the bismuth selenide when the counter electrode metal is sprayed on the layer, and the selenides of cadmium and tin may play an important part in the rectifying characteristics of the recti-

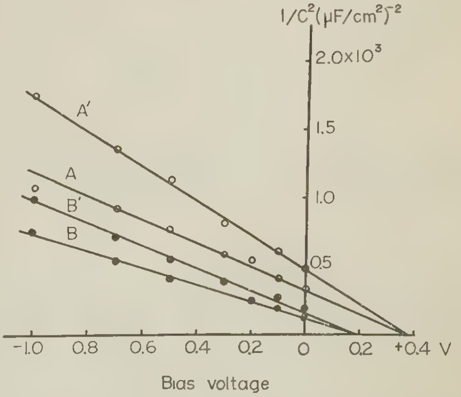

Fig. 16. $1/C^2$-voltage relation of Se rectifiers with SnSe layer. Curves A and B are respectively for the sample 10–6 and 14–1 before electrical forming, and curves A′ and B′ are for the same sample after forming at room temperature.

fier. The facts that there is no essential difference between the characteristics of the rectifiers with the Bi_2Se_3 and with the BiSe layers, and that the density of the impurity centers in the barrier layer does not agree with that of bulk materials, may suggest the above possibility, but it was impossible to ascertain this point in the present experiment.

(4) *Case of PbSe*

PbSe is a *p*-type semiconductor and its resistivity is of the same order with SnSe, so the behaviors of the rectifier with the PbSe layer may be expected to be similar to those with the SnSe layer. This expection seems to be well satiefied in the capacitance measurement as shown in Figs. 17 and 18. But the slope α obtained from the plot of $\ln i_f$ vs. $V-i_fR_S$ (Fig. 19) is fairly smaller than the theoretical value as shown in Table VI, and this may be attributed to the existence of the sub-barrier layer. The poor rectification shown in Fig. 5 seems to suggest that the main barrier layer is not so predominant. This fact shows that Pb is an undersirable component for the counter electrode alloy in the usual selenium rectifier.

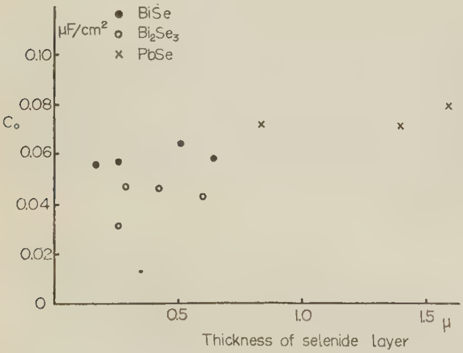

Fig. 17. The variation of zero-bias capacitance of Se rectifiers with thickness of Bi_2Se_3, BiSe and PbSe layers at room temperature.

(5) *Case of usual selenium rectifiers*

If a usual selenium rectifier has the selenides of cadnium, tin and bismuth between the bulk selenium and the counter electrode alloy, as mentioned in § 1, the characteristics of the rectifier must be considered from a point of view of "multi-contacts" of these selenides and the selenium or the counter electrode. Especially, the SnSe layer seems to play an important role in the rectification as well as the CdSe layer, and the following characteristics in the usual selenium rectifier may be explained from the above view-point:

(i) The value of apparent "diffusion potential" is not always constant but scatters in the range from about 0.3 to 0.6 volt. This is perhaps because of the fact that the SnSe layer ($V_D \approx 0.1$ volt), Bi_2Se_3 or BiSe layer ($V_D \approx 0.2$ volt) and CdSe layer ($V_D \approx 1.2$ volt) exist together and the fractions of the effective area of these selenides are different from sample to sample.

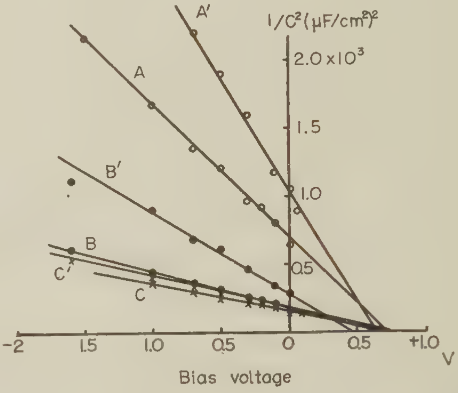

Fig. 18. $1/C^2$-bias voltage relation of Se rectifiers with Bi_2Se_3 (A, A'), BiSe (B, B') and PbSe (C, C') layers. Lines A, B and C are respectively for samples 4–1, 4–2 and 5–3 before electrical forming, and A', B' and C' are for the same samples after forming at room temperature.

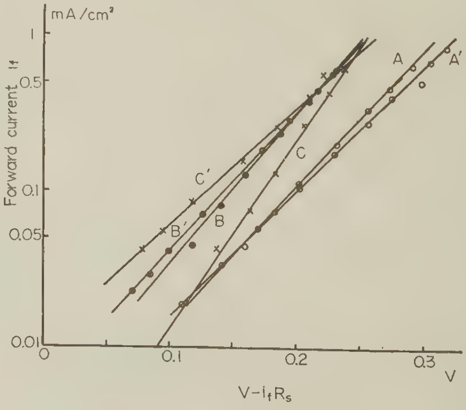

Fig. 19. The relation between the forward current and applied voltage in Se rectifiers with Bi_2Se_3 (A, A'), BiSe (B, B') and PbSe (C, C') layers. Lines A, B and C are respectively for the sample 13–6, 13–4 and 13–1 before electrical forming, and A', B' and C' are for the same samples after electrical forming at room temperature.

(ii) The slope of the line of $\ln i_f$ vs. $V-i_fR_S$ is smaller than that expected from the single barrier theory and the slope decreases as the bias voltage increases. Besides the double barrier theory, the "multi-contact" theory[11] has also been represented to explain this fact.

(iii) The "diffusion potential" increases[12] and the capacitance decreases[13] remarkably at low temperature. These may be explained by the considerations of the double barrier layer as mentioned in (1) and (2) of this section.

The above considerations suggest that though, of course, the *p–n* junction between the CdSe and selenium plays an important role in the rectifying characteristics of usual selenium rectifiers, the roles of the sub-barrier layer which exists between the selenides and the counter electrode, and of the other selenides layers besides CdSe should never be neglected.

Besides, it is expected that the CdSe in usual selenium rectifiers has a far smaller resistivity than the pure CdSe, some halogen being added in the bulk selenium; the difference in the resistivity between CdSe and the other selenides in usual rectifiers might not be so large as in the present experiments.

Some experiments have already been done to increase the breakdown voltage of the selenium rectifier by means of making an artificial layer between the bulk selenium and the counter electrode[14]. As the used materials have high resistances, the high resistance layer in the rectifier increases the forward resistance and decreases the rectification ratio. It is important to discuss what conditions are necessary to get a useful artificial layer.

(i) The material should not react with the selenium or the counter electrode metal to make other compound. This is necessary to avoid an aging effect in the rectifier.

(ii) The material is desirable to make a stable and single barrier layer with the selenium or the counter electrode, without making the sub-barrier layer. The effect of the sub-barrier layer is to increase the apparent threshold voltage and make the forword characteristics worse as is discussed relating to the action of the CdSe layer in (1) of this section.

(iii) The material should not have high resistivity if it makes a stable barrier layer. The layer of an insulator or high resistivity material is effective to increase the breakdown voltage in the insulator breakdown phenomena. The breakdown phenomena in rectifiers are, however, essentially different from those in the insulator, and it is well known that it is the weak points in the barrier layer, patches, which have the important meaning in the selenium rectifier breakdown phenomena[15]. Considering the above fact, it is rather more necessary to make a perfect, patchless barrier layer than to make a insulating layer in order to increase the breakdown voltage in the selenium rectifier. When an insulator or high resistivity material is used to make a layer thick enough to be patchless, the forward resistance of the rectifier increases and the rectification ratio becomes worse.

On the contrary, some material of low resistivity may make a stable barrier layer with the selenium or the counter electrode, and the layer may be thick enough to prevent patches and to increase the breakdown voltage without increasing the forward resistance of the rectifier. The SnSe used in the present experiment seems to be an example of such a material, though its diffusion potential is not so large that the breakdown voltage is not satisfactorily large.

Fig. 11 seems to show that the artificial CdSe layer should be thicker than 1 micron to make a stable and patchless barrier layer. The material which is desirable for making the artificial layer should have, therefore, the resistivity of smaller than $10^4\,\Omega$cm in order that one could neglect the resistance of the layer of 1 micron thickness compared with that of the bulk selenium.

In addition to the three conditions mentioned above, it is of course necessary that the material should make a high main barrier layer with the selenium or the counter electrode to give a high breakdown voltage, and from this view point SnSe is not very good. If there are some materials which satisfy the above conditions and have diffusion potentials of greater than a few tenth volt, they should be much available for artificial barrier layers in selenium rectifiers.

§ 4. Conclusion

The characteristics of selenium rectifiers,

which have an artificial layer of some selenides, were measured to give the following results:

(1) The CdSe layer plays an important role in a rectifying characteristics of selenium rectifiers, but it seems to make a double barrier layer with the bulk selenium and the counter electrode metal. The resistivity of pure CdSe is too large to give a good rectification ratio, though the CdSe in the usual selenium rectifier is expected to have a smaller resistance than the pure one, because some halogens are usually added in the bulk selenium of rectifiers.

(2) The SnSe layer also seems to play an important role in usual selenium rectifier, and it is of particular interest that the forward current voltage characteristic of the rectifier with the SnSe layer is in good agreement with the single barrier theory.

(3) The selenides of bismuth and lead should be unsuitable as an artificial layer because of the low main barrier and the comperatively high sub-barrier.

(4) Materials with resistivity smaller than about $10^4\ \Omega$cm seems to be preferable to materials with high resistivity as artificial layers in selenium rectifiers.

The author should like to express his sincere thanks to Prof. A. Okazaki for his kind guidance. The author is greatly indebted also to Prof. H. Tubota, Mr. H. Suzuki, Mr. K. Hashimoto, Mr. S. Asanabe and Shindengen Kogyo K. K. for the offer of the samples used in the present experiment.

Studies on (Ba-Pb)(Ti-Zr)O_3 System

By Takuro IKEDA

Kobayashi Institute of Physical Research, Kokubunji, Tokyo

(Received November 6, 1958)

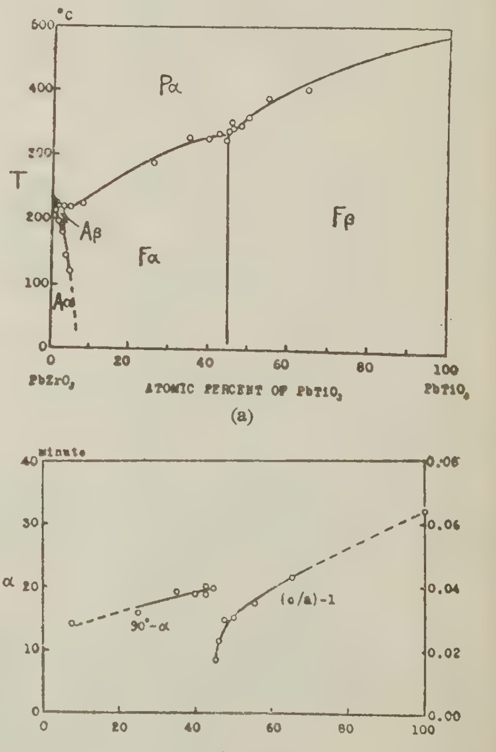
Structural studies on (Ba-Pb)(Ti-Zr)O_3 system were performed, and the phase diagram of the whole system was determined. In the vicinity of $BaTiO_3$, low temperature phases are brought to room temperature by adding Pb and Zr. Substituting some amount of Pb by Ba in Pb(Ti-Zr)O_3, Curie point becomes lower, but the morphotropic boundary between F_α and F_β phase shifts only gradually to the Ti side, and may lie nearly at the same composition with varying temperature. The axial ratio in F_β phase decreases with decreasing Ti concentration, while $90° - \alpha$ in F_α decreases with increasing Ba and hardly depends on Ti-Zr ratio,

Some solid solution ceramics along the morphotropic bundary with Ba 5–20% and Ti 40–50% are excellent for piezoelectric materials, and those containing Ba *ca.* 30% and Ti 5–25% have large dielectric constants and low temperature coefficients.

§ 1. Introduction

Many structural studies on the perovskite type crystals of $A^{2+}B^{4+}O_3$ have been published; *e.g.* $BaTiO_3$, $PbZrO_3$ etc. The properties of the binary and ternary systems of them have been also investigated. Above all, the solid solutions consisting of Ba^{++}, Pb^{++} and Ti^{4+}, Zr^{4+} are interesting from both physical and technical aspects. The structures of (Ba-Pb)TiO_3 system have been studied by Shirane et al[1], Pb(Ti-Zr)O_3 by Shirane[2] and Sawaguchi[3], and (Pb-Ba)ZrO_3 by Shirane *et al*[4]. Ferroelectricity of $BaTiO_3$ is strengthened by adding $PbTiO_3$. $PbTiO_3$ is ferroelectric at room temperature and transforms into the paraelectric phase at 490°C. $PbZrO_3$, on the other hand, is antiferroelectric and of orthorhombic structure at room temperature and transforms to cubic structure at 230°C. The solid solution system of $PbTiO_3$ and $PbZrO_3$ has been studied in detail by Sawaguchi[3]. The phase diagram and the crystal deformation of that system determined by him are shown in Fig. 1(a) and (b). A_α indicates the same antiferroelectric phase as that of $PbZrO_3$, and F_β the tetragonal and ferroelectric one. F_α is also a ferroelectric phase, but its crystal structure belongs to rhombohedral class. The phase boundary between F_α and F_β is nearly parallel to the temperature axis and is called "morphotropic". The phase relation of Ba(Ti-Zr)O_3 system has been given by a few authors. Fig. 2 is the one reported by Kell and Hellicar[5], which was determined by dielectric and elastic measurements.

From industrial aspects, improvements of the electromechanical properties of $BaTiO_3$ have been desired. The addition of $PbTiO_3$ to $BaTiO_3$ produces a better piezoelectric ceramics. For instance, Mason[6] has shown that an addition of several mole percent of



(a)

(b)

Fig. 1. Phase diagram and crystal deformation of Pb(Ti-Zr)O_3. (Sawaguchi)

Pb increases the coercive field and flattens the temperature variation of constants. The ceramics of Ba(Ti-Zr)O_3 with proper amount of Zr have large value of g, the piezoelectric output voltage coefficient, which is shown by Kell *et al*[5]. The ceramics of Pb(Ti-Zr)O_3 have been shown to be very useful by Jaffe and others[7]. The ceramics with composition near the morphotropic transformation show large piezoelectricity. (They are named PZT in short.) Fig. 3 shows one of their results, where k_r is the radial electromechanical coupling coefficient and ε the dielectric constant at room temperature. Varying composition, values of k_r and ε have sharp maxima at that boundary. Moreover, the solid solutions in the vicinity of the boundary have high Curie points ($>300°C$) and so their frequency constants, dielectric constants and coupling coefficients have relatively low temperature coefficients. Inspite of these good qualities, the sintering technique is difficult on account of the volatility of PbO.

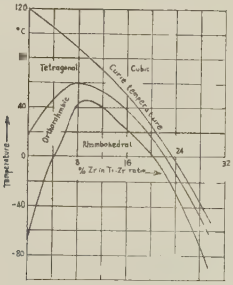


Fig. 2. Phase diagram of Ba(Ti-Zr)O_3. (Kell and Hellicar)

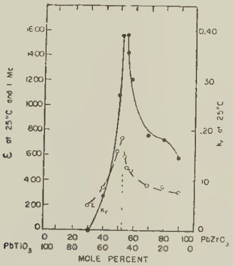

Fig. 3. Dielectric constant and radial coupling coefficient in Pb(Ti-Zr)O_3. (Jaffe *et al*)

The present author has mainly studied following respects: a determination of the phase diagram of (Ba-Pb)(Ti-Zr)O_3 system, measurements of anomalous properties of the solid solutions with composition near the morphotropic transformation, an examination of the phase relation in the vicinity of $BaTiO_3$ with small amount of Pb and Zr, and an improvement of piezoelectric ceramics PZT, etc.

Smolenskiĭ and others[8] have investigated the solid solution $BaTiO_3$-$PbZrO_3$, only a part of the present system, but have not reported a structural study. In the present paper, various properties of the whole system of (Ba-Pb)(Ti-Zr)O_3 are examined.

§ 2. Preparation of Samples

Proper mole percent of $BaCO_3$, PbO, TiO_2 and ZrO_2 were mixed and calcined at 1050°–1250°C. They were then crushed, pressed and sintered at 1250°–1500°C. (Samples containing larger amount of PbO were fired at lower temperatures.) $BaCO_3$ and ZrO_2 were of reagent grade, and PbO was of c.p. grade. TiO_2 was specially prepared by fractional distillation of $TiCl_4$, and was fairly pure (99.57%); impurities contained were Na_2O: 0.07, K_2O: 0.07, Fe: 0.003, $Zr < 0.01$, $SiO_2 < 0.01$. The evaporation of PbO during a firing process could not be ignored. Accordingly, a proper amount of PbO was laid around the sample in the crucible, and only inner parts of the piled-up discs of the sample were used for measurements. The samples fired were not chemically analyzed, but their compositions were specified by their mixing concentrations and were indicated by the amount of Ba and Ti in most cases.

§ 3. Solid Solutions with Small Concentration of Pb and Zr in the Vicinity of $BaTiO_3$

The polymorphic transitions show anomalies, as peaks or humps, on the curve of dielectric constant *vs.* temperature. The resonant frequency *vs.* temperature curve has clear minima or dents at the transition points. In the case of $BaTiO_3$, the temperatures at which any anomalies appear in the dielectric measurements are identical with those in the elastic one. The ceramics which have been pre-poled under the high electric field in the ferroelectric range show piezoelectricity and can be used for elastic measurement in the self-resonance. The phase diagram of Ba(Ti-Zr)O_3 system has been determined by Kell and Hellicar by such dielectric and elastic measurements, as shown in Fig. 2. With increasing Pb concentration, Curie point is raised, while two lower transition points are lowered. On the other hand, increasing Zr concentration, the two lower transition points are raised; the humps on the dielectric constant curve become less clear but the indentation on the elastic one are still distinguishable. With varying composition, these points determined by both dielectric and elastic means are plotted in Fig. 4 (a). The phase diagram at room temperature is given, as shown in Fig. 4 (b). F shows a ferroelectric phase, and P a paraelectric one (belonging to the cubic class). Suffix β indicates the tetragonal phase (after Sawaguchi's notation), and 1 and 2 correspond to the lower phases of $BaTiO_3$, *i.e.* the rhombohedral phase and the orthorhombic one, respectively. The boundaries which are not determined clearly are shown by dotted lines.

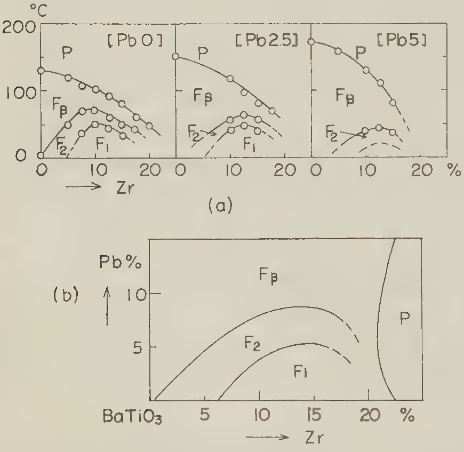

Fig. 4 (a). Shift of transition points. (b) Phase diagram in the vicinity of $BaTiO_3$.

The solid solution ceramics with proper amount of Pb and Zr have large dielectric constant and piezoelectric coefficient, owing to the shift of transition points. Various constants vary remarkably with temperature, and they seemed to be unpreferable for industrial purposes.

§ 4. Structural Studies of the Solid Solutions with Less than 50 Percent of Ba

(a) *Dielectric measurement*

In the solid solutions with small Ba concentration, the dielectric constant *vs.* temperature curve shows a sharp peak at Curie point. Increasing Ba concentration, Curie point becomes lower and the peak of the dielectric constant curve changes to a broad maximum, as shown in Fig. (a). The temperature corresponding to the maximum of the dielectric constant is considered to be Curie point, and these points of several solid solutions are plotted by dotts in Fig. (b). Some samples with small concentration of Ba and Ti near $PbZrO_3$ show other humps on the dielectric constant curve, which correspond to the transition from antiferroelectric state to ferroelectric one, according to Shirane[1] and Sawaguchi[3]. The solid solutions Pb(Ti-Zr)O_3 containing small amount of $PbTiO_3$ have been investigated in detail by Sawaguchi.

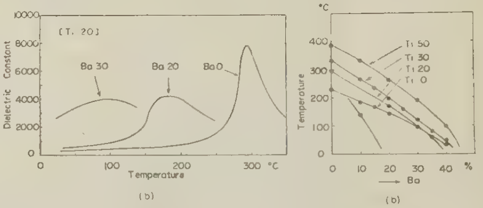

Fig. 5 (a). Dielectric constant of (Ba-Pb) (Ti20-Zr80)O_3. (b) Transition point for various composition.

(b) *X-ray measurement and phase diagram at room temperature*

In obtaining the phase diagram, the boundary between A_α and F_α was determened by above means; A_α is the antiferroelectric phase similar to $PbZrO_3$, and F_α is the ferroelectric one of rhombohedral structure appearing in Pb(Ti-Zr)O_3 and (Pb-Ba)ZrO_3 systems.

In the Pb(Ti-Zr)O_3 system, the boundary between F_α and F_β has been shown to be nearly parallel to the temperature axis and to be at the composition of Pb(Ti45-Zr55)O_3 by Sawaguchi[3]. In the present case, that boundary could not be determined by the dielectric means on account of absence of a hump. The powder photographs of several samples were taken at room temperature with a camera of 57.3 mm in diameter, using CuKα radiation. The lattice constants are shown in Fig. 6. The solid solutions on the left side with larger Ti concentration belong to F_β phase, and their tetragonalities become smaller with increasing Zr concentration, as shown in Fig. 7. These on the right side belong to F_α phase. Their rhombohedral angles α's were determined by using a diffractmeter of the Rigakudenki Co.; where the back reflection side ($h^2+k^2+l^2=20$, 22, 24 and 26) was examined (*cf.* the paper of Shirane and Hoshino[4]).

In the case of Ba 0, namely Pb(Ti-Zr)O_3, the boundary is located at the composition of Ti 42.5–45. With increasing Ba, the boundary shifts gradually to the larger Ti side at room temperature. The phase diagram at room temperature is thus determined and shown in Fig. 8. How the boundary between F_α and F_β changes with varying temperature is considered in the next paragraph.

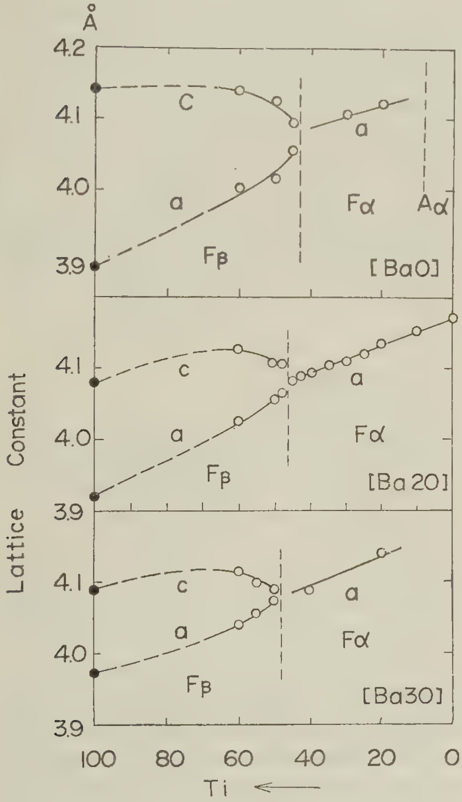

Fig. 6. Lattice constants (●—after Shirane)

(c) *Elastic measurement and examination of the boundary between* F_α *and* F_β

As the solid solution above the Curie point is not piezoelectric, a self-resonance method cannot be used for elastic measurement. The elastic property of a non-piezoelectric sample is determined by observing the resonance of the so-called composite-bar consisting of the quartz rod (X-cut and Y-long) and the specimen cemented endwise with each other.

In the case of the composition near $BaTiO_3$, a minimum or a dent appears at the temperature corresponding to a maximum or a hump of dielectric constant *vs.* temperature curve. In the solid solutions with less than 40% of Ba and 20–55% of Ti, peculiar phenomena are observed. A few examples of the temperature variations of the resonant-frequencies of the composite-bar are shown

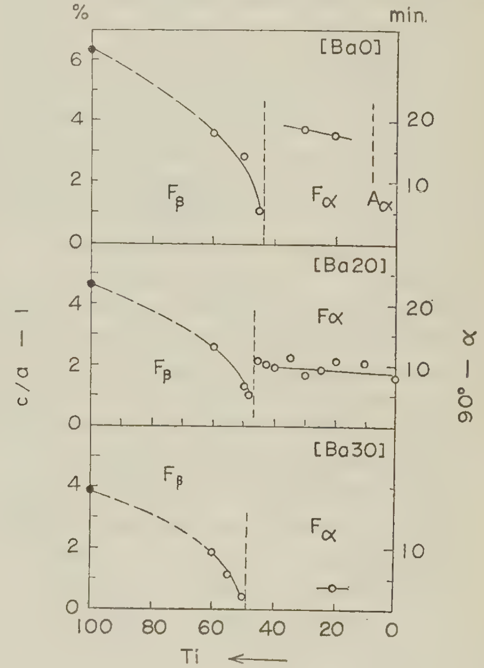

Fig. 7. Tetragonality in F_β and rhombohedrality in F_α.

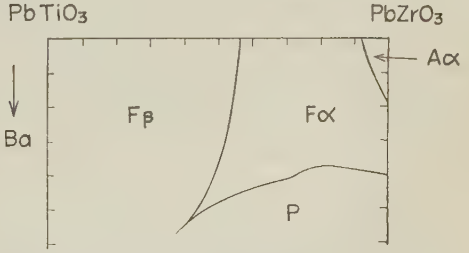

Fig. 8. Phase diagram (less than 60 Ba).

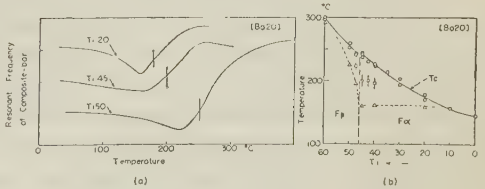

Fig. 9 (a). Resonant freqency of composite-bar (Vertical short line indicates Curie point). (b) Phase change in (Ba20-Pb80) (Ti-Zr)O_3.

○ Maximum of dielectric constant.

△ Minimum of resonant-frequency.

☐ X-ray measurement.

in Fig. 9 (a), where loose minima appear at the temperatures other than Curie points. In Fig. 9 (b), a solid curve shows the shift of Curie point with composition, and the variation of the temperature corresponding to the minimum of the resonant-frequency is shown by a dotted line.

An identification of phase of the region closed by both curves was performed by the powder photographs at temperatures indicated by square marks, using a camera with 70 mm diameter. Their patterns approach to pseudo-cubic ones, and the structures cannot be distinctly decided, but any deviation from each phase at room temperature is not observed. So the boundary between F_α and F_β phases may be almost parallel to the temperature axis (perpendicular to the composition axis), and is shown by the broken line in the figure. Then, that boundary may be called "morphotropic" also, by the same reasoning as in the case of $Pb(Ti\text{-}Zr)O_3$ system.

Such loose minima observed in the elastic measurements do not seem to be related with the phase transition, and often appear near the morphotropic boundary in the solid solutions with more than several percent of Ba. They may occur as a result of, for instance, a gradual temperature variation of elastic constant or a coexistence of the decreasing factor and increasing one. Thermal expansions of these specimens are extraordinarilly small below T_C and show only a bend at T_C, but any relation between these facts and above elastic data is not understood yet.

§ 5. Dielectric and Electromechanical Properties

(a) *Dielectric properties*

The dielectric constants of the solid solutions at room temperature changes systematically with composition. Even by using poorly sintered samples with 13–24% of porosity, the outline of the distribution is seen. Fig. 10 (a) shows the sections with various Ba concentration. Two maxima are found in each section; one of them (on the left side) is accompanied with the morphotropic transformation, and with increasing Ba, another large peak appears and shifts to the right side. The cause of an appearance of the latter maximum is not understood. Generally speaking, with increasing concentration of Ba, the value of the dielectric constant becomes larger and the peak at Curie point goes on to a broader one. The dense ceramics with composition of Ba 30–35 and Ti 5–25 have considerably large dielectric constant, *e.g.* 3000–6000. Fig. 10 (b) shows a few samples of their behavior *vs.* temperature (their porosity: 3–5%).

The dielectric hysteresis of the solid solution with larger amount of Ti and smaller of Ba does not reach a saturation yet by a field of 40 KV/cm (50 c/s) and so the coercive field is not determined quantitatively. Nonetheless, the tendency of the change of the coercive field with composition can be seen; the coercive field of the solid solution on the upper left side of the phase diagram (Fig. 8) is higher than that on the lower right side. The dielectric hysteresis of the one with larger than 20% of Ba and smaller than 50% of Ti seems to show a saturation by 40 KV/cm.

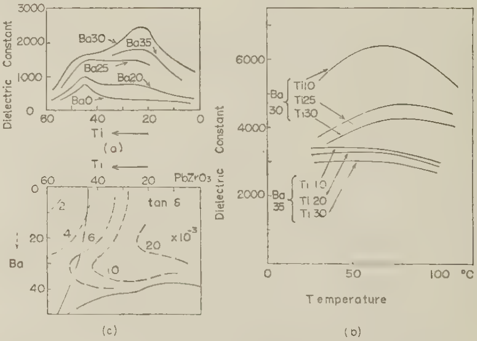

Fig. 10 (a). Dielectric constant at room temperature. (b) Temperature variation of dielectric constant (dense specimen). (c) Distribution of dielectric loss.

The dielectric loss factor (than δ) of the ceramics at room temperature was also examined. Fig. 10 (c) shows the distribution by several contour-lines. The values of the samples containing about 30% of Ba are larger than those on the upper left side, but they remain as small as 1–2%.

(b) *Electromechanical properties*

As described above, the electromechanical coupling of the solid solution ceramics becomes stronger with the composition near the morphotropic transformation of $Pb(Ti\text{-}Zr)O_3$, as reported by Jaffe *et al.* But, the poling field necessary to give a sufficient coupling is very high, and the ceramics with large Ti concentration have the coupling coefficients increasing with the poling field.

Substituting Pb by Ba, the situation can be improved. Namely, the poling field of even 30 KV/cm brings a sufficient coupling to the ceramics. The dense ceramics carefully sintered can have 40% of k_r, the radial electromechanical coupling coefficient. Fig. 11 (a) shows a tendency of the distribution of k_r; where the porosities of the samples are 12–20%.

The temperature variations of the frequency constant $f_r \cdot 2r$ (f_r: resonant frequency, $2r$: diameter) and the coupling k_r of an example are shown in Fig. 11 (b). The variations are smaller than those of other piezoelectric ceramics.

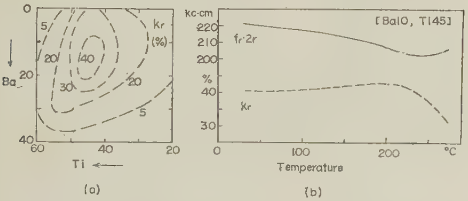

Fig. 11 (a). Distribution of radial electromechanical coupling coefficient (k_r) (prepoled by 30 KV/cm). (b) Temperature variation of frequency constant and k_r.

The internal frictions of these samples are of the order of $(1.5\text{–}3) \times 10^{-3}$, but the values for those with smaller loss depend more or less on their porosities, and so the distribution is hard to understand. Although the value of the internal friction is thus less reliable, a certain tendency is seen in its ratio to the dielectric loss; approximately speaking, the ratio becomes smaller in going on to the lower right side apart from $PbTiO_3$ side. This ratio may be considered to give a measure of the electromechanical coupling in the single crystal[9].

§ 6. Discussion and Conclusion

Roth[10] tended to classify perovskite crystals of ABO_3 including the solid solutions by the ionic radii of A^{++} and B^{4+} ions and the polarizability of A^{++} ion. His anticipation concerning the present system may be a success to some extent, but, for a detailed discussion, further knowledges on other solid solution systems (especially those containing Sn^{4+} ion) are necessary. Using the present datum and others to be studied in future, an experimental classification will be possible and advance Roth's consideration.

In the case of $Pb(Ti\text{-}Zr)O_3$ system, the axial ratio in F_β phase decreases with increasing Zr concentration, and on the contrary, the deviation from 90° in F_α is nearly constant with varying composition. Sawaguchi interpreted this fact by the latent meta-stability of F_α state in $PbTiO_3$ side. With increasing Ba content, both $c/a-1$ and $90°-\alpha$ become smaller, but above situation is the same in the section of constant Ba, and the morphotropic boundary does not shift so much to the Ti side, as shown in Figs. 7 and 8. Namely, the effect of Ba addition is a diminution of space for rattering of B^{4+} ion, which causes a lowering of Curie point and a weakening of ferroelectricity, and, on the other hand, the stabilities of F_α and F_β are decided mainly by the concentration ratio of Ti and Zr.

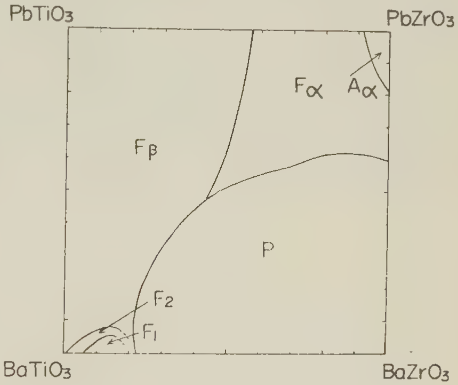

Fig. 12. Phase diagram of (Ba-Pb)(Ti-Zr)O_3 system.

Next, the elastic properties will be considered. s^P, the elastic compliance coefficient for constant polarization, changes by an amount at the phase transition and shows an ordinary temperature variation in one phase, and s^E, that for constant field, varies in correspondence with a change of electromechanical coupling; then, the elastic constant of the ceramics shows a minimum or a dent at the transition point. In the case of the solid solution near the morphotropic transformation, however, a loose minimum is seen in the curve of the resonant-frequency *vs.* temperature, and notwithstanding, any change of phase cannot be clearly found at that temperature. This may be considered as described in § 4 (c), but further study will be necessary to elucidate these phenomena.

In the present system, some useful materials were found for industrial applications. As shown in Fig. 11 (a), those possessing the radial coupling 40% by prepoling under the field of 30 KV/cm are obtained in certain compositions. These are considered to have better qualities than those investigated by Jaffe *et al* in a few respects; lower poling field, easier sintering, etc. The solid solutions containing about 30% of Ba have higher dielectric constants and relatively low dielectric losses. The ceramics of (Pb-Ba)ZrO_3 are often used for dielectric materials, but temperature coefficients of their dielectric constants are larger. The present dielectric ceramics may show some remarkable improvements.

Acknowledgement

The author wishes to express his sincere thanks to Dr. O. Nomoto, Mr. M. Marutake and Mr. A. Takeda in our institute for their useful discussions. He is also grateful to Dr. H. Hagihara and Mr. H. Yamashita in our institute for the X-ray photographing, to Mr. S. Nagasaki and Mr. K. Teranishi of the Rigakudenki Co. for the X-ray analysis by a diffractometer, and to Mr. K. Uchino and Mr. Y. Yasui of our institute and Mr. Y. Sasaki of the Waseda University for their help to the experiment.

The present study was supported by the Scientific Expenditure of the Ministry of Education.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 14, No. 2, FEBRUARY, 1959

The Electronic Structure of the M Center

By Hiroshi MIMURA and Teturo INUI
Department of Applied Physics, Faculty of Engineering,
University of Tokyo

(Received November 15, 1958)

The electronic structure of the *M* center for LiF has been investigated by L.C.A.O. approximation, assuming *L*-shape model by Seitz. In this treatment, we have orthogonalized the wave function of the *M* electron to the core state of Li ion, and evaluated the three center integrals more accurately than the former paper[1]. The calculated value for the M band absorption is 0.078 compared with the experimental value 0.103 in atomic unit. Some discussions concerning to the approximation and symmetry problem are given.

§1. Introduction

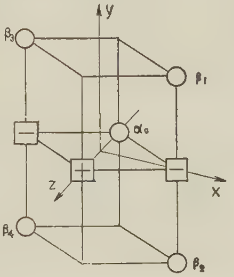
In a former paper[1], one of us (T.I.) in collaboration with Y. Uemura and Y. Toyozawa has investigated the electronic structure of the *M* center in L.C.A.O. approximation. A number of criticisms with respect to that paper and, in more general sense, to L.C.A.O. method applied to the color center problem have been given.

1) The A.O. belonging to the atom A has its charge density considerably in the region of a neighbouring atom B and therefore is not orthogonal to the core function of B[2),3)].

2) To reproduce the real charge distribution of a trapped electron faithfully, we should take many A.O.s so that there appear so many three center integrals[3)].

3) The energy is obtained as the difference of the several large quantities each of which is computed only approximately[4)].

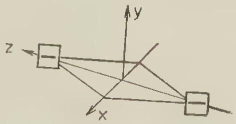
In the following we will try some improvements to answer the criticisms (1) and (3). We choose the case of LiF because of its simplicity. As before, we assume *L*-shaped model for the *M* center which consists of the complex of two adjacent negative ion vacancies and a positive vacancy. We take the rectangular axes x, y and z shown in Fig. 1.



⊞ (⊟) means the lattice vacancy of the positive (negative) ion.

○ represents the Li ion, the A.O. of which is taken into account on L.C.A.O. treatment.

Fig. 1. Seitz's model for the M center.



⊟ means the lattice vacancy of the negative ion.

Fig. 2. D_{2h} model for the M center.

§2. Calculation of Energy Levels

The one electron Hamiltonian assumed here for the *M* center electron is, neglecting the polarization of the ions,

$$H=-\tfrac{1}{2}\Delta+\sum_{(\mathrm{Li})} V(\boldsymbol{r}-\boldsymbol{R}_p)+\sum_{(\mathrm{F})} U(\boldsymbol{r}-\boldsymbol{R}_q)\,, \qquad (1)$$

where $V(\boldsymbol{r}-\boldsymbol{R}_p)$ (or $U(\boldsymbol{r}-\boldsymbol{R}_q)$) is the potential due to the p-th Li (or the q-th F) ion. We assign $p=0$ for the α ion, $p=1, 2, 3$ and 4 for the β ions, and $\sum_{(\mathrm{Li})}$ (or $\sum_{(\mathrm{F})}$) denotes the sum over Li ions (or F ions).

As F ions are more distant from the *M* center, $\sum_{(\mathrm{F})} U(\boldsymbol{r}-\boldsymbol{R}_q)$ is approximated by $\sum_{(\mathrm{F})}(1/|\boldsymbol{r}-\boldsymbol{R}_q|)$, hence it has no localized state. We approximate $V(\boldsymbol{r}-\boldsymbol{R}_p)$ by the Hartree potential for $2s$ orbital of free Li atom which

---

[*] Last year Dr. B. S. Gourary informed us kindly that the results of our 1st calculations[1)] are doubtful because the internuclear distances we used were wrong. Really we have made a foolish mistake in writing the numerical values of lattice constant of Lithium and Sodium Chlorides though the actual calculations were done using correct values. We made an independent calculation and confirmed every numerical values were correct within the accuracy of calculation. (Appendix III)

We express our thanks to Dr. B. S. Gourary for his valuable remarks.

has the following form[7]

$$V(\boldsymbol{r}-\boldsymbol{R}_p)=-\frac{1}{r_p}\{1+(2+5.4r_p)e^{-5.4r_p}\}\ ,$$
$$\text{where } \boldsymbol{r}_p=\boldsymbol{r}-\boldsymbol{R}_p\ . \quad (2)$$

We minimize the expectation value of the Hamiltonian H with the restriction that the corresponding wave function is orthogonal to the core (1*s*) functions which are the eigen functions of the *same* Hamiltonian. The (1*s*) function we have chosen has the analytic form $\phi_{1s}=Ne^{-\mu_0 r}$ where μ_0 is determined to minimize the expectation value of H. The actual procedure is as follows.

We neglect the overlap between the (1*s*) states and within the region where the charge distribution of the (1*s*) electron is remarkable we regard the potential as constant except $V(\boldsymbol{r}-\boldsymbol{R}_p)$, i.e.

$$\begin{aligned} H\phi_{1s,k}&=\left(E(\mu_0)+\frac{\alpha_M}{d}-\sum_m^{(\text{vac})}\frac{\pm 1}{|\boldsymbol{R}_k-\boldsymbol{R}_m|}\right)\phi_{1s,k}\\ &=E_{1s,k}\phi_{1s,k} \end{aligned} \quad (3)$$

α_M/d represents the Madelung potential, d is the lattice constant and $\sum_m^{(\text{vac})}$ denotes the sum of the Coulomb terms taken over the absent ions.

Determine μ_0 and $E(\mu_0)$ from the following equation

$$\left(\frac{\partial E(\mu)}{\partial \mu}\right)_{\mu_0}=0\ ,$$
$$\text{where } E(\mu)=\left(\phi_{1s}\left|-\frac{\varDelta}{2}+V(\boldsymbol{r}-\boldsymbol{R}_p)\right|\phi_{1s}\right) \quad (4)$$

then we obtain $\mu_0=2.2$, and $E(\mu_0)=-1.156$ (a.u.).

Let us now take our attention to the (localizing) site i, and denote the corresponding A.O. by ψ_i understanding that i represents the site as well as its quantum state.

We define the O.A.O. φ_i from the A.O. ψ_i by

$$\varphi_i=\psi_i-\sum_{(k\neq i)}S(\phi_{1s,k}|\psi_i)\phi_{1s,k}\ , \quad (5)$$

where $\phi_{1s,k}$ represents the (1*s*) state localized at the k-th ion, $\sum_{(k\neq i)}$ means the sum taken over all Li ions except the i-th ion. $S(\phi_{1s,k}|\psi_i)$ represents the overlap integral between $\phi_{1s,k}$ and ψ_i.

The matrix element of H with respect to φ_i and φ_j is given by

$$\begin{aligned} &(\varphi_i|H|\varphi_j)\\ &=(\psi_i|H|\psi_j)-\sum_{(k\neq i,j)}S(\phi_{1s,k}|\psi_i)S(\phi_{1s,k}|\psi_j)E_{1s,k}, \end{aligned} \quad (6)$$

where $E_{1s,k}$ is the eigenvalue of $\phi_{1s,k}$. The last term of the equation (6) represents the orthogonalization correction. We decompose $(\psi_i|H|\psi_j)$ into $(\psi_i|H_0|\psi_j)$ and $(\psi_i|H_1|\psi_j)$, where

$$\left.\begin{aligned} H_0&=-\frac{1}{2}\varDelta+V(\boldsymbol{r}-\boldsymbol{R}_i)+\sum_{(k\neq i)}\frac{\pm 1}{|\boldsymbol{r}-\boldsymbol{R}_k|}\\ H_1&=\sum_{\text{Li}(k\neq i)}\left(V(\boldsymbol{r}-\boldsymbol{R}_k)-\frac{-1}{|\boldsymbol{r}-\boldsymbol{R}_k|}\right). \end{aligned}\right\} \quad (7)$$

All the matrix elements which have been given in reference 1) are these matrix elements with respect to H_0 here, H_1 is the correction for it.

The wave functions are written as follows:

$$\left.\begin{aligned} &(A_1\text{ state})\quad \varPsi_{A_1}=\alpha_1\varPhi_1+\alpha_2\varPhi_2+\alpha_3\varPhi_3\\ &\qquad\begin{cases}\varPhi_1=\varphi_{s,0}\\ \varPhi_2=\varphi_{z,0}\\ \varPhi_3=\varphi_{s,1}+\varphi_{s,2}+\varphi_{s,3}+\varphi_{s,4}\ ,\end{cases}\\ &(B_1\text{ state})\quad \varPsi_{B_1}=\beta_1\varPhi_1+\beta_2\varPhi_2\\ &\qquad\begin{cases}\varPhi_1=\varphi_{x,0}\\ \varPhi_2=\varphi_{s,1}+\varphi_{s,2}-\varphi_{s,3}-\varphi_{s,4}\ ,\end{cases}\\ &(B_2\text{ state})\quad \varPsi_{B_2}=\gamma_1\varPhi_1+\gamma_2\varPhi_2\\ &\qquad\begin{cases}\varPhi_1=\varphi_{y,0}\\ \varPhi_2=\varphi_{s,1}-\varphi_{s,2}+\varphi_{s,3}-\varphi_{s,4}\ ,\end{cases} \end{aligned}\right\} \quad (8)$$

where φ_s, φ_z are 2*s*- and 2p_z-orbitals, the suffices 0, 1, 2, 3 and 4 indicate the position of ion to which the given O.A.O. belongs. We have only to solve the secular equations

$$\text{Det}|(\varPhi_m|H|\varPhi_n)-E(\varPhi_m|\varPhi_n)|=0 \quad (9)$$

for the above states.

The approximations to evaluate the three center integrals are as follows. In reference (1) we put

$$\int\psi_i\sum_{(k)}\frac{\pm 1}{|\boldsymbol{r}-\boldsymbol{R}_k|}\psi_j d\tau=\sum_k\frac{\pm 1}{|\boldsymbol{R}_m-\boldsymbol{R}_k|}\int\psi_i\psi_j d\tau\ , \quad (10)$$

where R_m is the maximum overlapping point of ψ_i and ψ_j. In this paper, we decompose $\int\psi_i\sum_{(k)}(\pm 1/|\boldsymbol{r}-\boldsymbol{R}_k|)\psi_j d\tau$ into two parts, i.e., the main part and the remainder. The former part consists of Coulomb terms due to a few neighbouring ions and is evaluated by Coulson-Barnett method[5]. As for the calculation of the remainder, we take sum $\sum_{k'}{}'(\pm 1/|\boldsymbol{R}_m-\boldsymbol{R}_{k'}|)$ over the remainder ions k's. For most combinations of ψ_i and ψ_j, the sums $\sum_{k'}{}' (\pm 1/|\boldsymbol{R}_m - \boldsymbol{R}_{k'}|)$ become zero and in these cases we put $\int \psi_i \sum_{k'}{}' (\pm 1/|\boldsymbol{r} - \boldsymbol{R}_{k'}|)\psi_j d\tau$ as zero. For $\int \psi_{s1} \sum_{k'}{}' (\pm 1/|\boldsymbol{r} - \boldsymbol{R}_{k'}|)\psi_{s2} d\tau$ the sum $\sum_{k'}{}' (\pm 1/|\boldsymbol{R}_m - \boldsymbol{R}_{k'}|)$ does not vanish, we apply Coulson-Barnett method for the ions for which $|\boldsymbol{R}_m - \boldsymbol{R}_k| \leq \sqrt{3}\, d$, and for the exterior ions we use the same approximation as (10), i.e.,

$$\int \psi_i \sum_{k'}{}' \frac{\pm 1}{|\boldsymbol{r} - \boldsymbol{R}_{k'}|} \psi_j d\tau = \sum_{k'}{}' \frac{\pm 1}{|\boldsymbol{R}_m - \boldsymbol{R}_{k'}|} \int \psi_i \psi_j d\tau \,.$$

For $\int \psi_{s1} \sum_{k} (\pm 1/|\boldsymbol{r} - \boldsymbol{R}_k|)\psi_{p\pi 0} d\tau$, where $\psi_{p\pi 0}$ is the component of p-type function perpendicular to the direction joining α and β ions, we have to take sum only over the absent ions and then to reverse sign.

§ 3. Results of Calculation and Remarks

The results are given in the Table I. As seen from the table, the difference of $E(A_1) - E(B_1)$ which corresponds to the M absorption band, does not depend critically on the

where $f_M = \frac{1}{3} \frac{2}{|E(A_1) - E(B_1)|} \left| \left(\Phi_{A_1} \middle| \frac{\partial}{\partial x} \middle| \Phi_{B_1} \right) \right|^2$, for $E(A_1) - E(B_1)$, we take the value of M band absorption wave length. $\langle \sigma_M{}^2 \rangle^{1/2}$ means the root mean square of the spin resonance line. f value calculated by the wave function in approximation (I) is 0.01.

approximations. Presumably this is caused by cancellation of errors common for upper and lower states. However, for the calculation of the oscillator strength, the approximation (I) gives a poor result inconsequence of the lack of the above-mentioned reason. To compare our results with experimental facts[8], we calculate oscillator strength f and hyperfine coupling constant a, using the wave function in approximation II. The results are plausible as shown in Table II.

The hyperfine interaction with α ion predominates over that with β ion, so that we should expect theoretically the resolved quartet which contradicts the experimental fact. For this point we would remark that we have neglected the interaction with F ion which has a possibility of broadening each component of the quartet to a broad line.

Lately, Gourary and Luke[4] have applied their "point ion lattice" method to the M center. Our results of approximation II resemble those of their "C.I. expansion" orthogonalized to the central ion core state, and it is not unreasonable because of their parallelism between both treatments. Although their C.S. expansion with strict point ion lattice model gives the good results for the absorption wave length, their results seem to be somewhat fortuitous because there remains some arbitrariness for the artificial selection of the wave function to avoid the rapid change near the nucleus.

Our treatment for the orthogonalization is, of course, not satisfactory, for we have used the one electron Hamiltonian in Hartree's sence, hence, neglected the exchange energy, (we are rather to use here the effective potential which reproduces the free atom spectrum which arises from the transition of the valence electron alone), and we have neglected the core state of the F ion. In spite of these facts, we believe that the estimation and check of the effect of the orthogonalization for L.C.A.O. approximation as done here is worthdoing.

Appendix I. The Model of *M* Center

Recently, Kuwabara and Misu[9] have suggested that the symmetry of the M center is D_{2h} instead of C_{2v} based on the assumption that the second and the third excited states are nearly degenerate. However, as the following estimation shows such degeneracy can not be expected if we consider the effect of crystalline field. A possible model which has D_{2h} symmetry is a pair of two negative vacancies trapping an electron which is responsible for E.S.R. The one electron Hamiltonian of the M electron for this model is given by $H=-\frac{1}{2}\Delta-\sum_{\substack{i=1,2\\ \text{(vacancy)}}} V_{\text{ion}}(i)+V_{\text{pol}}+V_{\text{crys}}$. If we assume the polarization field (V_{pol}) to be equal for the second and third excited states, and neglect V_{crys} (field from perfect crystal), both states are degenerate. Then we can estimate the splitting of levels taking the difference of the expectation values of V_{crys} with respect to ψ_{B_2} and ψ_{B_3}. Using the point ion lattice approximation and the simple p-type wave functions ($\psi_{px}=Nxe^{-\mu r/\bar{a}}$ and $\psi_{py}=Nye^{-\mu r/\bar{a}}$) set at the origin, we obtain $(\psi_{py}|V_{\text{crys}}|\psi_{py})=0$ and $(\psi_{px}|V_{\text{crys}}|\psi_{px})=\overline{V}_{\text{crys}}$. The order of magnitude for $\overline{V}_{\text{crys}}$ is estimated as about 1 eV. We subtract the expectation value of the term $-(\Delta/2)-\sum_{\substack{i=1,2,3\\ \text{(vacancy)}}} V_{\text{ion}}(i)$ from the total energy values for B_1 state of L-shape model which have been calculated by Gourary[4]. Such values are $-\overline{V}_{\text{crys}}=0.8$ eV ($\mu=1.25$) and 1.5 eV ($\mu=1.5$) for LiF. The corresponding value for KCl is $-\overline{V}_{\text{crys}}=1.1$ eV ($\mu=1.5$). Therefore it seems rather difficult to conclude from Kuwabara and Misu's experiment that the M center has D_{2h} symmetry. Does there remain any possibility that M center has C_{2v} symmetry from the same experiment ? To answer this question, we calculate the energy of the second A_1 state by approximation III which gives $E_{A_1}{}^{(2)}=0.022$ (a.u.) while $E_{B_2}=0.003_5$(a.u.). The difference is rather small. Thus the possibility of the accidental degeneracy of these state is not completely excluded.

Appendix II. The Ionic Potential

As mentioned in § 3 we are rather to use the effective potential which reproduces the spectrum of the free atom. Such a potential for Li is given nummerically in a paper by Kohn and Rostoker[6] and we approximate this by the following analytic form:

$$V(r)=-\frac{1}{r}(1+(2+3.4r)e^{-3.4r}) \qquad (11)$$

Using this $V(r)$ and carrying out similar procedure as mentioned above we obtain the value of $(\varphi_{s0}|H|\varphi_{s0})/(\varphi_{s0}|\varphi_{s0})$ which are summarized in the following table.

$(\psi_{s0}\|H\|\psi_{s0})/(\psi_{s0}\|\psi_{s0})$ $=-0.148$ (a.u.)	using approximation II
$(\varphi_{s0}\|H\|\varphi_{s0})/(\varphi_{s0}\|\varphi_{s0})$ $=-0.094$ (a.u.)	approximation III with Hartree potential (2)
$(\varphi_{s0}\|H\|\varphi_{s0})/(\varphi_{s0}\|\varphi_{s0})$ $=-0.099_5$ (a.u.)	approximation III with effective potential (11)

As seen from the table the dependence of the results on V_{ion} is rather insensitive.

Oxide-Cored Cathode

By Keiichi Ando*, Osami Kamigaito, Yoshihiro Kamiya, Shigetoshi Takahashi and Ryozi Uyeda

Physical Institute, Nagoya University, Nagoya, Japan

(Received September 3, 1958)

We invented the *oxide-cored cathode*. It is a fine platinum wire having an oxide-core. A thin platinum rod is bored along the axis, the empty core made by boring is filled with oxide powder and then the rod is drawn through a series of dies, forming a wire. For example, the diameter of the wire is 0.3 mm and that of the core 0.03 mm. The wire is cut into short pieces and when heated, the cross-section of the piece becomes an electron source.

The oxide-cored cathode was tested in conventional electron microscopes and was found to emit electrons from the cross-section of the core only and that generally, it is more durable than pure tungsten cathode.

§ 1. Introduction

Since Yamaguti[1)] used oxide-coated cathode in his electron diffraction experiment, the use of oxide-cathode has become a common technique of electron diffraction in Japan. After 1950, it was also used in electron microscopy and was adopted for commercial electron microscopes[2)].

The oxide-coated platinum cathode never burns out because of its low running temperature and yet it gives an electron source as bright as that of pure tungsten. Moreover, when a small area is activated, the electron source can be made small. By using such an electron source, Honjo[3)] obtained high resolution electron diffraction patterns with an old style diffraction camera and Sakaki and Möllenstedt[4)] increased the resolving power of the velocity analyzer. The defect of oxide-cathode is its instability, particulartly when the activated area is small. The electron emission gradually decays after a coating, following which a recoating is required every two hours, more or less, according to running conditions.

A few years ago, one of the authors (R.U.)[5)] invented a new type of oxide-cathode, the *oxide-cored cathode*, in which the above mentioned defect is almost entirely eliminated. The aim of the present paper is to describe the method used to prepare the new type cathode and to give some experimental results obtained from its use.

§ 2. Method of Preparation

The oxide-cored cathode is prepared as follows: A thin rod of platinum is bored along the axis not quite through, resulting in a center core with one end open and one end closed. The core is filled with strontium-barium carbonate which is especially prepared for oxide-cathode**. The carbonate is decomposed to oxide by heating in a vacuum at about 950°C for approximately one hour. Then the platinum rod is drawn through a series of dies, forming a wire. To prevent contamination of the oxide, the open end of the core must be closed when the rod is taken out of the vacuum.

The oxide-cored wire is cut into short lengths. Both ends are closed with knippers. If the ends are left open, the oxide absorbs water vapor, increases in volume and is extruded from the core. On that event, the oxide spreads over the tip, making the electron source large. One piece of oxide-cored wire is spot-welded to a heater-wire, as illustrated in Fig. 1, and the tip is cut off before it is used as an electron emitter. After the tip is cut, it is desirable to have it kept in vacuum. However, the tip is not affected within about one hour except when the atmosphere is unusually humid.

The thickness of the core is from $20\mu\phi$ to $100\mu\phi$. For example, the original platinum rod is $2\,\mathrm{mm}\phi$ with a core of $0.6\,\mathrm{mm}\phi$. When the rod is drawn finally through a die of 0.3 mmϕ, a core of 90μϕ is obtained. For a core thinner than 60μϕ, it is convenient to carry out the drawing in two stages. For example, the first rod is 1.8 mmϕ with a core of 0.7 mmϕ. When it is drawn through a die of 0.5 mmϕ, the core becomes 0.2 mmϕ. A core a little thicker than 0.5 mmϕ is bored in the second rod the outer diameter of which is also 1.8 mmϕ. The wire drawn from the first rod is inserted into the core of the second rod. Then the second rod is drawn through a die of 0.3 mmϕ. Thus a core of 35μϕ is obtained.

(b) Both ends of the cored piece closed.
(c) One end cut.
(d) Pasted with alumina.

The oxide-cored wire can also be made of nickel. Since, however, the drawing is much easier for platinum than for nickel, we used platinum in most cases. According to our experience, a core of about 60μϕ is most suitable for usual purposes of electron microscopy and electron diffraction. The outer diameter of the cored wire was, in most cases, 0.3 mmϕ. For the heater-wire, we tried platinum and tungsten. The former was used in most cases. To improve the heating effect, cored piece and the heater-wire were often covered with alumina paste (Fig. 1 d). We found that the effect of the paste was not remarkable.

§ 3. Experiment I

The arrangement used in the first experiment is schematically illustrated in Fig. 2. This is a Müller type electron microscope of very low magnification. The image of the emitting tip is observed on the fluorescent screen.

Electron emission. Early in the experiment complicated patterns appeared on the screen. They were caused by oxide contamination of the cathode tip through careless cutting. When the cathode tip was carefully cut, a single spot appeared on the screen. Searching for the meaning of the spot, the following experiment was tried. After confirming the presence of a single spot, the cathode was taken out of the vacuum. Using a binocular microscope, we put a tiny spot of oxide beside the cross-section of the core (Fig. 2b). This caused the appearance of a second spot beside the first one. Judging by the size of the two spots and the distance between, we proceeded on the inference that the first spot corresponds to the cross-section of the core. If the oxide were spread over the tip and formed an electron source much larger than the cross-section, the second spot would be superposed on the first. Even when the oxide is spread on the tip,[6] the oxide layer is

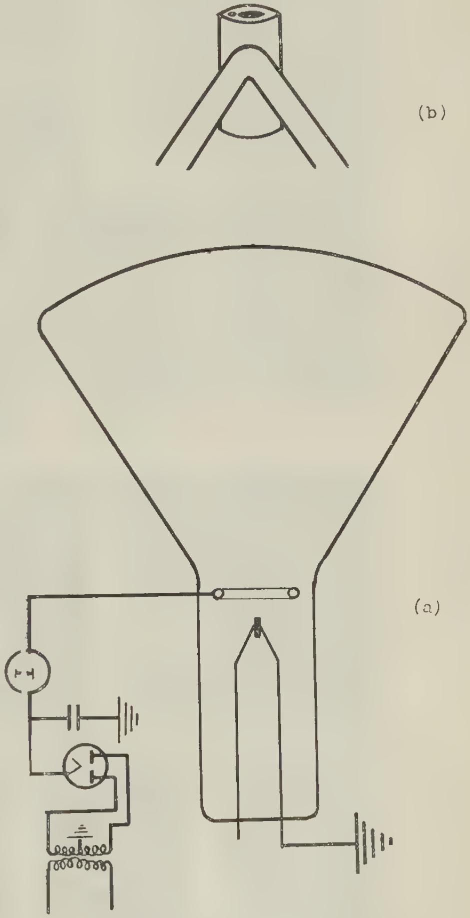

Fig. 2. Illustrating the arrangement of experiment I.

quickly removed in vacua which, in the present experiment, are 10^{-3}–10^{-4} mmHg.

Work function When the temperature of cathode was raised the spot on the screen grew brighter; but the size of the spot did not increase markedly. This indicates that the electron emitting area is almost the same independent of the temperature.

The temperature of the cathode was measured by an optical pyrometer and was varied between 1,100–1,600°K. Then the work function of the oxide-core was determined and it usually turned out to be between 1.5–2.5eV. Sometimes, however, it was as low as 1.2eV, the value in high vacuum[7], and sometimes more than 3.0eV. Results were not reproducible probably because partial pressures of gases and vapors in vacua could not be controlled. The current density was calculated by dividing total current I by the area of cross-section of the core. At 1,300°K it was usually between 0.1–1.0 A/cm². This is the same as the current density for pure tungsten between 2,400–2,600°K. Usually the work function increases gradually and accordingly the current density decreases with time. In the present experiment we often found a thin yellowish layer deposited over the cross-section of the core. This layer is one of the causes of cathode deterioration. The origin of the layer may be the oil vapor coming from the diffusion pump or other residual vapors in the vacuum.

§ 4. Experiment II

The arrangement of the second experiment is illustrated in Fig. 3. This is an old style electron microscope, the electron lenses of which were not used. The electron gun is of a telefocal type[8]. The oxide-cored cathode was set in the gun. To study the electron beam from a large electron emitter, sometimes the whole tip of the cored cathode was coated with oxide, referred to in this section as oxide-coated cathode. For comparison, the usual tungsten hair-pin cathode was also used.

Electron beam from the electron gun To study the electron beam from the gun, the aperture discs at the anode and at the specimen position were taken out (Fig. 3). Thus the whole electron beam fell on the screen. Since the usual fluorescent screen was too bright, we used a glass plate coated with gold. Patterns observed on the screen were remarkably different for different electron emitters, each varying with Wehnelt voltage V_w. Therefore, for each electron emitter we took a series of photographs with varying Wehnelt voltage. Series for oxide-cored, oxide-coated and tungsten hair-pin cathode are reproduced in Figs. 4, 5 and 6, respectively. To make the exposure time adequate, these photographs were taken at cathode temperatures much lower than those for practice in electron microscopy. The pattern on the screen changed slightly with the variation of the temperature. We confirmed, however, that there is no qualitative change such as the apparence and disapparence of the ring pattern (Fig. 5).

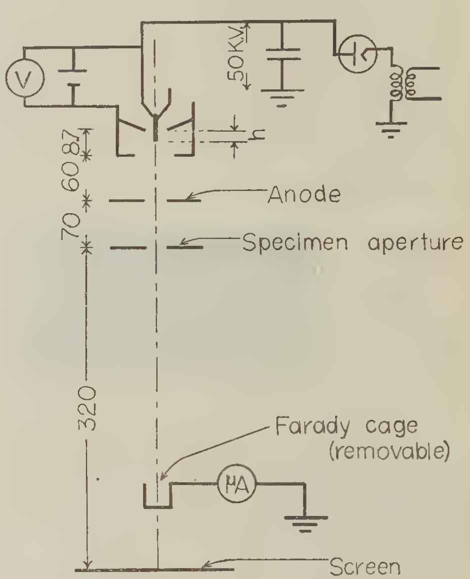

Fig. 3. Illustrating the arrangement of experiment II.

For the tungsten hair-pin cathode, there are the ring pattern indicating a hollow electron beam[9] and the cross-section of a caustic surface[8]. This series is essentially the same as that observed by Steigerwald[8]*. Also for oxide-coated cathode, the ring pattern is observed. The complexity of the pattern may be due to the heterogeneous electron emission at the tip. For the oxide-cored

---

* In "Abb. 6" of Steigerwald's paper, the ring and the caustic both contract to a spot at the same Wehnelt voltage. This is a merit of his electron gun.

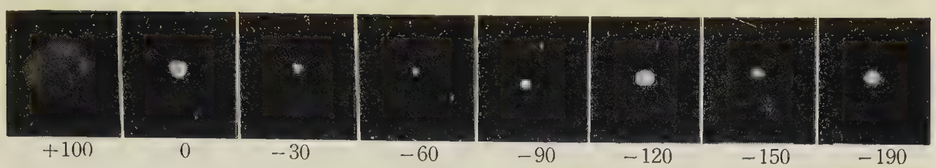

Fig. 4. Oxide-cored cathode. cut-off = −230 volt.

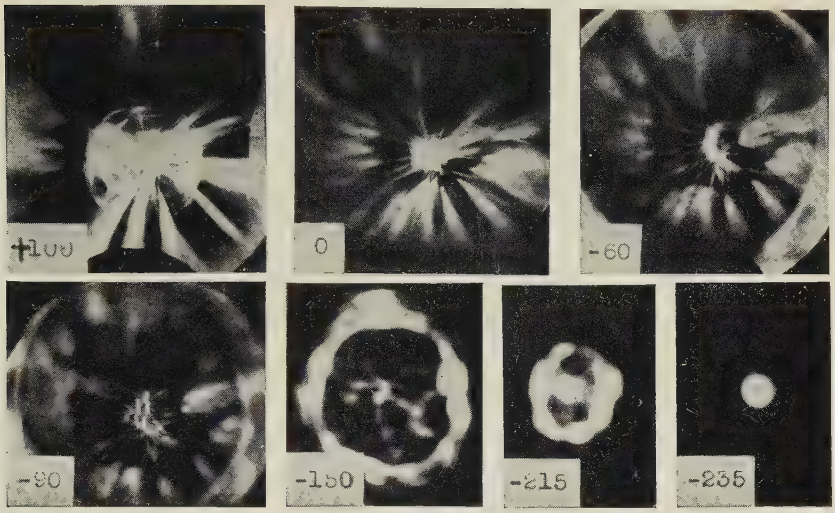

Fig. 5. Oxide-coated cathode. cut-off = −245 volt.

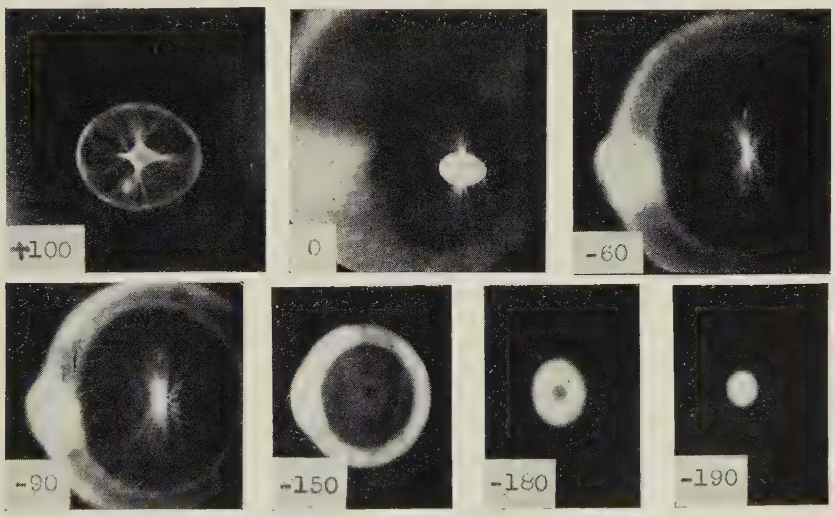

Fig. 6. Tungsten hair-pin cathode. cut-off = −200 volt.

cathode, it is remarkable that the electron beam is always thin showing no ring pattern. At Wehnelt voltage $V_w = -60$ volt, the spot is the smallest and it is the image of the cross-section of the oxide-core. This was confirmed by directly observing the shape of the cross-section by a light microscope. It was also confirmed as follows.

Using a razor blade, a thin line was marked on the face of a cored piece and then the oxide was placed on the line. With this cathode, the image of the core and the line appeared distinctly at a certain Wehnelt voltage (Fig. 7). The image of the very tip of the cathode may be formed in the same way for the tungsten hair-pin and the oxide-coated cathode. However, the image is not recognizable because electrons emitted from the area surrounding the very tip are not focussed simultaneously.

By this experiment we were able to reconfirm one of the results of the previous experiment, i.e. electrons are emitted only from the cross-section of the core. It is also noteworthy that this experiment is useful in a study of the focussing action of Wehnelt cylinder, although this problem is not treated in this paper.

Current density and total current In order to study the current density on the specimen plane as well as the total electron current from the gun, a small aperture of about 0.1 mmϕ was placed on the specimen table of the electron microscope and the current i through the aperture was measured through a Farady cylinder (Fig. 3). Current density j is given by i/s, where s is the area of the aperture. The position of the aperture was always adjusted by the specimen shifting mechanism of the electron microscope, so that i took the maximum value. In the following description, i and j both refer to the maximum values. For each electron emitter, measured values of I and j were plotted against V_w. Figs. 8, 9 and 10 give the plots for the oxide-cored, exide-coated and tungsten hair-pin cathode, respectively. It is remarkable that the result depends very much on the kind of electron emitter even when the same Wehnelt cylinder is used.

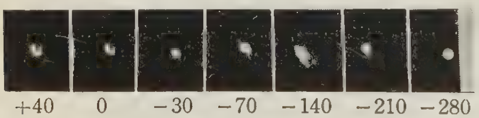

Fig. 7. Oxide-cored cathode with a knife mark.

For oxide-cored cathode, a sharp maximum of j appears at a certain value of V_w. This maximum corresponds to the focussed image of the cross-section of the core. Total current I is almost constant except near the cut-off voltage. This implies that almost all electrons emitted from the cross-section of the core depart from the electron gun.

For oxide-coated cathode, no distinct maximum of j appears because no distinct image is formed. Total current I increases rapidly with the decreases of $(-V_w)$. This implies that the electron emitting area is limited by the action of the Wehnelt cylinder. Total current I is increased when the area is enlarged with the decrease of $(-V_w)$. It is event that $j-V_w$ and $I-V_w$ diagrams depend not only on the design of Wehnelt cylinder but also on the size and shape of the electron emitter. We can say that Fig. 8 and Fig. 9 are an example of a small area and that of a large area electron emitter, respectively. The small area electron emitter gives a high current density with a small total current.

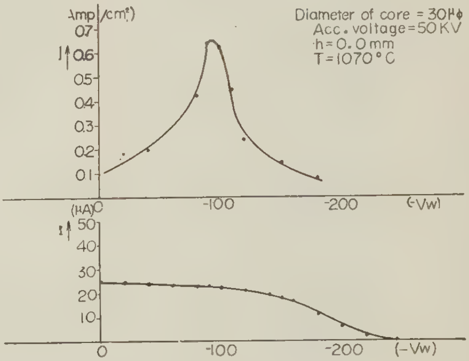

Fig. 8. Oxide-cored cathode.

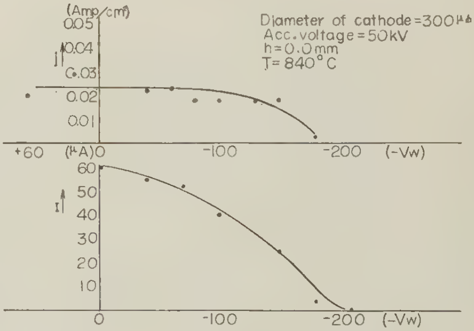

Fig. 9. Oxide-coated cathode.

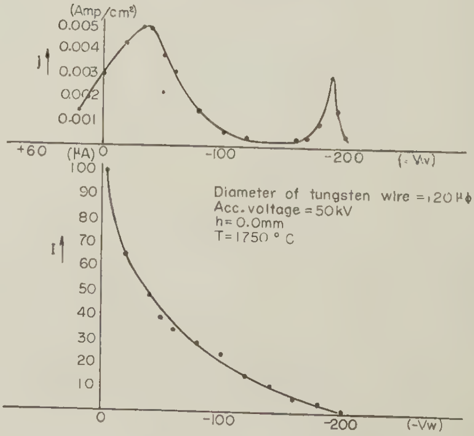

Fig. 10. Tungsten hair-pin cathode*.

For tungsten hair-pin cathode, two maxima of j appear.* The maximum near the *cut-off* appears when the ring of the hollow beam contracts to a spot and that at a lower value of $(-V_w)$ corresponds to the focussed image of the very tip of the hair-pin. Total current I increases rapidly with the decrease of $(-V_w)$.

Durability of oxide-cored cathode In the course of the experiment, we often took the cathode out of the vacuum and inspected the tip under a light microscope. Usually, the thin yellow layer, as described in Sec. 3, was found when the emission had decreased. Sometimes, however, the oxide evaporated gradually from the surface, resulting in a shallow hollow. Even under such a condition electrons were emitted not only from the boundary but from the whole cross-section of the hollow. In a few cases, we found that the core about 3 mm in length was perfectly hollow when the emission stopped.

It is most difficult to compare the durability of cathodes, because any comparison must be carried out under the same vacuum condition and at the same emission current density on the surface of emitters. In as much as we could not make a comparison under fixed conditions, we must infer the durability from our experience. We carried out a series of experiments with five tungsten hair-pin cathodes of 0.12 mmϕ and more than ten oxide-cored cathodes of core diameter 30–60 $\mu\phi$. During the experiments, the vacuum condition and the current density on the specimen surface (not on the emitter surface) were nearly the same. Tungsten cathode usually burned out after 10 hours while oxide-cored cathodes were still usable even after 30 hours. Thus we may say that the oxide-cored cathode is more durable than the tungsten cathode.

§ 5. Discussions

There are known to have been only a few trials for making electron sources smaller than 100$\mu\phi$. One is Hibi's "pointed filament".[10] He used a very sharp tungsten needle with a tip having the radius of curvature less than 5 microns. When the needle is heated, electrons are emitted not only from the conical side as well. Therefore, Wehnelt cylinder must have the area limiting action to make the effective electron source small. If the Wehnelt cylinder be appropriate, the "pointed filament" would give the smallest electron source.

Another trial was made by von Ardenne[6]. He covered a small crystal of lantern boride with a molybdenum sheet having a small hole in it. The crystal emits electrons through the hole. Although recent developments of his work are unknown, it would seem difficult to make electron sources smaller than 30$\mu\phi$ by his method.

Cored cathode is not only possible for oxide but also for any good electron emitter. We have already tried tantal-cored tungsten cathode and are going to try lantern boride-cored molybdenum cathode which, when completed, may give small electron emitter more stable and more durable than oxide-cored cathode.

Study of Metallic Carbides by Electron Diffraction
Part III. Iron Carbides

By Sigemaro NAGAKURA

Tokyo Institute of Technology, Oh-okayama, Meguro-ku, Tokyo

(Received October 2, 1958)

Thin iron films formed by evaporation were carburized in CO gas stream. The carbides ε, χ and θ were found to be formed in the temperature ranges (i) below 250°C, (ii) from 250° to 350°C and (iii) above 350°C, respectively. The ε-carbide is hexagonal with lattice constants $a=4.767$ Å and $c=4.354$ Å, and its structure belongs to the space group $P6_322$, iron atoms occupying $6g$ positions with the parameter $x=1/3$ and carbon atoms $2d$ positions. Irreversible phase transitions from ε to χ and from χ to θ take place at 380°~400°C and at about 550°C, respectively. By the transitions changes in the chemical compositions may be very small. Observation on the crystal growth suggests that a mechanism of the ε-carbide formation is different from that of the χ- and θ-carbide formations.

§ 1. Introduction

It has been reported that there exist four kinds of iron carbides: the ε-, χ-, θ- and cubic carbides. The θ-carbide (cementite) is the best known iron carbide of the chemical composition Fe_3C and of the orthorhombic structure.[1-3] The χ-carbide (Hägg carbide or percarbide) was found by Hägg[4], Jack[5], and Hofer, Cohn and Peebles[6]. It gives a complex X-ray powder pattern resembling that of the θ-carbide and according to Jack the structure is probably either orthorhombic or hexagonal. The ε-carbide was found by Hofer, Cohn and Peebles[6] and gives a X-ray powder pattern due to a c.p.h. structure. From the electron diffraction study, Pinsker[7] proposed the existence of a cubic carbide of lattice constant $a_0=3.875$ Å. Its chemical composition was considered to be Fe_4C. Different chemical compositions have been given to the ε- and χ-carbides: according to Cohn and Hofer[8], the chemical compositions of the ε- and χ-carbides are equal to each other and correspond to $Fe_{2.4}C$, while, according to Jack, the chemical composition of the χ-carbide is $Fe_{20}C_9$ ($Fe_{2.2}C$)[5] and that of the ε-carbide varies in a range from Fe_2C to Fe_3C[9].

Trillat and Oketani[10] studied by the electron diffraction thin evaporated iron films carburized by CO and $CO+H_2$ gases and produced the χ- and θ-carbides but failed in producing the ε-carbide. The present author studied the iron carbides by the same method and some of the results have been reported[11]. The present paper describes the results of their formation, crystal structure, decomposition and phase transition in detail.

§ 2. Experimental Method

The method of preparation of the iron carbides was similar to that of the nickel carbide reported in the previous paper (Part I of this series)[12]. Evaporated iron films of thickness 200~300 Å were carburized in CO gas stream. Two kinds of iron films were used, namely, polycrystalline films without preferred orientation (P.C. films) and films with single crystalline orientation (S.C. films). The P.C films were prepared by evaporating iron on cleavage faces of single crystal of rock-salt kept at room temperature and the S.C. films by evaporating on the faces kept at about 500°C. Photo. 1 (a) reproduces an electron diffraction pattern of a P.C. film, showing the Debye rings due to the α-iron (b.c.c.). The half-breadth of the rings corresponds to a mean particle size of 50 Å. The temperature of the cementation ranged from 140°C to 500°C and the time of the treatment, from 1 to 6 hrs.. When the temperature was lower than about 350°C, the iron films were not carburized but oxidized to Fe_3O_4, as reported by Trillat and Oketani.[10] It was found, however, that when the specimen films were covered by fine iron powder, prepared by reduction of iron oxide powder in hydrogen stream at about 400°C for several hours, they were carburized without oxidation even below 350°C. At temperatures above 400°C this procedure was rather unfavourable because it accelerated the deposition of amorphous carbon on the specimen film.

The phase transition and decomposition of the iron carbides in vacuum were studied in two ways: (i) the carbide films were heated in a vacuum furnace for 2 min.～16 hrs., and (ii) they were heated in an electron diffraction camera at the rate of temperature rise 2°～4°C per min. and changes of the diffraction pattern were continuously observed. The temperature of the specimen film was measured by a thermo-couple placed as near as possible to the film. The accuracy of the thermo-couple indication is considered to be several degrees[12]. In both the treatments no oxidation of the carbide films took place.

§ 3. Formation of Iron Carbides

The P.C. films were carburized comparatively easily: the cementation for several hours converted the iron films completely to the carbide ones. The carburized products which gave electron diffraction patterns as reproduced in Photo. 1 (b), (c) and (d) were obtained in the temperature ranges shown in Fig. 1 (a), i.e. (i) below 250°C, (ii) 250°～350°C and (iii) above 350°C, respectively. As shown later these products were identified with the ε-, χ- and θ-carbides. When the iron films were carburized at temperatures above 350°C, a pattern due to amorphous carbon superposed on the carbide pattern. Above 400°C the diffraction patterns were sometimes composed only of the amorphous carbon. No product which can be identified with the cubic carbide was found throughout this work.

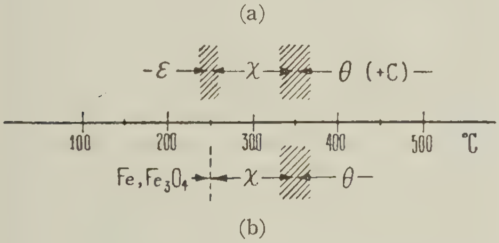

Fig. 1. Temperature range of the carbide formation (a) from P. C. films and (b) from S. C. films. The hatch indicates the region where two kinds of the carbides were produced.

Formation of the carbides from the S.C. films was more difficult than from the P.C. films. Fig. 1 (b) shows the temperature ranges of the carbide formation from the S.C. films. The ε-carbide could not be produced even after a prolonged treatment for 20 hrs., the heat treatment below 250°C only resulting in oxidation of the iron films. Above 250°C, however, the χ- and θ-carbides with certain epitaxial relations to the α-iron could be formed. The diffraction patterns of the χ-carbide were accompanied often by reflections due to Fe_3O_4 (Photo. 2).

Surface of the iron powder which was used to prevent the specimen films from being oxidized during the cementation was also examined. It was found that below 350°C the surface of the powder was oxidized to Fe_3O_4 and above 400°C it was covered by the amorphous carbon.

1. ε-carbide

Photo. 1 (b) is an electron diffraction pattern of the carbide produced by the cementation at 230°C for 6 hrs.. In Table I its spacings and intensities are tabulated. The reflections are classified in two groups: *M*- and *s*-reflections. The *M*-reflections are strong and can be indexed by a c.p.h. structure having lattice constants

$$a_h=2.752\text{Å},\quad c_h=4.353\text{Å}$$

and

$$c_h/a_h=1.576,$$

which are different only slightly from the X-ray data of the ε-carbide due to Hofer *et al.* ($a_h=2.749$ kX, $c_h=4.340$ kX, $c_h/a_h=1.579$)[6]. The mean particle size was estimated to be 55Å from the half-breadth of the Debye rings. It is worth-while to mention the fact that this particle size is not appreciably different from that of the original α-iron. The *s*-reflections are very weak and broad. All the reflections can be indexed by a new hexagonal lattice of constants

$$a=\sqrt{3}\,a_h=4.767\text{Å},\quad c=c_h=4.354\text{Å}$$

and

$$c/a=0.913_4.$$

The axial ratio c_h/a_h was measured in electron diffraction patterns at various temperatures and the result was plotted in Fig. 2. The plots

* See Reference No. 6.

against the temperature t can be fitted by a straight line

$$c_h/a_h=1.575(1+17\times10^{-6}t).$$

The temperature coefficient is remarkably larger than that of Ni_3C ($=6\times10^{-6}$). Details of the structure of the ε-carbide will be discussed in § 4.

2. *χ-carbide*

Photo. 1 (c) reproduces an electron diffraction pattern of the carbide produced by carburizing a P.C. film at 300°C for 3 hrs. and Photo. 2, that of the carbide produced by carburizing a S.C. film at 260°C for 6 hrs.. In Table II observed spacings and visual intensities of the Debye rings are tabulated. Most of them agree very well with the X-ray data of the χ-carbide due to Jack. However, many additional reflections which could not be observed in his pattern were found. From the X-ray powder pattern Jack mentioned that the unit-cell of the χ-carbide was probably either orthorhombic with lattice constants $a=9.04_3$ kX, $b=\sqrt{3}a=15.66_3$ kX and $c=7.92_1$ kX or hexagonal with lattice constants $a'=2a=18.08_6$ kX and $c'=c=7.92_1$ kX,[5] but these reflections could not be indexed by his unit-cell, suggesting that his unit-cell is not correct.

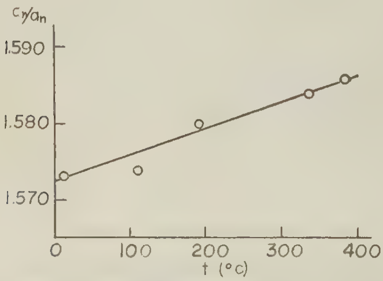

Fig. 2. Thermal change of the axial ratio c_h/a_h of ε-carbide.

3. *θ-carbide*

Photo. 1 (d) reproduces an electron diffraction pattern of the carbide formed by carburizing a P.C. film at 350°C for 3 hrs.. In Table III observed spacings and visual intensities are tabulated and compared with the X-ray data of the θ-carbide[13]. They agree very well. The structure is orthorhombic

1) (*hkl*) is the forbidden reflection. 2) Calculated from the lattice constants $a=4.5155$Å, $b=5.0773$Å, $c=6.7265$Å (25°C) due to W. Hume-Rothery *et al.*13). 3) See reference No. 2 (X-ray data).

with lattice constants

$a=4.516$ Å, $b=5.077$Å and $c=6.727$Å.

In the pattern many forbidden reflections are observed, but they may be considered to be due to the multiple reflection of electrons.

Photo. 3 reproduces an electron diffraction pattern of the θ-carbide formed from a S.C. film after the cementation at 500°C for 1 hr.. The carbide grows on the film of α-iron with a definite epitaxial relation: it is either

$$(1\bar{2}1)_\theta//(110)_\alpha,\quad [111]_\theta//[001]_\alpha,$$

or

$$(111)_\theta//(001)_\alpha,\quad [\bar{2}11]_\theta//[0\bar{1}0]_\alpha.$$

Trillat and Oketani represented the epitaxial relation by relations $(111)_\theta//(001)_\alpha$ and $(1\bar{2}1)_\theta//(110)_\alpha$[14]. But this representation is not consistent, because an angle between $(111)_\theta$ plane and $(1\bar{2}1)_\theta$ is 87°39′, while $(001)_\alpha$ and $(110)_\alpha$ are perpendicular.

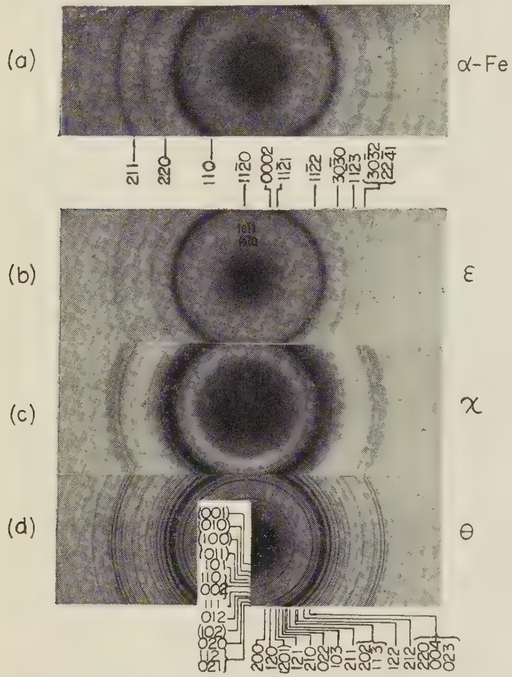

Photo. 1. Electron diffraction patterns of
(a) α-iron film evaporated in vacuum,
(b) ε-carbide film produced by the cementation at 230°C for 6 hrs,
(c) χ-carbide film produced by the cementation at 260°C for 6 hrs, and
(d) θ-carbide film produced by the cementation at 350°C for 3 hrs. Indices in brackets correspond to the forbidden reflections.

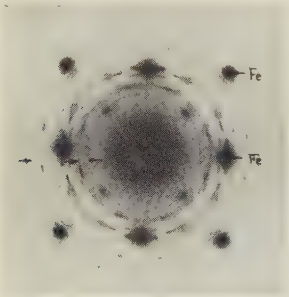

Photo. 2. Electron diffraction pattern of a S.C. film carburized at 260°C for 6 hrs., showing an epitaxial growth of χ-carbide with respect to α-iron. Spots and rings due to Fe_3O_4 (indicated by arrows) are also observed.

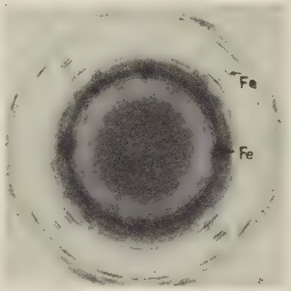

Photo. 3. Electron diffraction pattern of a S.C. film carburized at 500°C for 1 hr, showing an epitaxial growth of θ-carbide with respect to α-iron.

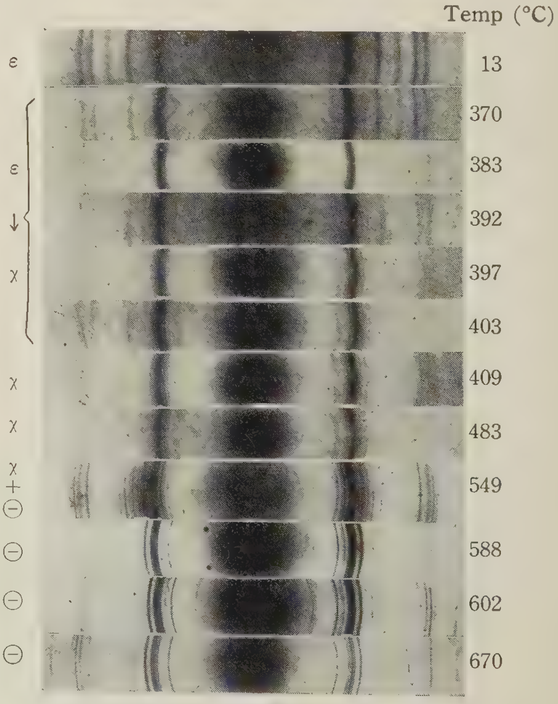

Photo. 4. A series of electron diffraction patterns showing the phase transition from ε-carbide to χ-carbide and from χ-carbide to θ-carbide.

§ 4. Crystal Structure of ε-carbide

The feature of the electron diffraction pattern of the ε-carbide mentioned in § 3.1 resembles that of the nickel carbide described in the previous paper (Part I[12] & II[15]). The strong M-reflections, which can be indexed by the c.p.h. lattice, suggest a c.p.h. arrangement of iron atoms similar to the case of the nickel carbide. The s-reflections are considered to be due to a regular arrangement of carbon atoms among the octahedral interstices of iron atoms. The systematic absence of the s-reflections of ε-carbide, however, is different from that of nickel carbide, resulting in the ' hexagonal lattice ' instead of the ' rhombohedral lattice ' of the nickel carbide. The most appropriate interpretation of the observed pattern of the ε-carbide is given by assuming the space group $P6_322$ and the atomic positions:

Fe atoms: $6g$, $x, 0, 0;\ 0, x, 0;\ \bar{x}, \bar{x}, 0;$
$\bar{x}, 0, 1/2;\ 0, \bar{x}, 1/2;\ x, x, 1/2,$
with $x=1/3$,

C atoms: $2d$, $1/3, 2/3, 3/4;\ 2/3, 1/3, 1/4,$
(or $2c$, $2/3, 1/3, 3/4;\ 1/3, 2/3, 1/4$).

In Table I calculated intensities are compared with the observed intensities. The observed intensities were obtained by photometry using Karle and Karle's method. Both values are normalized at the $(30\bar{3}0)$ ring. They coincide fairly well*. The basal plane projection of the structure is illustrated in Fig. 3. Here, iron atoms (A, B) take the c.p.h. arrangement and carbon atoms (C_2, C_3) occupy one-third of the octahedral interstices of the iron atoms. In the lattice the carbon atoms also form a c.p.h. stacking order. The stacking order of atomic planes along c-axis can be represented by a formula, $(C_2)A(C_3)B(C_2)\cdots$. The structure is different from that of the nickel carbide, $(C_1)A(C_2)B(C_3)A(C_1)B(C_2)A(C_3)B(C_1)\cdots$, only in respect of the stacking order of the carbon layers.

The half-breadth of M-reflections, β_M, was 1.1×10^{-3} for all the observed rings and that of s-reflections, β_s, was about 3×10^{-3}: β_s is about three times as large as β_M. This fact suggests that there exists a kind of disorder in the carbon lattice. In case of the nickel carbide the s-reflections elongated only along c^*-axis in the reciprocal lattice and this was considered to be due to a kind of one-dimensional stacking disorder of the carbon layers.[15]

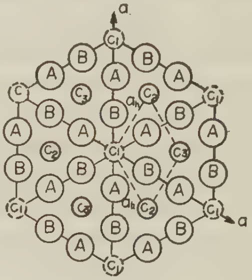

Fig. 3. Basal plane projection of the structure of ε-carbide. Iron atoms are indicated by A and B, and carbon atoms by C_2 and C_3. The position C_1 are unoccupied. The dashed lines indicate the unit-cell due to Hofer *et al.*. Height of atoms: A: 0, B: 1/2, C_2: 3/4, C_3: 1/4, (C_1: 1/4 or 3/4).

In case of the ε-carbide, however, no appreciable difference was found between the half-breadths of $(10\bar{1}1)$ and $(10\bar{1}0)$ rings, suggesting that the disorder takes place not only in the stacking order of the carbon layers but also in the carbon layers themselves. Thus, a domain of an ε-carbide crystal with respect to the arrangement of iron atoms is considered to be composed of a number of secondary domains with respect to the arrangement of carbon atoms. The domain sizes estimated from the half-breadths β_M and β_s are about 55Å and 20Å, respectively.

In the above we have discussed the structure by assuming that the chemical composition of the ε-carbide is Fe_3C. According to Jack, however, the composition varies in the range from Fe_3C to Fe_2C without any considerable structural difference. If so, ' extra ' carbon atoms should occupy the positions (C_1) in Fig. 2.

The epitaxial relation between the ε-carbide and α-iron could not be determined, since the ε-carbide was not formed from the S.C. films. But it is very likely that the epitaxial relation found in case of the transformation from b.c.c. into c.p.h. of Ti, Zr, Li etc. holds also in the present case: that is

---

* For the particle size of 55Å and the wavelength of 0.06Å (40 keV) the primary extinction coefficient $f\ (=I/|F|^2$, where I is the intensity and F the structure amplitude)[15] is calculated to be 0.97 for the (0002) reflection which has the largest structure amplitude. Therefore, the effect need not be taken into consideration.

$$(00.1)_{\varepsilon}//(\bar{1}01)_{\alpha},\quad [11.0]_{\varepsilon}//[111]_{\alpha},$$

were the c.p.h. index is used for the ε-carbide.

§ 5. Phase Transition of Iron Carbides

All kinds of iron carbide films kept in a desiccator more than a year showed no appreciable change of their electron diffraction patterns, indicating that they are very stable at room temperature. The diffraction pattern of ε-carbide films kept at 350°C in vacuum for 30 min. showed no appreciable change but it changed to the pattern of the χ-carbide when kept at 400°C for several min.. The pattern of the χ-carbide did not show any change by heating at 450°C for 30 min. but it changed to the pattern of the θ-carbide when kept at 550°C for 2 min.. When a θ-carbide film was heated at 600°C, iron rings appeared in the electron diffraction pattern after 10 min.. After heating for 16 hrs. at temperatures above 600°C the diffraction pattern was composed of rings due to the θ-carbide, the α-iron and the graphitic carbon. The pattern of the θ-carbide became very spotty by the heating, showing that a considerable crystal growth had taken place.

The changes in the electron diffraction pattern of the ε-carbide by heating were observed continuously using the high temperature electron diffraction camera. A series of the diffraction patterns is reproduced in Photo. 4. No appreciable change was observed up to 370°C but at 383°C new rings began to appear, their intensities increasing with temperature at the cost of those of the ε-carbide rings. Finally, the pattern changed to that of the χ-carbide at 403°C. The pattern of the χ-carbide changed at 549°C to become that of the θ-carbide. Thus, we can see that the ε-carbide transforms to the χ-carbide at 380°∼400°C and the χ-carbide transforms to the θ-carbide at about 550°C. The transformations are irreversible. It is worth mentioning that the ε-carbide did not show any appreciable crystal growth by the heating, while the χ- and θ-carbides showed crystal growth.

By the above phase transitions we could never find in our electron diffraction patterns any indication of precipitation of carbon, which should appear if the chemical compositions of the ε-, χ- and θ-carbides are as much different from each other as have been reported. This suggests that the change in the composition by the transitions is, if any, very small. A possible amount of the change can be estimated as follows. Let us put the chemical composition of the ε- or χ-carbide to $Fe_{3-x}C$ and that of the θ-carbide to Fe_3C, and compare the intensity of the $(0002)_C$ ring of the graphite with that of the $(101)_\theta$ ring of the θ-carbide on the assumption that the decomposition $Fe_{3-x}C \rightarrow Fe_3C + C$ took place by the phase transitions. The scattering angle of the $(0002)_C$ ring is near to that of the $(101)_\theta$ ring and the former ring is strongest among the graphite rings, while the latter ring is weakest among the lower order rings of the θ-carbide, though this could be clearly observed in our electron diffraction patterns (see Photo. 1 (d)). In general, the integrated intensity per unit length of a Debye ring is given by

$$P = p\beta = I_0 \frac{\lambda}{8\pi L} \frac{j}{s^2} \left| \frac{F}{v} \right|^2 \Delta V,$$

where p is the peak intensity, β the half-breadth, I_0 the intensity of incident electron, λ the wave-length, L the camera length, j the multiplicity factor, $s = 2\sin\theta/\lambda$ (θ: Bragg angle), F the structure amplitude, v the unit-cell volume and ΔV total volume of the sample irradiated by the electron beam. Calculation shows that

$$P_C = p_C\beta_C = I_0 \frac{\lambda}{8\pi L} \cdot 2.8\times10^{-1} \Delta V_C$$

for the $(0002)_C$ ring of graphite and

$$P_\theta = P_\theta\beta_\theta = I_0 \frac{\lambda}{8\pi L} \cdot 4.8\times10^{-3} \Delta V_\theta$$

for the (101) ring of the θ-carbide. The particle size of the precipitated carbon is usually so small that the half-breadth of its Debye ring may amount to ten times as broad as that of the θ-carbide (cf. Part I, Photo 7 & 8 of Ni_3C). In our electron diffraction pattern of the θ-carbide a ring, its peak height being one-tenth of p_θ, was observed clearly. Thus, if some amount of graphite was precipitated by the phase transitions to produce the $(0002)_C$ ring of the peak intensity $p_C = (1/10)p_\theta$, the above equations lead to

$$\frac{\Delta V_C}{\Delta V_\theta}=1.7\times10^{-2}.$$

Since ΔV=(number of molecules×molecular mass)/density, this gives

$$\frac{\text{number of molecules of carbon}}{\text{number of melecules of Fe}_3\text{C}}=\frac{1}{13}\,.$$

Then, the chemical composition of the initial carbide, $Fe_{3-x}C$, must be $13Fe_3C+C=Fe_{39}C_{14}$, or $Fe_{2.8}C$. Therefore, the amount of change in the composition x must be smaller than 0.2 by the phase transitions.

§ 6. Discussion

The ε-carbide could not be produced from the iron films prepared on the substrates kept at elevated temperatures though it could be produced easily from the P.C. films. This is considered to be due to that, for the ε-carbide formation, imperfections in α-iron crystals, such as lattice vacancies, dislocations and grain boundaries, play an important role to accelerate the diffusion of carbon atoms and to form nuclei of the carbide crystals as it was the case with the formation of the nickel carbide (Part I). As mentioned above (§ 3.1) the particle size of the ε-carbide is nearly equal to that of the original α-iron. This suggest that one crystal of α-iron converts to one ε-carbide crystal and no recrystallization takes place in the process of the ε-carbide formation. It was found that in the carbide lattice carbon atoms are distributed regularly among the octahedral interstices of iron atoms, though the regularity does not spread over the matrix crystal.

The χ- and θ-carbides could be produced always from both P.C. and S.C. films. Their crystal structures are very complex and bear no simple crystallographic relations to the α-iron. They are produced at higher temperatures than that of the ε-carbide formation and their particle size becomes much larger than that of the α-iron. Therefore, the mechanism of their formation is considered to be different from that of the ε-carbide: nuclei of the χ- and θ-carbide crystals are formed on the crystal surface of the α-iron and grow up gradually. The imperfections in the α-iron crystals are not considered to play an essential role in these cases.

It was revealed that the phase transition of iron carbides, $\varepsilon\to\chi\to\theta$, takes place irreversibly without any appreciable change in the composition. Hofer *et al.*[6] reported that the magnetic Curie point of the ε-carbide is 380°C, but according to the present result this temperature should not be the Curie point but the structural transition point from ε to χ. It was also found that the χ-carbide transforms to the θ-carbide at about 550°C. Cohn and Hofer[16] proposed a method of preparation of pure θ-carbide sample by heating a mixture of the χ-carbide and the α-iron, but admixing of the α-iron is unnecessary.

Acknowledgement

The author should like to express his hearty thanks to Professor S. Oketani for his guidance throughout the present work, and also to Professor G. Honjo for his valuable discussion and helpful advice. This work was supported by a Grant in Aid for Fundamental Scientific Research from the Ministry of Education.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 14, No. 2, FEBRUARY, 1959

On the Magnetic Properties of Vanadium Sulfide and Selenide*

By Ichiro TSUBOKAWA

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai, Japan

(Received November 4, 1958)

Magnetic, thermal and crystallographic properties of sulfide as well as selenide of vanadium with nickel arsenide structure were investigated experimentally. The antiferromagnetic Néel points for these compounds were found to be about 1040° and 163°K respectively. A correction for the atom core diamagnetism was applied to the observed susceptibilities; the inverse susceptibility decreased linearly with the fall of temperature. Based on this result, the Curie constant, C_M, the spin quantum number, S and the asymptotic Curie temperature, θ, were obtained as 1.63, 2.9/2 $-3000°$ for sulfide and 2.15, 3.2/2 and $-2570°$ for selenide respectively. Anomalous heat absorptions at the magnetic transition in both compounds were 615 and 50 cal/mol respectively. Experimental results obtained are discussed briefly.

§ 1. Introduction

It is well known that many of the compounds between the first transition elements and those of the fifth or the sixth group in the periodic table of elements have nickel arsenide structure. Investigations of the magnetic properties for these compounds were mostly concerned with those which contain cations with more than half filled 3d-shells. Anderson[1)] suggested that the superexchange interaction due to Kramers' model is ferromagnetic or antiferromagnetic according as the 3d-shells of cation are filled less than or more than half, respectively. Ferromagnetic chromium telluride[2)] as well as antiferromagnetic manganese telluride[3)] were thought to be a suitable example of his theory. Contrary to this consideration, however, chromium sulfide[4)], selenide[5)] and antimonide[6)] are known to be antiferromagnetic. From such a point of view, it is interesting to investigate whether the vanadium compounds, VS and VSe, are antiferromagnetic or ferromagnetic, since it is clear that the 3d-shell of these compounds is considered to be of less than half filled type.

§ 2. Specimens and Experimental Results

According to Bilts and Kocher[7)] as well as Hoschok and Klemm[8)], vanadium sulfide forms a eutectic with vanadium and was reported to have nickel arsenide structure with the parameters a=3.34Å, c=5.78Å and c/a=1.73. It was also reported that there is a nickel arsenide structure phase in V-Se system ranging from 55.5 to 61.5 atomic percentage of selenium with parameters a=3.587Å, c=5.989Å and c/a=1.670.

The specimens of these compounds used in the present experiment were prepared as follows: Powders of vanadium (99.8%) and sulfur or selenium (99.99%) were mixed in stoichiometric proportion (fifty atomic percent), sealed in evacuated silica tubes and preheated at 1000°C for a week. To promote the reaction, the products were pulverized, mixed again and reheated in the same way. All specimens thus obtained were examined by X-ray technique; the diffraction lines of vanadium sulfide and selenide shown in Table I could be indexed as the nickel arsenide structure, and their lattice constants were calculated to be a=3.33Å, c=5.82Å and a=3.66Å, c=5.95Å respectively. These values coincide well with the results of the former investigations mentioned above.

The temperature dependence of magnetic susceptibility was obtained by the magnetic balance of an automatically recording type[9)]. The values of susceptibility were corrected by taking into consideration the diamagnetism of inner atomic cores[10)]. Such corrections for each compound are shown in Table II.

The corrected values of susceptibility are

plotted aginst temperature in Fig. 1, which shows a maximum at 1040° and 163°K for vanadium sulfide and selenide respectively. The inverse of susceptibility is also traced in the same figure. These curves show that the Curie-Weiss law holds very well for the temperature range higher than the maximum of susceptibility.

The specific heats as a function of temperature for vanadium sulfide and also selenide were obtained by an automatically recording calorimeter of the adiabatic type[11]. In both compounds, Λ-shaped anomaly is found at about the same temperature corresponding to the maximum in χ-T curves. The results are shown in Fig. 2. Anomalous heat absorption considered to be due to the magnetic transformation for vanadium sulfide and selenide were estimated from the above C_p-T curves as 615 and 50 cal/mol respectively.

§ 3. Discussion of the Results

As shown in Fig. 1, each compound has a maximum in the susceptibility-temperature curve, and the temperature corresponding to this maximum of susceptibility may be considered as the antiferromagnetic Néel point, T_N. The values of T_N are listed in the last column of Table III. Such supposition was confirmed by the experimental results of specific heat, in which anomaly occurred at about the same temperature as that T_N. It should be noted here that in the case of vanadium sulfide, the temperature corresponding to the maximum of susceptibility is seen to be about 100° higher than that of the well-defined peak of the specific heat, however, it is also to be noticed that the hump in susceptibility shown in the figure is so broad that the point of maximum is not so well defined as in the case of specific heat. On the other

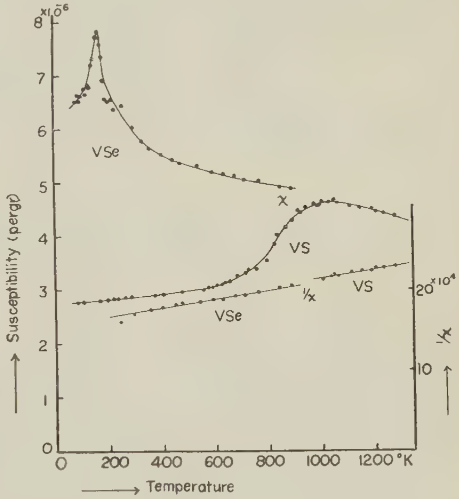

Fig. 1. Susceptibility versus temperature curves of vanadium sulfide and selenide. (Inverse susceptibility was also plotted.) These curves were corrected for the diamagnetism of inner atom core.

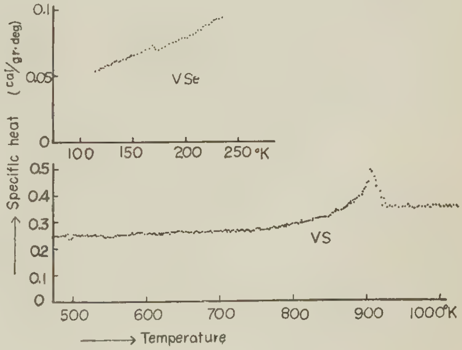

Fig. 2. Specific heat versus temperature curves of vanadium sulfide and selenide.

hand, Suzuoka et al[12] found the anomlous change of electrical resistivity and of dilatation due to temperature at about the same point as that corresponding to the maximum of susceptibility. From the inverse susceptibility above the Néel point, we can determine the Curie constant C_M, the magnetic spin quantum number S by assuming that the Landé factor is two and the asymptotic Curie temperature θ. The results are shown in Table III.

Table III. Curie constant C_M, spin quantum number S and asymptotic Curie point θf or vanadium compounds.

Compounds	C_M	θ	S	T_N
VS	1.68	−3000°	2.9/2	1040°K
VSe	2.15	−2570°	3.2/2	163°K

From the observed values of θ and T_N, the ratio θ/T_N were obtained to be −3 and −16 for vanadium sulfide and selenide respectively. In the case of the crystal lattice with nickel arsenide structure, each cation in the crystal has three kinds of cation neighbor with nearly equal inter-atomic distance. In the molecular field approximation, the ratio θ/T_N for such a case can be expressed as a function of ratios among the exchange integrals for each kind of neighbor, and it was found that the minimum value of θ/T_N is −5[13]. Hence the present result for sulfide is acceptable, while that for selenide lies beyond the theoretical expectation.

As the divalent ion of vanadium is in a state of ^{4}F, the spin quantum number of ca 3/2 obtained above seems to correspond to it. Thus the 3d shell of vanadium ion in the above mentioned compounds is considered to be less than half-filled; based on the simple Kramers and Anderson superexchange mechanism[1], it is to be expected that the sulfide and selenide of vanadium will be ferromagnetic, while the experimental results show that they are antiferromagnetic. However, a recent development of the theory by Slater[14], Anderson-Hasegawa[15] and Kanamori[16] shows that an other influence on the behavior of superexchange interaction arises from the different ionic states of cations in the crystal lattice. On this point of view, the superexchange mechanism of the present compounds should be discussed more in detail.

Acknowlegements

The author wishes to express his hearty thanks to Prof. T. Hirone for his kind encouragement throughout the course of the present study. He also wishes to express his sincere thanks to S. Maeda and N. Tsuya for their useful discussions.

Spectro-Polarization Characteristics of the Sodium Nitrate Polarizer

By Tasaburô YAMAGUTI
College of Arts and Sciences, Chiba University
Isao MAKINO, Shingo SHINODA and Ippei KUROHA
Taga works, Hitachi Ltd

(Read April 3, 1957; Received October 20, 1958)

The polarization characteristics of the sodium nitrate polarization prism are measured. Polarization effect is complete from 350 to 1,000 mμ; and transmission of light uncorrected for reflection at the surfaces is about 90% at above 400 mμ and 37% at 350 mμ. Possibility of making a polarization prism for a wide wavelength range from 250 to 1,000 mμ is discussed.

§ 1. Introduction

A method making the sodium nitrate polarization prism is already reported by one of the authors[1]. The present work is concerned with the polarization characteristics of the prism for monochromatic rays of several wavelengths from 350 to 1,000 mμ.

§ 2. Experimental

The polarization prism used for the measurement has a structure shown in Fig. 1, the length and aperture are 27 mm and 11×11 mm respectively; an angle between the prism axis and the thin single crystal plate of sodium nitrate is 23°. The optical axis of the crystal is perpendicular to the prism axis and makes an angle of 23° with the normal of the crystal plate.

In order to measure variations of transmission of polarized light through the prism with those of both wavelengths and angular positions of the prism, the prisms are set in Hitachi photo-electric spectrophotometer as are shown in Fig. 2.

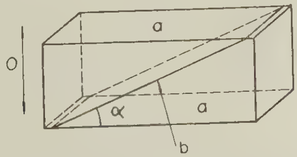

Fig. 1. A sodium nitrate polarization prism. a: SK5 glass, b: single crystal of sodium nitrate, o: the optical axis, and α: the angle 23° of the glass prism.

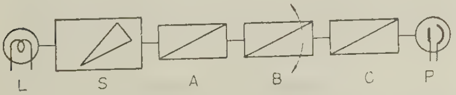

Fig. 2. Experimental apparatus. L: tungsten lamp, S: spectrometer, A, B and C: the polarization prisms and P: photocell.

In the early measurement with no use of the prism C in the figure, intensities of light passed through two prisms, A fixed in a definite angular position and B in positions rotated successively by 10°, were measured by the photocell P. The photocell, however, has sensitivities slightly varying with angles between the plane of polarization of the incident light and a definite plane of the photocell including the direction of the incident light. To eliminate these sensitivity differences and the effect of partially polarized light produced by the optical system, the polarization prism C is set in parallel to A. Keeping A and C in the fixed positions, the prism B is rotated to positions at which transmission measurements are to be done.

The experimental procedure is as follows. At first, the prism B is removed from the apparatus and intensity of the incident beam of each wavelength is adjusted so as the reading of the photocurrent indicates 100 for the light passed through the two prisms A and C. Then the prism B is set in the apparatus and is rotated successively by 10°, and at each position the photocurrent of the beam passed through the three prisms, i.e. transmission, is read. Curves in Fig. 3 show transmission thus measured for each wavelength versus rotation angles of B. These curves, however, are shown separately by displacing them towards the right hand side in distances nearly proportional to the wavelength differences of the incident light to see clearly the angular dependence of transmission

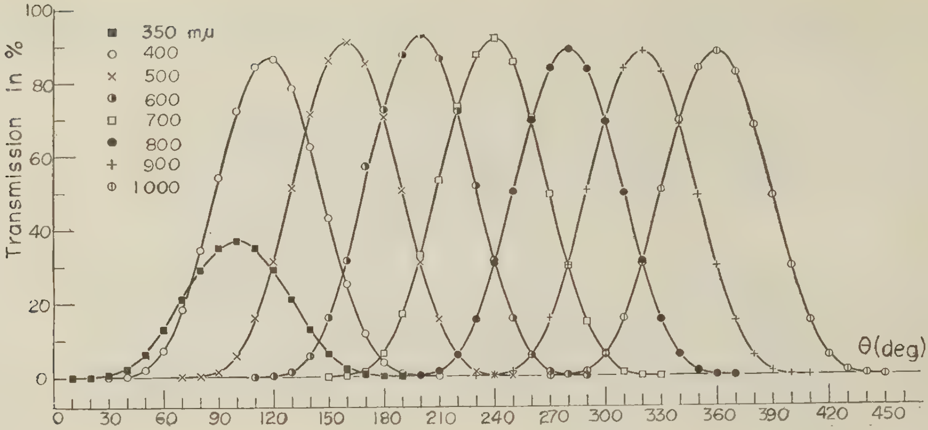

Fig. 3. Transmission of polarized monochromatic light versus rotation angles of the sodium nitrate analyser B. The curves for the different wavelengths are shown by shifting them each other to avoid confusion. Transmission values have not been corrected for reflection at the surfaces.

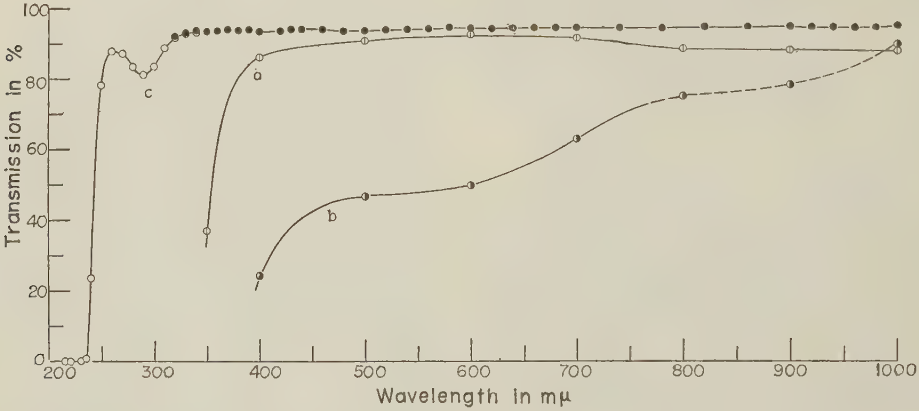

Fig. 4. Maximum transmission versus wavelengths. a: the sodium nitrate polarizer, b: H Polaroid, and c: two fused silica plates 1.5 mm thickness combined by the thin single crystal of sodium nitrate about 0.1 mm thickness.

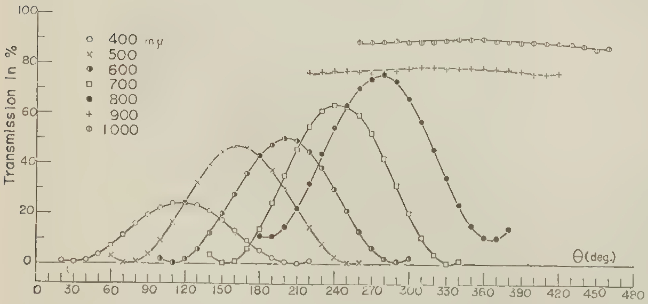

Fig. 5. Transmission versus rotation angles of H Polaroid. Light of 800 mμ being partially polarized, infra-red of more longer wavelengths completely unpolarized.

for all the wavelengths. Denoting the angle of B rotated from the position parallel to A by θ, the transmission can be expressed by $\cos^4\theta$ in the present arrangement of the three prisms. Actually, transmission observed to each wavelength is in a good agreement with $\cos^4\theta$.

In Fig. 4 the curve a represents the maximum transmission of polarized light passed through B plotted against the wavelengths. We can see from the figure that the transmission for infra-red and visible light is about 90% and is still large 37% at a short wavelength 350 mμ. To compare these polarization characteristics with those of H type Polaroid, two plates of Polaroid are set in place of the prisms A, B and C. Holding the plate placed near to the light source in a fixed position, another is rotated as in the above case to measure the photoelectric current of the photocell P. The results are given in Fig. 5. If Polaroid used in the present experiment is complete one as a polarization plate, the intensity must be expressed by $\cos^2\theta$. From the curves in the figure it can be said that the polarization effect is complete for visible light, whereas is remarkably incomplete at 800 mμ and is lost completely at longer wavelengths. Transmisson observed at parallel positions of the two plates versus wavelength is gived by the curve b in Fig. 4. It is remarkably small at 400 mμ and increases to the value of the order of 50% at visible light region. Large values at infra-red, however, are due to the unpolarized light passed through Polaroids which lost the polarization properties over these wavelength ranges.

§ 3. Discussions

Remarkable decrease of transmission of the present polarization prism for ultra-violet below 350 mμ can be ascribed to the absorption of SK5 glass. To make a polarization prism for ultra-violet it will be adequate to use prisms of fused silica, between which a sodium nitrate single crystal is to be grown. The limit of short wavelength of light to be polarized by such a polarization prism is experimentally determined, putting as an absorber two fused silica plates of 1.5 mm thickness combined by the thin single crystal of sodium nitrate of about 0.1 mm thickness in the photo-electric spectrophotometer. The light source is a tungsten lamp for above 320 mμ and a hydrogen discharge tube below 340 mμ. The results are shown by the curve c in Fig. 4, transmission values are not corrected for reflections at the plate surfaces. The plate transmits light above 250 mμ nearly perfectly. Since usual fused silica has absorption band at 240 mμ, the absorption below 250 mμ may be due to fused silica and the small adsorption at 290 mμ observed is considered as being due to absorption by sodium nitrate. Hence it can be expected that a sodium nitrate polarization prism made of fused silica prism will have a superior properties enabling to polarize light from 250 to 1,000 mμ or even longer. Several polarization prisms of this type were abready made and the characteristics of them will be reported in another paper.

In conclusion one of the authors (T. Y.) thanks to the Educational Department for financial suport.

The Steady Flow of Viscous Fluid at Low Reynolds Numbers passing obliquely through a Plane Grid made of Equal Parallel Circular Cylinders

By Kō TAMADA

Department of Aeronautical Engineering, Faculty of Engineering, Kyoto University

and Hiroomi FUJIKAWA

(Received September 30, 1958)

The flow of a viscous fluid at low Reynolds numbers passing obliquely through a plane grid made of equal, parallel, circular cylinders regularly spaced is discussed on the basis of Oseen's equations of motion. Explicit expressions for the force experienced by a cylinder in the grid, for the direction of the flow at infinity downstream, and for the pressure drop caused by the grid are obtained correct to the first order in the Reynolds number and in the diameter-distance ratio of the grid.

Among these the following results may be worth mentioning. The flow is deflected by the grid more or less to the direction of the normal to the grid surface and is always slowed down at infinity downstream. At very small Reynolds numbers, the flow becomes almost perpendicular to the grid even at far upstream and, hence, the component of force tangential to the grid surface vanishes, while the normal component of force to the grid surface becomes equal, in its magnitude, to the drag when the grid is set at right angles to the uniform stream whose velocity is equal to the normal component of the original velocity.

§ 1. Introduction

In a previous paper[1], the present writers have investigated on the basis of Oseen's equations the flow of a viscous incompressible fluid passing perpendicularly through a plane grid made of equal, parallel, regularly spaced, circular cylinders. The type of drag force obtained there suggests that the solution of Stokes's equations may also exist for this problem. (As is well known, there is no solution of Stokes's equations for the case of a single cylinder.) This was really verified recently by Miyagi[2]. The Oseen solution tends to the Stokes's for vanishingly small Reynolds numbers. However, the situation is somewhat different when the flow impinges on the grid obliquely. Namely, Stokes's equations do not permit an oblique flow to the grid surface. Thus, we are obliged to appeal, at least, to the Oseen approximation to treat the oblique case. In this respect, it may be interesting to investigate the behaviour of the Oseen solution at very small Reynolds numbers. Also, the new case may have some interesting characteristics. Especially, each cylinder experiences additional components of force parallel to the grid surface owing to the presence of the corresponding components of the flow, and, as a result, the direction of the flow at far downstream will be deflected. It is the purpose of the present paper to study theoretically the problem just mentioned. The whole analysis is based on the Oseen approximation as in the previous paper. The flow in question is quasi-two-dimensional in the sense that the state of flow is quite the same in all planes perpendicular to the axes of the cylinders. As a consequence, the two components of fluid velocity lying in these planes are independent of the remaining component which is parallel to the axes of the cylinders. This fact takes an important role in the analysis and produces considerable simplification. However, the analysis is yet fairly complicated, and the writers content themselves this time with the derivation of the first order solution for small Reynolds numbers. Explicit expressions for the force acting on a cylinder, for the velocity at infinity downstream and for the angle of deflection of the flow are derived to this approximation. Transition from the Oseen to the Stokes approximation is also discussed. Detailed numerical calculations are made concerning the force and flow deflection for various Reynolds numbers and for three values of the diameter-distance ratio of the grid, assuming a fixed initial flow direction.

§ 2. Fundamental Equations and Solutions

We take the rectangular coordinates x, y, z in such a way that the fluid velocity has the components U, 0, W at infinity upstream, that the z-axis coincides with the axis of one cylinder of the grid and that the grid surface makes an angle ω with the x-direction (Fig. 1). Also, let a be the radius of each cylinder, h the distance between the axes of two neighbouring cylinders, p the pressure, and u, v, w the x, y, z components of the velocity at any point. Since all quantities such as u, v, w and p are obviously independent of the z-coordinate in the present problem, Oseen's equations of motion and the equation of continuity may be written in the forms

$$\left.\begin{aligned} &U\frac{\partial u}{\partial x}=-\frac{1}{\rho}\frac{\partial p}{\partial x}+\nu\Delta u\,,\\ &U\frac{\partial v}{\partial x}=-\frac{1}{\rho}\frac{\partial p}{\partial y}+\nu\Delta v\,,\\ &U\frac{\partial w}{\partial x}=\nu\Delta w\,,\\ &\text{and}\\ &\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}=0\,, \end{aligned}\right\} \tag{1}$$

where ρ is the density of the fluid, ν the kinematic coefficient of viscosity and Δ stands for $(\partial^2/\partial x^2)+(\partial^2/\partial y^2)$. Three components u, v, w of the velocity should all vanish on the surface of each cylinder.

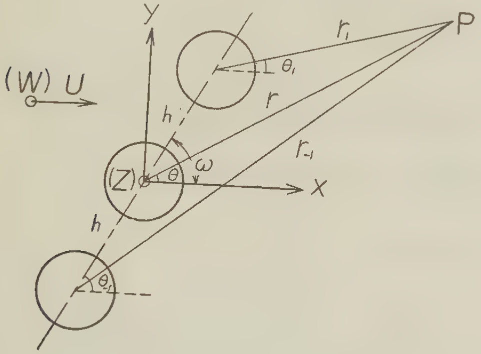

Fig. 1.

Elimination of p from (1) yields

$$\left(\Delta-2k\frac{\partial}{\partial x}\right)\left(\frac{\partial}{\partial\bar{\zeta}}\right)(u-iv)=0\,,\qquad \left(\Delta-2k\frac{\partial}{\partial x}\right)w=0\,,\qquad \Re\frac{\partial}{\partial\bar{\zeta}}(u-iv)=0\,, \tag{1.a}$$

with

$$\zeta=x+iy\,,\qquad \bar{\zeta}=x-iy\,,\qquad k=U/2\nu\,. \tag{2}$$

Eqs. (1) and the boundary conditions clearly show that the flow component in the z-direction does not affect at all the components of flow in the x, y plane. That is to say, u, v and p are identical with those for the purely two-dimensional case in which $w=0$. Thus, (u, v)-field and w-field may be treated separately. In the following discussions, however, we shall treat both fields in parallel for convenience sake. Now, when there is only one cylinder in the otherwise uniform stream, appropriate solutions of (1.a) take on the forms

$$u-iv=U+f(\zeta)+g(r,\theta)\,,\qquad w=W+g^*(r,\theta)\,, \tag{3}$$

where

$$\left.\begin{aligned} &f(\zeta)=\sum_{m=1}^{\infty}A_m(a/\zeta)^m\,,\qquad \zeta=re^{i\theta}\,,\\ &g(r,\theta)=e^{kr\cos\theta}\sum_{m=-\infty}^{\infty}a_mK_m(kr)e^{im\theta}\,,\\ &a_{-j}=\bar{a}_{j-1}\,,\qquad (j=1,2,\cdots)\\ &g^*(r,\theta)=e^{kr\cos\theta}\sum_{m=-\infty}^{\infty}C_mK_m(kr)e^{im\theta}\,,\\ &C_{-j}=\bar{C}_j\,,\qquad (j=0,1,2,\cdots) \end{aligned}\right\} \tag{4}$$

A_m's ,a_m's, C_m's being arbitrary constants and K_m denotes the modified Bessel function*. Therefore, introducing auxiliary coordinates

$$\zeta_s = r_s e^{i\theta_s} = \zeta - she^{i\omega} , \qquad (s=0, \pm 1, \cdots) \tag{5}$$

we may generalize for the present problem the said solutions in the forms

$$u - iv = U + \mathcal{E} + \sum_{s=-\infty}^{\infty} \{f(\zeta_s) + g(r_s, \theta_s)\} , \qquad w = W + \sum_{s=-\infty}^{\infty} g^*(r_s, \theta_s) , \tag{6}$$

where the functional forms of f, g and g^* are the same as in (4). Insertion of one more constant $\mathcal{E}$ will be understood in the following.

§ 3. Boundary Conditions

Let us first consider the boundary condition at infinity. Since g and g^* in (6) vanish exponentially at infinity upstream, we obtain the results: (cf. Appendix, (A.2))

$$u - iv \rightarrow U + \mathcal{E} - i\pi a h^{-1} e^{-i\omega} A_1 , \qquad w \rightarrow W , \qquad \text{for} \quad x \rightarrow -\infty .$$

Since $u - iv$ must be equal to U there, we get

$$\mathcal{E} = i\pi a h^{-1} e^{-i\omega} A_1 . \tag{7}$$

On the other hand, at infinity downstream, it can be shown (Appendix, 1) that

$$\left.\begin{aligned} &u - iv \rightarrow U + 2i\frac{\pi a}{he^{i\omega}} A_1 + \frac{2\pi}{kh \sin\omega} \Re \sum_{m=0}^{\infty} a_m , \\ &w \rightarrow W + \frac{\pi}{kh \sin\omega} \sum_{m=-\infty}^{\infty} C_m , \qquad \text{for} \quad x \rightarrow +\infty . \end{aligned}\right\} \tag{8}$$

Thus, it may be seen that the velocity at infinity downstream is different from that of the undisturbed stream, i.e. the flow is deflected by the grid, and, as is shown later, the flow is always slowed down. Owing to continuity, however, the component of velocity normal to the grid surface should obviously be recovered at infinity downstream, and this requires the relation

$$\Re\left(A_1 + \frac{1}{ka} \sum_{m=0}^{\infty} a_m \right) = 0 . \tag{9}$$

In view of the change in velocity at infinity downstream, there may be some doubt in applying the Oseen approximation in a manner as above where the x-component U of the undisturbed flow is taken as the representative velocity. However, this point is not serious as far as the induced flow in the y-direction remains small. Moreover, as will be seen later, a large part of the flow field reduces to the Stokes field at sufficiently small Reynolds numbers, and the Oseen field survives only at far upstream.

We now proceed to the fulfilment of the boundary conditions on the cylinders. As the solutions (6) satisfy already the periodicity of the flow field, it is sufficients to consider the boundary conditions $u = v = w = 0$ on the cylinder $r = a$ only. In order to apply the conditions, we expand the solutions (6) in Fourier series in θ on the surface $r = a$ (Appendix, 2). Then, by equating each coefficient of $e^{in\theta}$ $(n = 0, \pm 1, \cdots)$ to zero, we obtain the following sets of simultaneous algebraic equations for determining A_m's, a_m's and C_m's:

$$\left.\begin{aligned} &A_n + \sum_{m=-\infty}^{\infty} \{g_{m(-n)} + G_{m(-n)}\} a_m = 0 , \qquad (n=1, 2, \cdots) \\ &\sum_{s=1}^{\infty} F_{sn} A_s + \sum_{m=-\infty}^{\infty} \{g_{mn} + G_{mn}\} a_m = \begin{cases} -U , & (n=0) \\ 0 , & (n=1, 2, \cdots) \end{cases} \\ &\sum_{m=-\infty}^{\infty} (g_{mn} + G_{mn}) C_m = \begin{cases} -W , & (n=0) \\ 0 . & (n=\pm 1, \pm 2, \cdots) \end{cases} \end{aligned}\right\} \tag{10}$$

---

* The relation $a_{-j} = \bar{a}_{j-1}$ follows from the equation of continuity, the third Eq. in (1.a).

The expressions for g_{mn}, G_{mn} and F_{sn} are given in (11.a) below. By means of these equations and the two relations in (4):

$$a_{-m}=\bar{a}_{m-1}\,,\quad (m=1,2,\cdots)\qquad C_{-m}=\bar{C}_m\,,\quad (m=0,1,2,\cdots)$$

we can solve the unknowns A_m's, a_m's and C_m's. Thus, elimination of A_n's from (10) gives

$$\left.\begin{aligned} &\sum_{m=-\infty}^{\infty}\chi_{mn}a_m=\begin{cases}-U\,, & (n=0)\\ 0\,, & (n=1,2,\cdots)\end{cases}\\ &\text{with}\\ &\chi_{mn}=g_{mn}+G_{mn}-H_{mn}\,,\end{aligned}\right\}\tag{11}$$

where

$$\left.\begin{aligned} &g_{mn}=K_m(ka)I_{m-n}(ka)\,,\\ &G_{mn}=2\sum_{l=-\infty}^{\infty}(-1)^l e^{i(l+m)\omega}T_{l+m}I_l(ka)I_{l+n}(ka)\,,\\ &T_{l+m}=\sum_{s=1}^{\infty}K_{l+m}(skh)\begin{matrix}\cosh\\ \sinh\end{matrix}(skh\cos\omega)\,,\qquad \begin{matrix}(l+m=\text{even})\\ (l+m=\text{odd})\end{matrix}\\ &H_{mn}=\sum_{s=1}^{\infty}F_{sn}\{g_{m(-s)}+G_{m(-s)}\}\,,\\ &F_{sn}=\begin{cases}\dfrac{(-1)^s}{s!\,n!}\dfrac{s}{s+n}B_{(s+n)/2}\left(\dfrac{2\pi a}{he^{i\omega}}\right)^{s+n}, & (s+n=\text{even})\\ 0\,, & (s+n=\text{odd}\geqq 3)\end{cases}\\ &F_{1,0}=i\pi ah^{-1}e^{-i\omega}\,,\end{aligned}\right\}\tag{11.a}$$

$I_m(ka)$ and $K_m(ka)$ in these expressions denote the modified Bessel functions and B_m's are the Bernoulli numbers. It may be remarked here that the first equation in (10) proves the relation (9) expected previously. (Detailed proof is given in the Appendix, 3.)

§ 4. Approximate Solutions for $ka \ll 1$ and $(kh)^{-1}=O(1)$

There are two parameters ka and kh besides ω in the present problem. Since $k=U/2\nu$, $4ka$ and $2kh$ are the Reynolds numbers of the flow referred respectively to the diameter of the cylinder and the central distance between the neighbouring cylinders. We shall first treat the case in which ka is very small but kh is not. Close examination of the coefficients of the equations (10) and (11) for this case suggests a method of successive approximation. In the present paper, however, the first step only will be carried out for brevity. Namely, we retain only first three constants A_1, a_0 and C_0. (These three are sufficient to represent relevant characteristics of the flow at low Reynolds numbers.) Thus, Eqs. (10) and (11) may be replaced by

$$\left.\begin{aligned} &\chi_{00}a_0+\chi_{(-1)0}\bar{a}_0=-U\,,\\ &A_1+\{g_{0(-1)}+G_{0(-1)}\}a_0-\{g_{(-1)(-1)}+G_{(-1)(-1)}\}\bar{a}_0=0\,,\\ &(g_{00}+G_{00})C_0=-W\,.\end{aligned}\right\}\tag{12}$$

Making use of the expansions of $I_m(ka)$ and $K_m(ka)$ for small ka, we obtain (Appendix, 4)

$$\chi_{00}=S+2T_0+O\{(ka)^2\}\,,\qquad \chi_{(-1)0}=\frac{1}{2}+2T_1e^{-i\omega}-\frac{i\pi}{kh}e^{-i\omega}+O\{(ka)^2\}\,,$$

where

$$\left.\begin{aligned} &S=\log\frac{2}{ka}-\gamma\ ,\\ &T_0=\sum_{s=1}^{\infty}K_0(skh)\cosh\,(skh\ \cos\omega)\ ,\\ &T_1=\sum_{s=1}^{\infty}K_1(skh)\sinh\,(skh\cos\omega)\ ,\end{aligned}\right\}\tag{13}$$

γ being Euler's constant. With these expansions the first equation in (12) and its conjugate give at once

$$a_0=-\frac{U}{\Delta}\left\{S-\frac{1}{2}+2T_0-\left(2T_1-\frac{i\pi}{kh}\right)e^{-i\omega}\right\}+O\{(ka)^2\}\ ,\tag{14}$$

with

$$\Delta=(S+2T_0)^2-\left(2T_1+\frac{1}{2}\cos\omega\right)^2-\left(\frac{\pi}{kh}-\frac{1}{2}\sin\omega\right)^2+O\{(ka)^2\}\ .\tag{14.a}$$

Then, from the second equation in (12) combined with the expansions (cf. Appendix, 4)

$$\begin{aligned} &g_{0(-1)}=O(ka)\ ,\qquad g_{(-1)(-1)}=(ka)^{-1}+O(ka)\ ,\\ &G_{0(-1)}=-\overline{G}_{(-1)(-1)}=O(ka)\ ,\end{aligned}$$

we find

$$A_1=-(ka)^{-1}\bar{a}_0+O(ka)\ .\tag{15}$$

Further, it can be shown (Appendix, 4) that

$$g_{00}=S+O\{(ka)^2\}\ ,\qquad G_{00}=2T_0+O\{(ka)^2\}\ ,$$

and hence the last equation in (12) gives

$$C_0=-W(S+2T_0)^{-1}+O\{(ka)^2\}\ .\tag{16}$$

§ 5. Force and Velocity

By summing up the stress acting on the surface of a cylinder (Appendix, 5) or by applying the theorem of momentum to the fluid between two control surfaces taken parallel to the grid surface at $x=\pm\infty$, we can deduce formulae for calculating the force acting on the cylinder. These may be written as

$$X+iY=2\pi\rho UaA_1\ ,\qquad Z=-2\pi\mu\sum_{m=-\infty}^{\infty}C_m\ ,\tag{17}$$

where X, Y, Z are respectively the x, y, z-components of force per unit length of the cylinder and μ is the viscosity coefficient of the fluid. Inserting (15) and (16) into (17) and making some calculations, we get the results:

$$\left.\begin{aligned} &\frac{F_n}{\mu U}=\frac{4\pi}{\Delta}\left\{\left(S+2T_0-\frac{1}{2}\right)\sin\omega+\frac{\pi}{kh}\right\}\ ,\\ &\frac{F_t}{\mu U}=\frac{4\pi}{\Delta}\left\{\left(S+2T_0-\frac{1}{2}\right)\cos\omega-2T_1\right\}\ ,\\ &Z/(\mu W)=2\pi(S+2T_0)^{-1}\ ,\end{aligned}\right\}\tag{18}$$

where F_n and F_t denote respectively the force components normal and tangential (in the x, y-plane) to the grid surface, namely

$$F_n = X\sin\omega - Y\cos\omega\,, \qquad F_t = X\cos\omega + Y\sin\omega\,, \tag{19}$$

and the expressions for S, T_0, T_1 and Δ were given in (13) and (14.a) before. If we take, as a special case, $\omega=\pi/2$ and $W=0$ in (18), the result is seen to agree with that given in the previous paper[1]. Again, if we make $h\to\infty$ in (18), we reproduce the result derived by Tomotika, Aoi and Yosinobu[3] for the case of a single cylinder.

On the other hand, we may evaluate the velocity at infinity downstream ($x\to+\infty$) by the preceding equations (8) and (9) combined with (15) and (16). After some calculations, we may obtain

$$(q_n)_\infty = Q_n\,, \qquad (q_t)_\infty = Q_t - F_t/(\rho h Q_n)\,, \qquad (w)_\infty = W - Z/(\rho h Q_n)\,, \tag{20}$$

where we have put as in (19)

$$\left.\begin{aligned} q_n &= u\sin\omega - v\cos\omega\,, & q_t &= u\cos\omega + v\sin\omega\,,\\ Q_n &= U\sin\omega\,, & Q_t &= U\cos\omega\,. \end{aligned}\right\} \tag{21}$$

It will be seen that the second and the third equations in (20) represent the momentum balance in the t and z-directions respectively, while the first equation indicates continuity as mentioned earlier. Further, momentum consideration in the n-direction leads to the equation

$$h(p_{-\infty} - p_\infty) = F_n \tag{22}$$

which gives the pressure drop at far downstream.

The deflection of the flow at infinity downstream may also be estimated by (20). In particular, when the flow is two-dimensional, i.e. $W=0$, the angle of deflection δ is given by the equation

$$\tan\delta = \frac{v_\infty}{u_\infty} = -\frac{F_t}{\rho U^2 h - F_t\cot\omega}\,. \tag{23}$$

§ 6. Approximate Solutions for $ka \ll 1$ and $kh \ll 1$

We next proceed to consider the case where the parameters ka and kh are both small. Though the preceding analysis is based on the assumption that kh is not small, the main result (18) does never diverge when $kh\to 0$. In fact, if we reconsider the course of the preceding analysis, for the case ka and kh are both small, we shall find at each stage of reductions that the neglected terms happen to be higher order than the retained with respect to ka or kh or both. Thus, it may be seen that the final result (18) are also valid for the case under consideration. However, the series (13) defining the functions T_0 and T_1 in (18) are shown to converge quite slowly when kh is very small. Therefore, it is necessary first to find out some suitable expressions of these functions for small kh. This is done in the Appendix, 6. According to the analysis given there, T_0 and T_1 can be expanded asymptotically as

$$\left.\begin{aligned} &2T_0 \sim \frac{\pi}{\sin\omega}\,\frac{1}{\lambda} + \log\frac{\lambda}{4\pi} + \gamma + O(\lambda)\,,\\ &2T_1 \sim (\pi\cot\omega)\lambda^{-1} - \cos\omega + O(\lambda)\,, \qquad \lambda = kh\,, \end{aligned}\right\} \tag{24}$$

Inserting these in (18) and making some reductions, we get

$$\left.\begin{aligned} &\frac{F_n}{\mu Q_n} = \frac{4\pi}{\Delta} + O\{(kh)^2\}\,, & &\Delta = \log\frac{h}{2\pi a} + \frac{1}{2}\,,\\ &F_t = \rho h Q_n Q_t\,, & &Z = \rho h Q_n W\,, \end{aligned}\right\} \tag{25}$$

where F_n, F_t, Z and Q_n, Q_t, W are respectively the n, t, z-components of force and of velocity as before. Comparing the first equation with the result obtained in the previous paper[1], it is found that the force component F_n normal to the grid surface becomes equal to the drag when the grid is placed at right angles to the direction of the uniform stream of velocity $Q_n = U \sin \omega$. Also, it is seen that the expressions for F_t and Z are both quadratic in velocity and do not depend upon μ explicitly. Further, substituting (25) in (20), we find that the direction of the flow at infinity downstream becomes normal to the plane of the grid.

§ 7. Numerical Discussion

In Figs. 2~4 are shown the results of numerical calculations concerning the components of force acting on a cylinder, per unit length, of the grid. In these figures, the full-line and the chain-line curves represent the results for the case $\omega = 60°$ computed by the formulae (18) and (25) respectively, while the broken-line curves are for the case $\omega = 90°$. From Fig. 2 it will be seen that $F_n/\mu Q_n$ $(Q_n = U \sin \omega)$ is little influenced by the stagger angle ω and its dependence on the Reynolds number is much the same as in the case $\omega = 90°$ (cf. reference 1).

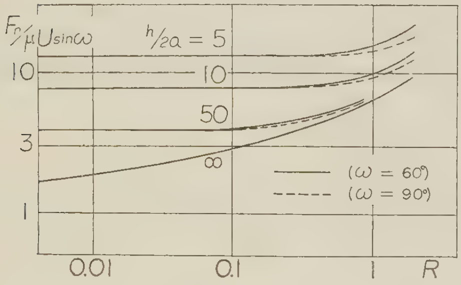

Fig. 2.

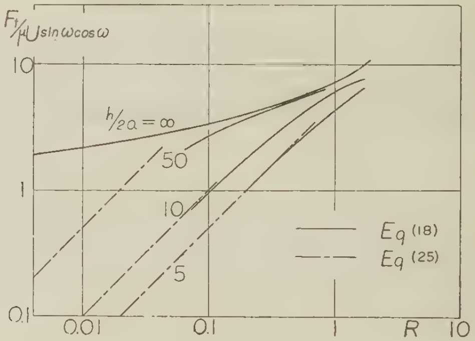

Fig. 3. (ω=60°)

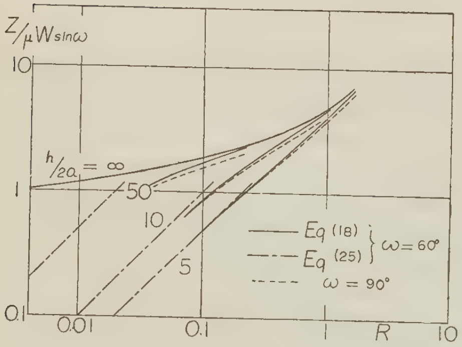

Fig. 4.

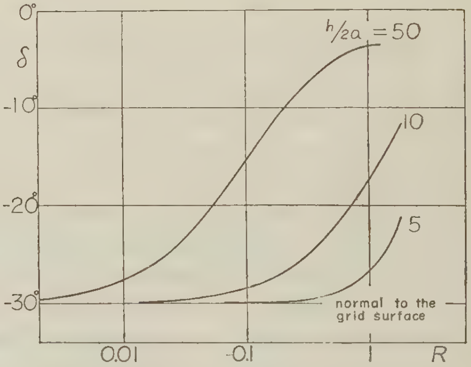

Fig. 5. (ω=60°)

Table I. Values of $F_n/(\mu U \sin \omega)$.

R \ ω, h/2a	60°			90°			
	5	10	50	5	10	50	∞
0	13.03	7.580	3.846	13.03	7.580	3.846	0
0.08	13.03	7.592	3.956	13.04	7.593	3.915	2.775

3.2	72.5			28.13	19.55	15.71	14.98

On the other hand, we see in Fig. 3 and Fig. 4 that F_t and Z decrease rapidly with decreasing Reynolds number. This indicates that the mean direction of the flow in the vicinity of the grid becomes more and more perpendicular to the grid surface as the Reynolds number is reduced. The tendency is evidently more marked for closer spaced grid (smaller $h/2a$).

Fig. 5 shows the angle of deflection of the flow for the two-dimensional motion in the x, y-plane, as calculated by Eq. (23) for $\omega=60°$. From this figure we see clearly how nearly the flow becomes normal to the grid surface at low values of the Reynolds number. Further, since δ is always negative and since the normal component of the flow is continuous, we may conclude that the flow is necessarily slowed down at infinity downstream.

Some of the numerical data for drawing Figs. 2~5 are also listed in Tables I~III. We may compute, if necessary, the components of force X, Y, the velocity and pressure drop at infinity downstream, from these data together with Eqs. (19), (20) and (22).

The writers wish to express their thanks to the Ministry of Education for a grant-in-aid for fundamental scientific research.

Appendices

1. Velocity at infinity

According to (4), (5), (6) in the main text, the complex velocity $u-iv$ in the x, y-plane is given by

$$\left.\begin{array}{l} u-iv=U+\mathcal{E}+\sum\limits_{s=-\infty}^{\infty} f(\zeta_s)+\sum\limits_{s=-\infty}^{\infty} g(r_s,\theta_s)\,, \\ \text{where} \\ \zeta_s=r_s e^{i\theta_s}=\zeta-she^{i\omega}\,, \qquad \zeta=re^{i\theta}\,, \\ f(\zeta_s)=\sum\limits_{m=1}^{\infty} A_m(a/\zeta_s)^m\,, \\ g(r_s,\theta_s)=e^{kr_s\cos\theta_s}\sum\limits_{m=-\infty}^{\infty} a_m K_m(kr_s)e^{im\theta_s}\,, \\ \qquad a_{-m}=\bar{a}_{m-1}\,. \qquad (m=1,2,\cdots) \end{array}\right\} \qquad (A.1)$$

For $|\zeta|\gg a$, $f(\zeta_s)\cong A_1a/\zeta_s$ and we get

$$\sum_{s=-\infty}^{\infty} f(\zeta_s)=A_1a\left\{\frac{1}{\zeta}+\sum_{s=1}^{\infty}\frac{2\zeta}{\zeta^2-(she^{i\omega})^2}\right\}=-i\frac{\pi a}{he^{i\omega}}A_1\coth\left\{\frac{\pi r}{h}e^{i(\theta-\omega-(\pi/2))}\right\}.$$

Therefore, when $r\to\infty$

$$\sum_{s=-\infty}^{\infty} f(\zeta_s) \to \mp i \frac{\pi a}{h e^{i\omega}} A_1 \,, \qquad \begin{array}{l} \pi+\omega > \theta > \omega \ \text{(upstream)} \\ \omega > \theta > \omega-\pi \ \text{(downstream)} \end{array} \tag{A.2}$$

On the other hand, viscous term $\sum g(r_s, \theta_s)$ is seen to vanish exponentially at infinity upstream, but it may have finite contribution at far downstream. To show this, we use the well-known formula

$$\left. \begin{array}{l} K_m(R) e^{im\Theta} = \dfrac{1}{2} \displaystyle\int_0^\infty (\pm it)^m \exp\left\{ \mp \frac{i}{2}\left(Zt - \frac{\bar{Z}}{t} \right) \right\} \frac{dt}{t} \,, \\ Z = Re^{i\Theta} \,, \qquad \Im(Z) \lesseqgtr 0 \,. \end{array} \right\} \tag{A.3}$$

By means of this, we may rewrite $g(r_s, \theta_s)$ for $h/2 > \Im(\zeta) > -h/2$ in integral forms

$$\begin{aligned} g(r_s, \theta_s) = \frac{1}{2} e^{kx} \int_0^\infty \exp\Big[& \mp \frac{ik}{2}\left(\zeta t - \frac{\bar{\zeta}}{t} \right) \\ & - skh \left\{ \cos\omega \mp \frac{i}{2}\left(e^{i\omega} t - \frac{e^{-i\omega}}{t} \right) \right\} \Big] \alpha(\pm it) \frac{dt}{t} \,, \qquad \begin{array}{l} (s \geqq 1) \\ (s \leqq -1) \end{array} \end{aligned} \tag{A.4}$$

with

$$\alpha(\xi) = \sum_{m=-\infty}^{\infty} a_m \xi^m \,.$$

Then, summing up the results with respect to s, we obtain

$$\begin{aligned} \sum_{s=s_1}^{s_2} g(r_s, \theta_s) = \mp \frac{1}{2} e^{kx} \int_0^\infty & \exp\left\{ \mp \frac{ik}{2}\left(\zeta t - \frac{\bar{\zeta}}{t} \right) \right\} \\ & \times \left[1 - \exp kh \left\{ \cos\omega \mp \frac{i}{2}\left(e^{i\omega} t - \frac{e^{-i\omega}}{t} \right) \right\} \right]^{-1} \alpha(\pm it) \frac{dt}{t} \,, \end{aligned} \tag{A.5}$$

where $s_1 = 1$, $s_2 = \infty$ with upper signs, and $s_1 = -\infty$, $s_2 = 0$ with lower signs. Now, for the estimation of the velocity at far downstream, it will be sufficient to take a special limit $\zeta = x \to +\infty$. Changing the variable of integration in (A.5) by

$$u = i + \frac{1}{2}\left(t - \frac{1}{t} \right) ,$$

we get

$$\begin{aligned} \sum_{s=1}^{\infty} g(r_s, \theta_s) = \frac{1}{2} \int_{i-\infty}^{i+\infty} & e^{-ikxu} [\exp kh \{ \sqrt{(-iu)(2+iu)} \sin\omega - iu \cos\omega \} - 1]^{-1} \\ & \times \tilde{\alpha}(u) \{ (-iu)(2+iu) \}^{-1/2} du \,, \end{aligned}$$

with $\tilde{\alpha}(u) = \alpha(\pm it)$.

To evaluate this integral, we consider a contour integral as shown in Fig. 6. Since there is no singular point inside the contour, and the integral along the upper branch gives just the integral in question, we find

$$\sum_{s=1}^{\infty} g(r_s, \theta_s) = \frac{1}{2} \left\{ -i\pi R + \int_{-X}^{-\varepsilon} + \int_{\varepsilon}^{X} \right\} .$$

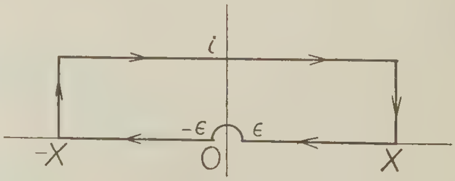

Fig. 6.

Here, the residue R at $u=0$ $(t=-i)$ is easily calculated to be*

$$R = \frac{i\alpha(1)}{2kh \sin\omega} \,, \qquad \alpha(1) = 2\Re \sum_{m=0}^{\infty} a_m \,.$$

---

* The relation $a_{-m} = \bar{a}_{m-1}$ has been used.

Further, for its highly oscillatory character for $kx \gg 1$, the integrand of the remaining integrals may be replaced by its approximate form near $u=0$. Thus we obtain

$$\lim_{x \to +\infty} \sum_{s=1}^{\infty} g(r_s, \theta_s) = \frac{i\alpha(1)}{4kh \sin \omega} \left\{ -i\pi + \left(\int_{-X}^{-\varepsilon} + \int_{\varepsilon}^{X} \right) \frac{e^{-ikxu}}{u} du \right\} . \tag{A.6}$$

Now, as (A.5) shows, the corresponding expression for the sum taken from $s=-\infty$ to $s=0$ can be obtained from the above by replacing i by $-i$, ω by $-\omega$ and changing the sign of the resulting expression. Then, adding this to (A.6), we arrive at the result

$$\lim_{x \to +\infty} \sum_{s=-\infty}^{\infty} g(r_s, \theta_s) = \frac{\alpha(1)}{2kh \sin \omega} \left\{ \pi + \int_{-\infty}^{\infty} \frac{\sin kxu}{u} du \right\} = \frac{\pi \alpha(1)}{kh \sin \omega} = \frac{2\pi}{kh \sin \omega} \Re \sum_{m=0}^{\infty} a_m . \tag{A.7}$$

This, in conjunction with (A.2), proves the first equation in (8) in the main text. Quite similarly the second equation in (8) may be verified, since, as is seen from (4), g^* has a common form with g except for the constants C_m's.

2. Fourier expansion of the velocity on a cylinder

On the cylinder $|\zeta| = a$, we have

$$f(\zeta) = \sum_{n=1}^{\infty} A_n e^{-in\theta} , \tag{A.8}$$

and for $|s| \geqq 1$

$$f(\zeta_s) = \sum_{m=1}^{\infty} A_m a^m (\zeta - she^{i\omega})^{-m} = \sum_{n=0}^{\infty} \left\{ \sum_{m=1}^{\infty} (-1)^m \frac{(m+n-1)!}{n!(m-1)!} \left(\frac{a}{she^{i\omega}} \right)^{m+n} A_m \right\} e^{in\theta} .$$

Also, making use of the formula

$$e^{ka \cos \theta} = \sum_{l=-\infty}^{\infty} I_l(ka) e^{il\theta} ,$$

we get at once the expansion

$$g(r, \theta) = \sum_{n=-\infty}^{\infty} \left\{ \sum_{m=-\infty}^{\infty} g_{mn} a_m \right\} e^{in\theta} , \qquad g_{mn} = K_m(ka) I_{m-n}(ka) . \tag{A.9}$$

On the other hand,

$$g(r_s, \theta_s) = e^{-skh \cos \omega} e^{ka \cos \theta} \sum_{m=-\infty}^{\infty} a_m K_m(kr_s) e^{im\theta_s} ,$$

and $K_m(kr_s)e^{im\theta_s}$ can be expanded by the addition theorem for the modified Bessel function (Ref. 4), i.e. for $s \geqq 1$

$$K_m(kr_s) e^{im\theta_s} = (-1)^m \sum_{l=-\infty}^{\infty} K_{m+l}(skh) I_l(ka) e^{i(l+m)\omega} e^{-il\theta} .$$

Inserting this and rearranging, we get

$$g(r_s, \theta_s) = \sum_{n=-\infty}^{\infty} \left\{ \sum_{m=-\infty}^{\infty} (-1)^m a_m \sum_{l=-\infty}^{\infty} e^{-skh \cos \omega} K_{m+l}(skh) I_l(ka) I_{n+l}(ka) e^{i(m+l)\omega} \right\} e^{in\theta} , \qquad (s \geqq 1)$$

and replacing ω by $\omega + \pi$, a corresponding result for $s \leqq -1$. Then, summation with respect to s yields

$$\mathcal{E} + \sum_{s=-\infty}^{\infty}{}' f(\zeta_s) = \sum_{n=0}^{\infty} \left(\sum_{m=1}^{\infty} F_{mn} A_m \right) e^{in\theta} , \tag{A.10}$$

and

$$\sum_{s=-\infty}^{\infty}{}' g(r_s, \theta_s) = \sum_{n=-\infty}^{\infty} \left(\sum_{m=-\infty}^{\infty} G_{mn} a_m \right) e^{in\theta} , \tag{A.11}$$

where $\sum'$ means a sum excluding the term for $s=0$, and F_{mn} as well as G_{mn} are given in (11.a) in the main text*. Thus, substituting (A.8)∼(A.11) in (A.1), we finally obtain

$$\begin{aligned}(u-iv)_{r=a} = U + \sum_{n=1}^{\infty} A_n e^{-in\theta} + \sum_{n=-\infty}^{\infty} \left\{ \sum_{m=-\infty}^{\infty} g_{mn} a_m \right\} e^{in\theta} \\ + \sum_{n=0}^{\infty} \left\{ \sum_{m=1}^{\infty} F_{mn} A_m \right\} e^{in\theta} + \sum_{n=-\infty}^{\infty} \left\{ \sum_{m=-\infty}^{\infty} G_{mn} a_m \right\} e^{in\theta} .\end{aligned} \tag{A.12}$$

In a similar manner, we may obtain

$$(w)_{r=a} = W + \sum_{n=-\infty}^{\infty} \left\{ \sum_{m=-\infty}^{\infty} (g_{mn} + G_{mn}) C_m \right\} e^{in\theta} . \tag{A.13}$$

Equating to zero the coefficients of $e^{in\theta}$ in (A.12) and (A.13), we arrive at the results (10) in the main text.

3. Verification of Eq. (9)

The first equation of (10) in the main text reads

$$\left.\begin{aligned} A_1 + \sum_{m=-\infty}^{\infty} \{ g_{m(-1)} + G_{m(-1)} \} a_m = 0 , \\ g_{mn} = K_m I_{m-n} , \qquad G_{mn} = 2 \sum_{l=-\infty}^{\infty} (-1)^l e^{i(l+m)\omega} T_{l+m} I_l I_{l+n} . \end{aligned}\right\} \tag{A.14}$$

The argument ka of the functions K_m and I_m will be omitted for brevity. Now, since $a_{-m} = \bar{a}_{m-1}$ $(m=1, 2, \cdots)$,

$$\Re \sum_{m=-\infty}^{\infty} g_{m(-1)} a_m = \Re \sum_{m=0}^{\infty} (K_m I_{m+1} a_m + K_{m+1} I_m \bar{a}_m) = \frac{1}{ka} \Re \sum_{m=0}^{\infty} a_m , \tag{A.15}$$

where the well-known relation $I_m K_{m+1} + I_{m+1} K_m = 1/ka$ has been used. On the other hand, taking the relation $a_{-m} = \bar{a}_{m-1}$ into account,

$$\sum_{m=-\infty}^{\infty} G_{m(-1)} a_m = 2 \sum_{m=0}^{\infty} \left[\sum_{l=-\infty}^{\infty} (-1)^l T_{l+m} I_l I_{l-1} e^{i(l+m)\omega} a_m + \sum_{l=-\infty}^{\infty} (-1)^l T_{l-m-1} I_l I_{l-1} e^{i(l-m-1)\omega} \bar{a}_m \right] .$$

Rewriting l as $-l+1$ in the second sum and noting $T_{-l-m} = T_{l+m}$ which is obvious from (11.a) in the main text, it is easily seen that

$$\Re \sum_{m=-\infty}^{\infty} G_{m(-1)} a_m = 0 . \tag{A.16}$$

Insertion of (A.15) and (A.16) into (A.14) proves the relation (9) in the main text.

4. Expansions for small *ka*

Here we concern the expansion of χ_{mn} given in (11) and (11.a) for small ka. First, we assume that $ka \ll 1$ but $kh = O(1)$, so that $a/h = O(ka)$. Making use of the expansions for $I_m(ka)$ and $K_m(ka)$, we obtain

$$g_{00} = K_0 I_0 = S + O\{(ka)^2\} , \qquad S = \log(2/ka) - \gamma ,$$

where γ denotes as before Euler's constant. Also, $T_l(kh) = O(1)$ and $I_{\pm l}(ka) = O\{(ka)^l\}$, and we have

---

* The relation (7) in the text has also been taken into account.

$$G_{00}=2\sum_{l=-\infty}^{\infty}(-1)^l T_l I_l^2 e^{il\omega}=2T_0+O\{(ka)^2\}\ .$$

Further, since

$$\begin{aligned}
&g_{0(-s)}=K_0 I_s=O\{(ka)^s\}\ ,\\
&F_{s0}=O\{(a/h)^s\}=O\{(ka)^s\}\ , \qquad \text{or} \qquad 0\ ,\\
&G_{0(-s)}=2\sum_{l=-\infty}^{\infty}(-1)^l T_l I_l I_{l-s}\, e^{il\omega}=O\{(ka)^s\}^{*}\ ,
\end{aligned}$$

it will be seen that

$$H_{00}=\sum_{s=1}^{\infty}F_{s0}\{g_{0(-s)}+G_{0(-s)}\}=O\{(ka)^2\}\ .$$

From these, we attain

$$\chi_{00}=g_{00}+G_{00}-H_{00}=S+2T_0+O\{(ka)^2\}\ . \tag{A.17}$$

In the next place, we get likewise the results

$$g_{(-1)0}=K_1 I_1=\frac{1}{2}+O\{(ka)^2\}\ ,$$

$$G_{(-1)0}=2\sum_{l=-\infty}^{\infty}(-1)^l T_{l-1} I_l^2 e^{i(l-1)\omega}=2T_1 e^{-i\omega}+O\{(ka)^2\}\ .$$

Also, we have

$$H_{(-1)0}=\sum_{s=1}^{\infty}F_{s0}\{g_{(-1)(-s)}+G_{(-1)(-s)}\}=\frac{i\pi}{kh}e^{-i\omega}+O\{(ka)^2\}\ ,$$

because

$$\begin{aligned}
&F_{s0}=\begin{cases} i\pi a/(he^{i\omega})\ , & \qquad\qquad\qquad\qquad (s=1)\\ O\{(ka)^s\}\ , \qquad\qquad \text{or} \quad 0\ , & (s=2,\ 3,\ \cdots)\end{cases}\\
&g_{(-1)(-s)}=K_1 I_{s-1}=K_1 I_0\ , \quad (s=1) \quad \text{or} \quad O\{(ka)^{s-2}\}\ , \quad (s=2,\ 3,\ \cdots)\\
&G_{(-1)(-s)}=2\sum_{l=-\infty}^{\infty}(-1)^l T_{l-1} I_l I_{l-s}\, e^{i(l-1)\omega}=O\{(ka)^s\}\ .
\end{aligned}$$

These results lead to

$$\chi_{(-1)0}=g_{(-1)0}+G_{(-1)0}-H_{(-1)0}=\frac{1}{2}+2T_1 e^{-i\omega}-i\pi/(khe^{i\omega})+O\{(ka)^2\}\ . \tag{A.18}$$

5. Formulae for the force components

By summing up the stress acting on the surface of a cylinder and taking into account the boundary conditions $u=v=0$ there, we can verify without difficulty a general formula

$$X+iY=\oint(ip+\mu\Omega)d\zeta\ , \qquad \Omega=(\partial v/\partial x)-(\partial u/\partial y)\ , \tag{A.19}$$

where p, μ, X, Y are respectively the pressure, the viscosity coefficient and x, y-components of force experienced by the cylinder, and integration should be carried out along the surface of the cylinder. Again, we have for the z-component of force the formula

---

[*] $I_l I_{l-s}=O\{(ka)^{|l|+|l-s|}\}$ and $|l|+|l-s|\geqq s$.

$$Z=a\mu\int_0^{2\pi}(\partial w/\partial r)_{r=a}d\theta\ , \tag{A.20}$$

where r, θ are the polar coordinates having the origin at the centre of the cylinder. Now, it can be shown after some reduction that to the Oseen approximation

$$p=-\rho U u_h\ , \qquad \mu\Omega=\rho U v_u\ , \tag{A.21}$$

where the suffices h and u mean the harmonic and unharmonic parts respectively. Introducing these results in (A.19) and remembering the condition $v_h+v_u=0$ on the cylinder, we reach the formula

$$X+iY=-i\rho U\oint(u-iv)_h\,d\zeta\ . \qquad \text{(A.22}$$

Substitution in this the expression

$$(u-iv)_h=U+\mathcal{E}+\sum_{s=-\infty}^{\infty}\sum_{m=1}^{\infty}A_m\left(\frac{a}{\zeta_s}\right)^m$$

proves the first formula of (17) in the main text. We next treat Z. First, we may obtain Fourier expansion in θ of w at an arbitrary point simply by replacing ka by kr in (A.13). Then, differentiating this, putting $r=a$ and inserting the result into (A.20), we have

$$Z=2\pi a\mu\sum_{m=-\infty}^{\infty}C_m(g'_{m0}+G'_{m0})\ .$$

But, by means of the recurrence formulae for I_m and K_m, we get

$$g'_{m0}=k(g_{m,1}-g_{m+1,1})\ , \qquad G'_{m0}=k(G_{m,1}+G_{m(-1)})\ .$$

Substituting these and using the third set of equations (for $n=\pm1$) of (10) in the main text, we have

$$Z=-2\pi\mu(ka)\sum_{m=-\infty}^{\infty}C_m(g_{m+1,1}+g_{m,-1})\ .$$

From the definition of g_{mn} together with the well-known relation $I_mK_{m+1}+I_{m+1}K_m=(ka)^{-1}$, we finally obtain the second formula of (17) in the main text.

6. Expansions for small *kh*

The asymptotic expansions (24) used in the main text will now be derived. To this end, we consider a function $T_j^*(\lambda, \omega)$ defined as

$$T_j^*(\lambda, \omega)=\sum_{s=1}^{\infty}e^{s\lambda\cos\omega}K_j(s\lambda)\ . \tag{A.23}$$

By means of the formula

$$K_j(\rho)=\frac{1}{2}\int_{-\infty}^{\infty}e^{-\rho\cosh\tau-j\tau}d\tau\ ,$$

this function may be written in the form

$$T_j^*=\frac{1}{2}\int_{-\infty}^{\infty}\frac{e^{-\lambda x}}{1-e^{-\lambda x}}e^{-j\tau}d\tau\ , \qquad x=\cosh\tau-\cos\omega\ . \tag{A.24}$$

Then, inserting the expansion

$$\frac{1}{1-e^{-\lambda x}}=\frac{1}{\lambda x}+\frac{1}{2}+\sum_{n=1}^{\infty}(-1)^{n+1}\frac{B_n}{(2n)!}\lambda^{2n-1}x^{2n-1}\ , \qquad (B_n\text{: Bernoulli number})$$

and performing term-wise integration formally, we get

$$2T_j{}^*=J_{-1}^{(j)}\frac{1}{\lambda}+\frac{1}{2}J_0^{(j)}+\sum_{n=1}^{\infty}(-1)^{n+1}\frac{B_n}{(2n)!}J_{2n-1}^{(j)}\lambda^{2n-1}\,, \tag{A.25}$$

where

$$J_{-1}^{(j)}=-\int^{\lambda}J_0^{(j)}d\lambda\,,\qquad J_0^{(j)}=2e^{\lambda\cos\omega}K_j(\lambda)\,,\qquad J_{2n-1}^{(j)}=(-1)^{2n-1}\frac{d^{2n-1}}{d\lambda^{2n-1}}J_0^{(j)}\,. \tag{A.26}$$

In particular, for $j=0$, it can be shown that

$$J_{-1}^{(0)}=\frac{2(\pi-\omega)}{\sin\omega}+2\left(\gamma-1+\log\frac{\lambda}{2}\right)\lambda+O(\lambda^2)\,,$$

$$J_0^{(0)}=-2\left(\gamma+\log\frac{\lambda}{2}\right)+O(\lambda)\,,$$

$$J_{2n+1}^{(0)}=2\{(2n)!\}\lambda^{-(2n+1)}+O(\lambda^{-2n})\,.$$

Substitution of these in (A.25) yields

$$2T_0{}^*=\frac{2(\pi-\omega)}{\sin\omega}\frac{1}{\lambda}+\log\frac{\lambda}{2}+\gamma-2+\sum_{n=0}^{\infty}\frac{(-1)^nB_{n+1}}{(n+1)(2n+1)}+O(\lambda)$$

However, since

$$\sum_{n=0}^{\infty}\frac{(-1)^nB_{n+1}}{(n+1)(2n+1)}=4\int_0^{\infty}\frac{\tan^{-1}\tau}{e^{2\pi\tau}-1}d\tau=2-\log(2\pi)\,,$$

we have

$$2T_0{}^*=\frac{2(\pi-\omega)}{\sin\omega}\frac{1}{\lambda}+\log\frac{\lambda}{4\pi}+\gamma+O(\lambda)\,. \tag{A.27}$$

In a similar manner, for $j=1$, we get

$$J_{-1}^{(1)}=-2\{\log(\lambda/2)+\gamma\}+2(\pi-\omega)\cot\omega-(2\cos\omega)\lambda+O(\lambda^2)\,,$$

$$J_0^{(1)}=2\lambda^{-1}+2\cos\omega+O(\lambda)\,,$$

$$J_{2n+1}^{(1)}\cong 2\{(2n+1)!\}\lambda^{-(2n+2)}\,.$$

These results combined with (A.25) give

$$2T_1{}^*=\left[-2\{\log(\lambda/2)+\gamma\}+2(\pi-\omega)\cot\omega+1+\sum_{n=0}^{\infty}\frac{(-1)^nB_{n+1}}{n+1}\right]\frac{1}{\lambda}-\cos\omega+O(\lambda)\,.$$

Further we note that

$$\sum_{n=0}^{\infty}\frac{(-1)^nB_{n+1}}{n+1}=4\int_0^{\infty}\frac{1}{e^{2\pi t}-1}\frac{t}{1+t^2}dt=2\gamma-1$$

which can be derived by putting $z=0$ after differentiating Binet's formula:

$$\log\Gamma(z)=\{z-(1/2)\}\log z-z+(1/2)\log(2\pi)+2\int_0^{\infty}\frac{\tan^{-1}(t/z)}{e^{2\pi t}-1}dt\,.\qquad(\Re(z)>0)$$

Thus, we arrive at

$$T_1{}^*=\{-\log(\lambda/2)+(\pi-\omega)\cot\omega\}\lambda^{-1}-(1/2)\cos\omega+O(\lambda)\,. \tag{A.28}$$

Finally, (A.27), (A.28) and the relation

$$T_j(\lambda, \omega)=(1/2)\{T_j^*(\lambda, \omega)+(-1)^j T_j^*(\lambda, \pi-\omega)\}$$

yield the required expansions (24) in the main text.

Some Problems on Heat Conduction in Stratiform Bodies

By Václav VODIČKA
Plzeň Czechoslovakia

(Received October 8, 1958)

Problems on heat conduction in multilayer bodies lead usually to complicated calculations[1-5]. The present paper gives an idea of specific difficulties arising in the case of infinite composite solides. General deductions are applied to a special class of questions.

I. GENERAL THEORY

This first main part of our paper gives mathematical formulation of the basic problem. We also indicate a formal solution by means of the Laplace transformation method combined with a systematic use of matrix analysis.

§1. Statement of the Problem

Let

$$x_0 < x_1 < x_2 < \cdots < x_{n-2} < x_{n-1} \qquad (n \geq 1)\,,$$

a_k^2, λ_k, u_{k0} $(k=1, 2, \cdots, n)$, u_0 and ω be given constants. We have to determine the solution $u_k=u_k(x, t)$ of the equations

$$\frac{\partial u_k}{\partial t}=a_k^2\frac{\partial^2 u_k}{\partial x^2}\,, \quad x_{k-1}<x<x_k \qquad (k=1, 2, \cdots, n-1)\,, \quad t>0 \tag{1.1}$$

$$\frac{\partial u_n}{\partial t}=a_n^2\frac{\partial^2 u_n}{\partial x^2}\,, \quad x>x_{n-1}\,, \qquad t>0 \tag{1.2}$$

with the initial data

$$u_k(x, 0)=u_{k0}\,, \quad x_{k-1}<x<x_k \qquad (k=1, 2, \cdots, n-1) \tag{2.1}$$

$$u_n(x, 0)=u_{n0}\,, \quad x>x_{n-1} \tag{2.2}$$

and with the local conditions

$$u_1(x_0, t)=u_0 \cos \omega t\,, \quad t>0 \tag{3.1}$$

$$u_k(x_k, t)=u_{k+1}(x_k, t) \qquad (k=1, 2, \cdots, n-1)\,, \quad t>0 \tag{3.2}$$

$$\lambda_k\frac{\partial u_k}{\partial x}=\lambda_{k+1}\frac{\partial u_{k+1}}{\partial x}\,, \quad x=x_k \qquad (k=1, 2, \cdots, n-1)\,, \quad t>0\,. \tag{3.3}$$

In addition to this, $u_n(x, t)$ must be finite for $x \to +\infty$.

The physical interpretation of the relations (1.1)–(3.3) in the sense of one-dimensional heat conduction in solids is obvious.

§ 2. The Laplace Transforms of (1.1)–(3.3)

Putting generally

$$L[f(t)]=F(p)=p\int_0^\infty e^{-pt}f(t)dt\ , \qquad f(t)=L^{-1}[F(p)]=\frac{1}{2\pi i}\int_{\gamma-i\infty}^{\gamma+i\infty}\frac{E(p)}{p}e^{pt}dp \tag{4}$$

the above problem reduces to finding the solution $U_k=U_k(x, p)$ of

$$U_k''=\frac{p}{a_k^2}U_k=-\frac{p}{a_k^2}u_{k0}\ , \quad x_{k-1}<x<x_k \qquad (1\le k\le n-1) \tag{5.1}$$

$$U_n''-\frac{p}{a_n^2}U_n=-\frac{p}{a_n^2}u_{n0}\ , \quad x>x_{n-1} \tag{5.2}$$

$$U_1(x_0, p)=u_0\frac{p^2}{p^2+\omega^2} \tag{6.1}$$

$$U_k(x_k, p)=U_{k+1}(x_k, p) \qquad (1\le k\le n-1) \tag{6.2}$$

$$\lambda_k U_k'(x_k, p)=\lambda_{k+1}U'_{k+1}(x_k, p) \qquad (1\le k\le n-1) \tag{6.3}$$

with the finite value of $\lim\limits_{x\to+\infty} U_n(x, p)$, primes denote the x-derivatives.

From (5.1) and (5.2) we have generally

$$U_k(x, p)=A_k\,\mathrm{ch}\,\frac{(x-x_{k-1})\sqrt{p}}{a_k}+B_k\,\mathrm{sh}\,\frac{(x-x_{k-1})\sqrt{p}}{a_k}+u_{k0}\ , \quad x_{k-1}<x<x_k \qquad (1\le k\le n-1) \tag{7.1}$$

$$U_n(x, p)=A_n\exp\left[-\frac{(x-x_{n-1})\sqrt{p}}{a_n}\right]+u_{n0}\ , \quad x>x_{n-1} \tag{7.2}$$

and the conditions (6.1)–(6.3) lead to the system

$$A_1=u_0\frac{p^2}{p^2+\omega^2}-u_{10} \tag{8.1}$$

$$\left.\begin{aligned}A_{k+1}&=A_k\,\mathrm{ch}\,\frac{l_k\sqrt{p}}{a_k}+B_k\,\mathrm{sh}\,\frac{l_k\sqrt{p}}{a_k}+u_{k0}-u_{k+1,0}\\ B_{k+1}&=\frac{a_{k+1}\lambda_k}{a_k\lambda_{k+1}}\left(A_k\,\mathrm{sh}\,\frac{l_k\sqrt{p}}{a_k}+B_k\,\mathrm{ch}\,\frac{l_k\sqrt{p}}{a_k}\right) \qquad (1\le k\le n-2)\end{aligned}\right\} \tag{8.2}$$

$$\left.\begin{aligned}A_n&=A_{n-1}\,\mathrm{ch}\,\frac{l_{n-1}\sqrt{p}}{a_{n-1}}+B_{n-1}\,\mathrm{sh}\,\frac{l_{n-1}\sqrt{p}}{a_{n-1}}+u_{n-1,0}-u_{n0}\\ B_n&=-\frac{a_n\lambda_{n-1}}{a_{n-1}\lambda_n}\left(A_{n-1}\,\mathrm{sh}\,\frac{l_{n-1}\sqrt{p}}{a_{n-1}}+B_{n-1}\,\mathrm{ch}\,\frac{l_{n-1}\sqrt{p}}{a_{n-1}}\right)\ ;\end{aligned}\right\} \tag{8.3}$$

$$l_k=x_k-x_{k-1} \qquad (1\le k\le n-1_0) \tag{8.4}$$

of equations for the unknowns $A_k\ B_k$.

§ 3. Solution of the System (8.1)–(8.3)

Introducing the matrices

$$\left.\begin{aligned} &K_k=\left\|\begin{matrix}A_k\\ B_k\end{matrix}\right\| \quad (1\le k\le n-1)\,, \qquad P_k=\left\|\begin{matrix}u_{k0}-u_{k+1,0}\\ 0\end{matrix}\right\| \quad (1\le k\le n-2) \\ &M_k(p)=\left\|\begin{matrix} \operatorname{ch}\dfrac{l_k\sqrt{p}}{a_k}\,, & \operatorname{sh}\dfrac{l_k\sqrt{p}}{a_k} \\ \beta_k \operatorname{sh}\dfrac{l_k\sqrt{p}}{a_k}\,, & \beta_k\operatorname{ch}\dfrac{l_k\sqrt{p}}{a_k}\end{matrix}\right\|, \quad \beta_k=\frac{a_{k+1}\lambda_k}{a_k\lambda_{k+1}} \qquad (1\le k\le n-2)\end{aligned}\right\} \tag{9}$$

enables us to write the equations (8.2) in the form

$$K_{k+1}=M_k(p)K_k+P_k \qquad (1\le k\le n-2)\,. \tag{9.1}$$

Putting

$$N^{(k,\kappa)}=N^{(k,\kappa)}(p)=M_k(p)M_{k-1}(p)M_{k-2}(p)\cdots M_\kappa(p) \qquad (\kappa=1,2,\cdots,k;\ k=1,2,\cdots,n-2) \tag{10}$$

we obtain from (9.1)

$$K_{k+1}=N^{(k,1)}K_1+Q^{(k)} \qquad (1\le k\le n-2) \tag{11}$$

$$Q^{(1)}=P_1\,,\quad Q^{(k)}=\sum_{\kappa=1}^{k-1}N^{(k,\kappa+1)}P_\kappa+P_k \qquad (2\le k\le n-2)\,. \tag{11.1}$$

If we define β_{n-1} by the analogous relation

$$\beta_{n-1}=\frac{a_n\lambda_{n-1}}{a_{n-1}\lambda_n} \tag{12}$$

to the other β_k —see (9)—, then we conclude from (8.3)

$$\left(\operatorname{ch}\frac{l_{n-1}\sqrt{p}}{a_{n-1}}+\beta_{n-1}\operatorname{sh}\frac{l_{n-1}\sqrt{p}}{a_{n-1}}\right)A_{n-1}+\left(\operatorname{sh}\frac{l_{n-1}\sqrt{p}}{a_{n-1}}+\beta_{n-1}\operatorname{ch}\frac{l_{n-1}\sqrt{p}}{a_{n-1}}\right)B_{n-1}=u_{n0}-u_{n-1,0}\,.$$

Substituting into this equation for A_{n-1}, B_{n-1} from the last relation (11) yields

$$\begin{aligned}&\left[n_{11}^{(n-2,1)}\left(\operatorname{ch}\frac{l_{n-1}\sqrt{p}}{a_{n-1}}+\beta_{n-1}\operatorname{sh}\frac{l_{n-1}\sqrt{p}}{a_{n-1}}\right)+n_{21}^{(n-2,1)}\left(\operatorname{sh}\frac{l_{n-1}\sqrt{p}}{a_{n-1}}+\beta_{n-1}\operatorname{ch}\frac{l_{n-1}\sqrt{p}}{a_{n-1}}\right)\right]A_1\\ &\quad+\left[n_{12}^{(n-2,1)}\left(\operatorname{ch}\frac{l_{n-1}\sqrt{p}}{a_{n-1}}+\beta_{n-1}\operatorname{sh}\frac{l_{n-1}\sqrt{p}}{a_{n-1}}\right)+n_{22}^{(n-2,1)}\left(\operatorname{sh}\frac{l_{n-1}\sqrt{p}}{a_{n-1}}+\beta_{n-1}\operatorname{ch}\frac{l_{n-1}\sqrt{p}}{a_{n-1}}\right)\right]B_1\\ &\quad=-q_{11}^{(n-2)}\left(\operatorname{ch}\frac{l_{n-1}\sqrt{p}}{a_{n-1}}+\beta_{n-1}\operatorname{sh}\frac{l_{n-1}\sqrt{p}}{a_{n-1}}\right)-q_{21}^{(n-2)}\left(\operatorname{sh}\frac{l_{n-1}\sqrt{p}}{a_{n-1}}+\beta_{n-1}\operatorname{ch}\frac{l_{n-1}\sqrt{p}}{a_{n-1}}\right)\\ &\quad+u_{n0}-u_{n-1,0}\,;\end{aligned} \tag{13}$$

$n_{rs}^{(n-2,1)}$ and $q_{rs}^{(n-2)}$ are the elements of the matrices $N^{(n-2,1)}$ and $Q^{(n-2)}$, as defined in (10) and (11.1).

Recapitulating, the values A_k, B_k $(1\le k\le n-1)$, A_n are determined as follows: A_1 by (8.1), B_1 by (13), A_k, B_k $(2\le k\le n-1)$ are expressible in terms of A_1 and B_1 by means of (11) and the same can be done for A_n by means of the second relation (8.3).

§ 4. Theoretical Solution of the Problem (1.1)–(3.3)

Inserting the values A_k, B_k into (7.1) and (7.2) gives the Laplace transforms $U_k(x, p)$ and from this we obtain by (4) the wanted functions $u_k(x, t)$.

Practically, the unusual difficulty of our problem is evident from the impossibility of giving, in the general case, explicit forms of the matrices (10) which have a substantial role in the above deductions. Nevertheless, even in those exceptional cases where it is possible to calculate the matrices (10) one obtains complicated transforms $U_k(x, p)$ and the integration needed in the second formula (4) is not easy.

Now, we shall treat briefly an interesting class of cases where the above mathematical complications become smaller or disappear on the whole.

II. A SPECIAL SUBCLASS OF PROBLEMS

This second main part is devoted to the problems characterised by $\beta_k=1$ $(1 \leq k \leq n-2)$. Having deduced general formulas we shall treat some special questions of this group.

§ 5. The Case $\beta_k=1$ $(1 \leq k \leq n-2)$

Here we have by (9)

$$M_{\nu+1}(p)\cdot M_\nu(p)=\begin{Vmatrix} \operatorname{ch}\left(\frac{l_\nu}{a_\nu}+\frac{l_{\nu+1}}{a_{\nu+1}}\right)\sqrt{p}\,, & \operatorname{sh}\left(\frac{l_\nu}{a_\nu}+\frac{l_{\nu+1}}{a_{\nu+1}}\right)\sqrt{p} \\ \operatorname{sh}\left(\frac{l_\nu}{a_\nu}+\frac{l_{\nu+1}}{a_{\nu+1}}\right)\sqrt{p}\,, & \operatorname{ch}\left(\frac{l_\nu}{a_\nu}+\frac{l_{\nu+1}}{a_{\nu+1}}\right)\sqrt{p} \end{Vmatrix}; \qquad \nu=1, 2, \cdots, n-3$$

and from this, according to (10),

$$N^{(k,\kappa)}=\begin{Vmatrix} \operatorname{ch}\sigma_{k\kappa}\sqrt{p}\,, & \operatorname{sh}\sigma_{k\kappa}\sqrt{p} \\ \operatorname{sh}\sigma_{k\kappa}\sqrt{p}\,, & \operatorname{ch}\sigma_{k\kappa}\sqrt{p} \end{Vmatrix}, \quad \sigma_{k\kappa}=\sum_{\nu=\kappa}^{k}\frac{l_\nu}{a_\nu} \qquad (1 \leq \kappa \leq k,\ 1 \leq k \leq n-2)\,. \tag{14}$$

Using this, along with (9), formulae (11.1) give without difficulty

$$Q^{(1)}=\begin{Vmatrix} u_{10}-u_{20} \\ 0 \end{Vmatrix}, \quad Q^{(k)}=\begin{Vmatrix} u_{k0}-u_{k+1,0}+\sum\limits_{\kappa=1}^{k-1}(u_{\kappa 0}-u_{\kappa+1,0})\operatorname{ch}\sigma_{k,\kappa+1}\sqrt{p} \\ \sum\limits_{\kappa=1}^{k-1}(u_{\kappa 0}-u_{\kappa+1,0})\operatorname{sh}\sigma_{k,\kappa+1}\sqrt{p} \end{Vmatrix} \qquad (2 \leq k \leq n-2) \tag{15}$$

and the relation (13) appears in the form

$$\left.\begin{aligned} &A_1(\operatorname{ch}\sigma_{n-1,1}\sqrt{p}+\beta_{n-1}\operatorname{sh}\sigma_{n-1,1}\sqrt{p})+B_1(\operatorname{sh}\sigma_{n-1,1}\sqrt{p}+\beta_{n-1}\operatorname{ch}\sigma_{n-1,1}\sqrt{p}) \\ &\quad =u_{n0}-u_{n-1,0}+\sum_{\kappa=1}^{n-2}(u_{\kappa+1,0}-u_{\kappa 0})(\operatorname{ch}\sigma_{n-1,\kappa+1}\sqrt{p}+\beta_{n-1}\operatorname{sh}\sigma_{n-1,\kappa+1}\sqrt{p})\,, \\ &\sigma_{n-1,1}=\sum_{\nu=1}^{n-1}\frac{l_\nu}{a_\nu}\,, \quad \sigma_{n-1,\kappa+1}=\sum_{\nu=\kappa+1}^{n-1}\frac{l_\nu}{a_\nu} \qquad (1 \leq \kappa \leq n-2)\,. \end{aligned}\right\} \tag{16}$$

Calculating, by means of (8.1), (16), (11), (14), (15) and (8.3), the expressions A_k, B_k and substituting into (7.1), (7.2) leads to the following complicated transforms $U_k(x, p)$ of the wanted functions $u_k(x, t)$:

$$\left.\begin{aligned} U_1(x, p)&=\frac{1}{\operatorname{sh}\sigma_{n-1,1}\sqrt{p}+\beta_{n-1}\operatorname{ch}\sigma_{n-1,1}\sqrt{p}}\left\{\left(u_0\frac{p^2}{p^2+\omega^2}-u_{10}\right)\right. \\ &\times\left[\operatorname{sh}\left(\sigma_{n-1,1}-\frac{x-x_0}{a_1}\right)\sqrt{p}+\beta_{n-1}\operatorname{ch}\left(\sigma_{n-1,1}-\frac{x-x_0}{a_1}\right)\sqrt{p}\right]+\operatorname{sh}\frac{(x-x_0)\sqrt{p}}{a_1} \\ &\times\left.\left[u_{n0}-u_{n-1,0}+\sum_{\kappa=1}^{n-2}(u_{\kappa+1,0}-u_{\kappa 0})(\operatorname{ch}\sigma_{n-1,\kappa+1}\sqrt{p}+\beta_{n-1}\operatorname{sh}\sigma_{n-1,\kappa+1}\sqrt{p})\right]\right\}+u_{10} \\ U_{k+1}(x, p)&=\frac{1}{\operatorname{sh}\sigma_{n-1,1}\sqrt{p}+\beta_{n-1}\operatorname{ch}\sigma_{n-1,1}\sqrt{p}}\left\{\left(u_0\frac{p^2}{p^2+\omega^2}-u_{10}\right)\right. \\ &\times\left[\operatorname{sh}\left(\sigma_{n-1,k+1}-\frac{x-x_k}{a_{k+1}}\right)\sqrt{p}+\beta_{n-1}\operatorname{ch}\left(\sigma_{n-1,k+1}-\frac{x-x_k}{a_{k+1}}\right)\sqrt{p}\right]+\operatorname{sh}\left(\frac{x-x_k}{a_{k+1}}+\sigma_{k1}\right) \\ &\times\left.\sqrt{p}\left[u_{n0}-u_{n-1,0}+\sum_{\kappa=1}^{n-2}(u_{\kappa+1,0}-u_{\kappa 0})(\operatorname{ch}\sigma_{n-1,\kappa+1}\sqrt{p}+\beta_{n-1}\operatorname{sh}\sigma_{n-1,\kappa+1}\sqrt{p})\right]\right\} \\ &+(u_{k0}-u_{k+1,0})\operatorname{ch}\frac{(x-x_k)\sqrt{p}}{a_{k+1}}+\sum_{\kappa=1}^{k-1}(u_{\kappa 0}-u_{\kappa+1,0})\operatorname{ch}\left(\frac{x-x_k}{a_{k+1}}+\sigma_{k,\kappa+1}\right)\sqrt{p}+u_{k+1,0} \\ &\qquad\qquad\left(1 \leq k \leq n-2;\ \sum_{\kappa=1}^{0}=0\right) \end{aligned}\right\} \tag{17}$$

$$U_n(x,p)=u_{n0}+\frac{\beta_{n-1}}{\operatorname{sh}\sigma_{n-1,1}\sqrt{p}+\beta_{n-1}\operatorname{ch}\sigma_{n-1,1}\sqrt{p}}\exp\left(-\frac{x-x_{n-1}}{a_n}\sqrt{p}\right)$$
$$\times\left[u_0\frac{p^2}{p^2+\omega^2}-u_{10}+\sum_{\kappa=1}^{n-1}(u_{\kappa0}-u_{\kappa+1,0})\operatorname{ch}\sigma_{\kappa1}\sqrt{p}\right].$$

The wanted functions $u_k(x, t)$ are to be found from their Laplace transforms (17) by contour integration, according to the second formula (4). Of course, the results are in general formidably complicated and so we confine ourselves merely to some simpler special cases which are also of considerable physical interest.

§ 6. A Homogeneous Semiinfinite Solid

In this simplest case we have to put $a_k=a$, $\lambda_k=\lambda$ $(1\le k\le n)$ and it follows

$$\beta_{n-1}=1\,,\qquad \sigma_{k\kappa}=\frac{1}{a}(x_k-x_{\kappa-1})\,.$$

The Laplace transforms (17) appear in the form

$$\left.\begin{aligned}
U_1(x,p)&=u_{10}+\left(u_0\frac{p^2}{p^2+\omega^2}-u_{10}\right)\exp\left(-\frac{x-x_0}{a}\sqrt{p}\right)\\
&\quad+\operatorname{sh}\frac{(x-x_0)\sqrt{p}}{a}\sum_{\kappa=1}^{n-1}(u_{\kappa+1,0}-u_{\kappa0})\exp\left(-\frac{x_\kappa-x_0}{a}\sqrt{p}\right)\\
U_{k+1}(x,p)&=u_{k+1,0}+\left(u_0\frac{p^2}{p^2+\omega^2}-u_{10}\right)\exp\left(-\frac{x-x_0}{a}\sqrt{p}\right)\\
&\quad+\operatorname{sh}\frac{(x-x_0)\sqrt{p}}{a}\sum_{\kappa=1}^{n-1}(u_{\kappa+1,0}-u_{\kappa0})\exp\left(-\frac{x_\kappa-x_0}{a}\sqrt{p}\right)+\sum_{\kappa=1}^{k}(u_{\kappa0}-u_{\kappa+1,0})\operatorname{ch}\frac{(x-x_\kappa)\sqrt{p}}{a}\\
&\qquad\qquad(1\le k\le n-2)\\
U_n(x,p)&=u_{n0}+\exp\left(-\frac{x-x_0}{a}\sqrt{p}\right)\left[u_0\frac{p^2}{p^2+\omega^2}-u_{10}+\sum_{\kappa=1}^{n-1}(u_{\kappa0}-u_{\kappa+1,0})\operatorname{ch}\frac{(x_\kappa-x_0)\sqrt{p}}{a}\right]
\end{aligned}\right\}\tag{18}$$

or, with a single formula valid in the whole range $x>x_0$,

$$U(x,p)=u_{10}\left\{1-\exp\left(-\frac{x-x_0}{a}\sqrt{p}\right)\right\}+\frac{1}{2}\sum_{\kappa=1}^{n-1}(u_{\kappa+1,0}-u_{\kappa0})\left[1-\exp\left(-\frac{x+x_\kappa-2x_0}{a}\sqrt{p}\right)\right.$$
$$\left.+\operatorname{sgn}(x-x_\kappa)\left\{1-\exp\left(-\frac{|x-x_\kappa|}{a}\sqrt{p}\right)\right\}\right]+u_0\frac{p^2}{p^2+\omega^2}\exp\left(-\frac{x-x_0}{a}\sqrt{p}\right).\tag{18.1}$$

Regarding the well-known operational relations

$$\left.\begin{aligned}
&L^{-1}[1-e^{-|\kappa|\sqrt{p}}]=\operatorname{sgn}\kappa\,\Phi\left(\frac{\kappa}{2\sqrt{t}}\right),\quad \Phi(x)=\frac{2}{\sqrt{\pi}}\int_0^x e^{-\xi^2}d\xi\\
&L^{-1}\left[\frac{p^2}{p^2+\omega^2}e^{-\kappa\sqrt{p}}\right]=e^{-\kappa\sqrt{\omega/2}}\cos(\omega t-\kappa\sqrt{\omega/2})-\frac{1}{\pi}\int_0^\infty\frac{\rho e^{-\rho t}}{\rho^2+\omega^2}\sin\kappa\sqrt{\rho}\,d\rho\\
&\quad=\frac{2}{\sqrt{\pi}}\int_{\kappa/(2\sqrt{t})}^\infty e^{-\xi^2}\cos\omega\left(t-\frac{\kappa^2}{4\xi^2}\right)d\xi\,,\qquad \kappa>0
\end{aligned}\right\}\tag{19}$$

we obtain from (18.1) the following solution of our special case:

$$u(x,t)=u_{10}\Phi\left(\frac{x-x_0}{2a\sqrt{t}}\right)+\frac{1}{2}\sum_{\kappa=2}^{n-1}(u_{\kappa+1,0}-u_{\kappa0})\left[\Phi\left(\frac{x+x_\kappa-2x_0}{2a\sqrt{t}}\right)+\Phi\left(\frac{x-x_\kappa}{2a\sqrt{t}}\right)\right]$$
$$+u_0\left[\exp\left(-\frac{x-x_0}{a}\sqrt{\frac{\omega}{2}}\right)\cos\left(\omega t-\frac{x-x_0}{a}\sqrt{\frac{\omega}{2}}\right)-\frac{1}{\pi}\int_0^\infty\frac{\rho e^{-\rho t}}{\rho^2+\omega^2}\sin\frac{(x-x_0)\sqrt{\rho}}{a}d\rho\right]$$

$$
\begin{aligned}
&= u_{10}\Phi\left(\frac{x-x_0}{2a\sqrt{t}}\right)+\frac{1}{2}\sum_{\kappa=1}^{n-1}(u_{\kappa+1,0}-u_{\kappa 0})\left[\Phi\left(\frac{x+x_\kappa-2x_0}{2a\sqrt{t}}\right)+\Phi\left(\frac{x-x_\kappa}{2a\sqrt{t}}\right)\right] \\
&\quad+\frac{2u_0}{\sqrt{\pi}}\int_{x-x_0/(2a\sqrt{t})}^{\infty} e^{-\xi^2}\cos\omega\left[t-\frac{(x-x_0)^2}{4a^2\xi^2}\right]d\xi\,,
\end{aligned}
\tag{20}
$$

§ 7. A Semiinfinite Solid Composite of Two Homogeneous Parts

Let the first part be $x_0 \leq x \leq x_{n-1}$, the second $x > x_{n-1}$; let the corresponding thermal constants be a, λ in the first and A, Λ in the second part of the solid.

Hence, we have to put, in (17),

$$
a_k = a\,,\quad \lambda_k=\lambda \qquad (1\leq k\leq n-1)\,,\qquad a_n=A\,,\quad \lambda_n=\Lambda\,.
$$

It follows

$$
\beta_{n-1}=\frac{A\lambda}{a\Lambda}\,,\quad \sigma_{k\kappa}=\frac{1}{a}(x_k-x_{\kappa-1})\,,\qquad 1\leq k\leq n-1,\ 1\leq\kappa\leq k
$$

and the Laplace transforms (17) appear in the form

$$
\begin{aligned}
U_{k+1}(x,p) &= u_{k+1,0}+\frac{1}{\operatorname{sh}\dfrac{x_{n-1}-x_0}{a}\sqrt{p}+\beta_{n-1}\operatorname{ch}\dfrac{x_{n-1}-x_0}{a}\sqrt{p}} \\
&\times\left\{\left(u_0\frac{p^2}{p^2+\omega^2}-u_{10}\right)\left(\operatorname{sh}\frac{x_{n-1}-x}{a}\sqrt{p}+\beta_{n-1}\operatorname{ch}\frac{x_{n-1}-x}{a}\sqrt{p}\right)\right. \\
&\left.+\operatorname{sh}\frac{x-x_0}{a}\sqrt{p}\sum_{\kappa=1}^{n-1}(u_{\kappa+1,0}-u_{\kappa 0})\left(\frac{x_{n-1}-x_\kappa}{a}\sqrt{p}+\beta_{n-1}\operatorname{sh}\frac{x_{n-1}-x_\kappa}{a}\sqrt{p}\right)\right\} \\
&+\sum_{\kappa=1}^{k}(u_{\kappa 0}-u_{\kappa+1,0})\operatorname{ch}\frac{x-x_\kappa}{a}\sqrt{p}\qquad\left(0\leq k\leq n-2,\ \sum_{\kappa=1}^{0}=0\right)
\end{aligned}
\tag{21.1}
$$

$$
\begin{aligned}
U_n(x,p) &= u_{n0}+\frac{\beta_{n-1}}{\operatorname{sh}\dfrac{x_{n-1}-x_0}{a}\sqrt{p}+\beta_{n-1}\operatorname{ch}\dfrac{x_{n-1}-x_0}{a}\sqrt{p}}\exp\left(-\frac{x-x_{n-1}}{A}\sqrt{p}\right) \\
&\times\left[u_0\frac{p^2}{p^2+\omega^2}-u_{10}+\sum_{\kappa=1}^{n-1}(u_{\kappa 0}-u_{\kappa+1,0})\operatorname{ch}\frac{x_\kappa-x_0}{a}\sqrt{p}\right].
\end{aligned}
\tag{21.2}
$$

Of course, it is obvious, by technical sense of our problem, that there must exist a single expression of all $U_k(x, p)$, $1\leq k\leq n-1$, valid in the whole region $x_0 < x < x_{n-1}$. And in fact, difficult transformations lead to the following formula replacing all the relations (21.1):

$$
\begin{aligned}
U(x,p) &= u_0\frac{p^2}{p^2+\omega^2}\cdot\frac{N(x)}{N(x_0)}+\frac{1}{2}(u_{n0}-u_{10})+u_{10}\left[1-\frac{N(x)}{N(x_0)}\right] \\
&+\frac{1}{4}\sum_{\kappa=1}^{n-1}(u_{\kappa+1,0}-u_{\kappa 0})\left\{2\operatorname{sgn}(x-x_\kappa)\left\{1-\exp\left(-\frac{|x-x_\kappa|}{a}\sqrt{p}\right)\right\}\right. \\
&-\frac{1}{N(x_0)}\left[(\beta+1)\exp\left(\frac{-x+x_0-x_\kappa+x_{n-1}}{a}\sqrt{p}\right)+(\beta-1)\left(\exp\left(\frac{x+x_0-x_\kappa-x_{n-1}}{a}\sqrt{p}\right)\right.\right. \\
&\left.\left.\left.+2\exp\left(-\frac{x_{n-1}-x_\kappa}{a}\sqrt{p}\right)\operatorname{sh}\frac{x-x_0}{a}\sqrt{p}\right)\right]\right\}\,,\qquad x_0\leq x\leq x_{n-1}\,;
\end{aligned}
\tag{22}
$$

$$
N(x)=\operatorname{sh}\frac{x_{n-1}-x}{a}\sqrt{p}+\beta\operatorname{ch}\frac{x_{n-1}-x}{a}\sqrt{p}\,,\qquad \beta=\frac{A\lambda}{a\Lambda}\,,
\tag{22.1}
$$

The problem is then reduced to finding the original functions $u(x, t)$ and $u_n(x, t)$ from their Laplace transforms (22) and —see (21.2)—

$$\begin{aligned}U_n(x,p)&=\beta u_0\frac{p^2}{p^2+\omega^2}\cdot\frac{\exp\left(-\frac{x-x_{n-1}}{A}\sqrt{p}\right)}{N(x_0)}+u_{n0}-\beta u_{10}\frac{\exp\left(-\frac{x-x_{n-1}}{A}\sqrt{p}\right)}{N(x_0)}\\&+\beta\frac{\exp\left(-\frac{x-x_{n-1}}{A}\sqrt{p}\right)}{N(x_0)}\sum_{\kappa=1}^{n-1}(u_{\kappa 0}-u_{\kappa+1,0})\,\mathrm{ch}\,\frac{x_\kappa-x_0}{a}\sqrt{p}\,,\qquad x>x_{n-1}\,.\end{aligned}\tag{23}$$

To obtain the solution $u(x,t)$, $u_n(x,t)$ of our problem we make use of the very general operational relation

$$\begin{aligned}&L^{-1}\left[\frac{p^2}{p^2+\omega^2}\cdot\frac{\mathrm{sh}\,\kappa\sqrt{p}+\alpha\,\mathrm{ch}\,\kappa\sqrt{p}}{\mathrm{sh}\,\lambda\sqrt{p}+\gamma\,\mathrm{ch}\,\lambda\sqrt{p}}\right]\\&=\frac{2}{(\gamma^2+1)\,\mathrm{ch}\,2\lambda\sqrt{\frac{\omega}{2}}+2\gamma\,\mathrm{sh}\,2\lambda\sqrt{\frac{\omega}{2}}+(\gamma^2-1)\cos 2\lambda\sqrt{\frac{\omega}{2}}}\Bigg\{\cos\omega t\Bigg[\left(\mathrm{sh}\,\kappa\sqrt{\frac{\omega}{2}}+\alpha\,\mathrm{ch}\,\kappa\sqrt{\frac{\omega}{2}}\right)\\&\times\left(\mathrm{sh}\,\lambda\sqrt{\frac{\omega}{2}}+\gamma\,\mathrm{ch}\,\lambda\sqrt{\frac{\omega}{2}}\right)\cos\kappa\sqrt{\frac{\omega}{2}}\cos\lambda\sqrt{\frac{\omega}{2}}+\left(\mathrm{ch}\,\kappa\sqrt{\frac{\omega}{2}}+\alpha\,\mathrm{sh}\,\kappa\sqrt{\frac{\omega}{2}}\right)\\&\times\left(\mathrm{ch}\,\lambda\sqrt{\frac{\omega}{2}}+\gamma\,\mathrm{sh}\,\lambda\sqrt{\frac{\omega}{2}}\right)\sin\kappa\sqrt{\frac{\omega}{2}}\sin\lambda\sqrt{\frac{\omega}{2}}\Bigg]+\sin\omega t\Bigg[\left(\mathrm{sh}\,\kappa\sqrt{\frac{\omega}{2}}+\alpha\,\mathrm{ch}\,\kappa\sqrt{\frac{\omega}{2}}\right)\\&\times\left(\mathrm{ch}\,\lambda\sqrt{\frac{\omega}{2}}+\gamma\,\mathrm{sh}\,\lambda\sqrt{\frac{\omega}{2}}\right)\cos\kappa\sqrt{\frac{\omega}{2}}\sin\lambda\sqrt{\frac{\omega}{2}}-\left(\mathrm{ch}\,\kappa\sqrt{\frac{\omega}{2}}+\alpha\,\mathrm{sh}\,\kappa\sqrt{\frac{\omega}{2}}\right)\\&\times\left(\mathrm{sh}\,\lambda\sqrt{\frac{\omega}{2}}+\gamma\,\mathrm{ch}\,\lambda\sqrt{\frac{\omega}{2}}\right)\sin\kappa\sqrt{\frac{\omega}{2}}\cos\lambda\sqrt{\frac{\omega}{2}}\Bigg]\Bigg\}\\&-\frac{2}{\pi}\int_0^\infty\frac{\xi^3e^{-\xi^2t}}{\xi^4+\omega^2}\cdot\frac{\alpha\cos\kappa\xi\sin\lambda\xi-\gamma\sin\kappa\xi\cos\lambda\xi}{\sin^2\lambda\xi+\gamma^2\cos^2\lambda\xi}d\xi\,,\qquad\kappa>\lambda\,.\end{aligned}\tag{24}$$

This complicated formula follows from the second relation (4) and its derivation presupposes an adequate experience in calculating contour integrals of multivalued functions in their Riemann surfaces.

Specialising in suitable way the parameters α, γ, κ, λ, ω, the formula (24) yields all the original functions needed in (22), (23) and the complete solution of the problem appears with toilsome calculations in the form

$$\begin{aligned}u(x,t)&=\frac{u_0}{\Delta}\Bigg\{(\beta+1)^2\exp\left(\frac{-x-x_0+2x_{n-1}}{a}\sqrt{\frac{\omega}{2}}\right)\cos\left(\omega t-\frac{x-x_0}{a}\sqrt{\frac{\omega}{2}}\right)\\&+(\beta-1)^2\exp\left(\frac{x+x_0-2x_{n-1}}{a}\sqrt{\frac{\omega}{2}}\right)\cos\left(\omega t+\frac{x-x_0}{a}\sqrt{\frac{\omega}{2}}\right)+(\beta^2-1)\Bigg[\exp\left(\frac{x-x_0}{a}\sqrt{\frac{\omega}{2}}\right)\\&\times\cos\left(\omega t+\frac{x+x_0-2x_{n-1}}{a}\sqrt{\frac{\omega}{2}}\right)+\exp\left(-\frac{x-x_0}{a}\sqrt{\frac{\omega}{2}}\right)\cos\left(\omega t-\frac{x+x_0-2x_{n-1}}{a}\sqrt{\frac{\omega}{2}}\right)\Bigg]\Bigg\}\\&-\frac{2\beta u_0}{\pi}\int_0^\infty\frac{\xi^3e^{-\xi^2t}}{(\xi^4+\omega^2)D(\xi)}\sin\frac{(x-x_0)\xi}{a}d\xi+\frac{2\beta u_{10}}{\pi}\int_0^\infty\frac{e^{-\xi^2t}}{\xi D(\xi)}\sin\frac{(x-x_0)\xi}{a}d\xi\\&+\frac{1}{2}\sum_{\kappa=1}^{n-1}(u_{\kappa+1,0}-u_{\kappa 0})\Bigg\{\Phi\left(\frac{x-x_\kappa}{2a\sqrt{t}}\right)+\frac{2}{\pi}\int_0^\infty\frac{e^{-\xi^2t}}{\xi D(\xi)}\Bigg[\beta\sin\frac{x-2x_0+x_\kappa}{a}\xi\\&+(\beta-1)\sin\frac{x-x_\kappa}{a}\xi\left(\sin^2\frac{x_{n-1}-x_0}{a}\xi-\beta\cos^2\frac{x_{n-1}-x_0}{a}\xi\right)\Bigg]d\xi\Bigg\}\,,\\&\qquad x_0\le x\le x_{n-1}\end{aligned}\tag{25.1}$$

$$
\begin{aligned}
u_n(x,t)=\frac{2\beta u_0}{\Delta}\Bigg\{&(\beta+1)\exp\left[\left(\frac{x_{n-1}-x_0}{a}-\frac{x-x_{n-1}}{A}\right)\sqrt{\frac{\omega}{2}}\right]\cos\left[\omega t-\left(\frac{x_{n-1}-x_0}{a}+\frac{x-x_{n-1}}{A}\right)\sqrt{\frac{\omega}{2}}\right]\\

&+\frac{2\beta}{\pi}\sum_{\kappa=1}^{n-1}(u_{\kappa+1,0}-u_{\kappa 0})\int_0^\infty\frac{e^{-\xi^2t}}{\xi D(\xi)}\cos\frac{x_\kappa-x_0}{a}\xi\left(\sin\frac{x_{n-1}-x_0}{a}\xi\cos\frac{x-x_{n-1}}{A}\xi\right.\\
&\left.+\beta\cos\frac{x_{n-1}-x_0}{a}\xi\sin\frac{x-x_{n-1}}{A}\xi\right)d\xi\,,\qquad x>x_{n-1}
\end{aligned}
\tag{25.2}
$$

$$
\left.
\begin{aligned}
\Delta=(\beta+1)^2\exp\left[\frac{2(x_{n-1}-x_0)}{a}\sqrt{\frac{\omega}{2}}\right]&+(\beta-1)^2\exp\left[-\frac{2(x_{n-1}-x_0)}{a}\sqrt{\frac{\omega}{2}}\right]\\
&+2(\beta^2-1)\cos\frac{2(x_{n-1}-x_0)}{a}\sqrt{\frac{\omega}{2}}\\
D(\xi)=\sin^2\frac{x_{n-1}-x_0}{a}\xi+\beta^2\cos^2\frac{x_{n-1}-x_0}{a}\xi\,,&\qquad\beta=\frac{A\lambda}{a\Lambda}\,.
\end{aligned}
\right\}
\tag{25.3}
$$

Apart from many new questions on the heat conduction in semiinfinite solids our formulae (25.1)–(25.3) include as simple special cases numerous current problems as known from elementary textbooks on the subject[6,7]. We expressly remind of two simple examples.

7.1. The case $A=a$, $\Lambda=\lambda$. Here we have a homogeneous semiinfinite solid as treated in § 6. And in fact, our formulae (25.1)–(25.3) change in the present conditions into the former result (20). Especially fargoing simplifications occur if $u_{10}=u_{20}=\cdots=u_{n0}$ or if $\omega=0$.

7.2. The case $\beta\neq 1$. This corresponds to a semiinfinite solid consisting of two homogeneous parts. Special attention is to be paid to the case $u_{10}=u_{20}=\cdots=u_{n-1,0}$ and to the class of problems characterised by $\omega=0$.

§ 8. A Nonhomogeneous Solid of n Parts

It is possible to find the original functions to the Laplace transforms (17), but the result is formidably complicated. In order to have reasonable formulae we make here, in addition to the above basic assumption $\beta_1=\beta_2=\cdots=\beta_{n-2}=1$, another simplifying presupposition $u_{10}=u_{20}=\cdots=u_{n0}=u^{(0)}$. In this case our general relations (17) give

$$
\left.
\begin{aligned}
U_{k+1}(x,p)&=u^{(0)}+\frac{1}{Q}\left(u_0\frac{p^2}{p^2+\omega^2}-u^{(0)}\right)\\
&\times\left[\operatorname{sh}\left(\sigma_{n-1,k+1}-\frac{x-x_k}{a_{k+1}}\right)\sqrt{p}+\beta\operatorname{ch}\left(\sigma_{n-1,k+1}-\frac{x-x_k}{a_{k+1}}\right)\sqrt{p}\right]\qquad(0\leq k\leq n-2)\\
U_n(x,p)&=u^{(0)}+\frac{\beta}{Q}\left(u_0\frac{p^2}{p^2+\omega^2}-u^{(0)}\right)\exp\left(-\frac{x-x_{n-1}}{a_n}\sqrt{p}\right)
\end{aligned}
\right\}
\tag{26}
$$

$$
Q=\operatorname{sh}\sigma_{n-1,1}\sqrt{p}+\beta\operatorname{ch}\sigma_{n-1,1}\sqrt{p}\,,\qquad\beta=\frac{a_n\lambda_{n-1}}{a_{n-1}\lambda_n}\;;
\tag{26.1}
$$

the values $\sigma_{k\kappa}$ are defined in (14) and (16).

Making appropriate use of the operational formula (24) one obtains from (26) the following solution of our present case:

$$\left.\begin{aligned}
u_{k+1}(x,t)=\frac{u_0}{\varDelta}\Big\{&(\beta+1)^2\exp\left[\left(\sigma_{k1}+2\sigma_{n-1,k+1}-\frac{x-x_k}{a_{k+1}}\right)\sqrt{\frac{\omega}{2}}\right]\cos\left[\omega t-\left(\sigma_{k1}+\frac{x-x_k}{a_{k+1}}\right)\sqrt{\frac{\omega}{2}}\right]\\
&+(\beta-1)^2\exp\left[-\left(\sigma_{k1}+2\sigma_{n-1,k+1}-\frac{x-x_k}{a_{k+1}}\right)\sqrt{\frac{\omega}{2}}\right]\cos\left[\omega t+\left(\sigma_{k1}+\frac{x-x_k}{a_{k+1}}\right)\sqrt{\frac{\omega}{2}}\right]\\
&+(\beta^2-1)\exp\left[\left(\sigma_{k1}+\frac{x-x_k}{a_{k+1}}\right)\sqrt{\frac{\omega}{2}}\right]\cos\left[\omega t-\left(\sigma_{k1}+2\sigma_{n-1,k+1}-\frac{x-x_k}{a_{k+1}}\right)\sqrt{\frac{\omega}{2}}\right]\\
&+(\beta^2-1)\exp\left[-\left(\sigma_{k1}+\frac{x-x_k}{a_{k+1}}\right)\sqrt{\frac{\omega}{2}}\right]\cos\left[\omega t+\left(\sigma_{k1}+2\sigma_{n-1,k+1}-\frac{x-x_k}{a_{k+1}}\right)\sqrt{\frac{\omega}{2}}\right]\Big\}\\
&-\frac{2\beta u_0}{\pi}\int_0^\infty\frac{\xi^3e^{-\xi^2t}}{\xi^4+\omega^2}\cdot\frac{\sin\left(\sigma_{k1}+\frac{x-x_k}{a_{k+1}}\right)\xi}{\sin^2\sigma_{n-1,1}\xi+\beta^2\cos^2\sigma_{n-1,1}\xi}\,d\xi\\
&+\frac{2\beta u^{(0)}}{\pi}\int_0^\infty\frac{e^{-\xi^2t}}{\xi}\cdot\frac{\sin\left(\sigma_{k1}+\frac{x-x_k}{a_{k+1}}\right)\xi}{\sin^2\sigma_{n-1,1}\xi+\beta^2\cos^2\sigma_{n-1,1}\xi}\,d\xi\,,\qquad x_k\le x\le x_{k+1}\qquad(0\le k\le n-2)\\
u_n(x,t)=\frac{2\beta u_0}{\varDelta}\Big\{&(\beta+1)\exp\left[\left(\sigma_{n-1,1}-\frac{x-x_{n-1}}{a_n}\right)\sqrt{\frac{\omega}{2}}\right]\cos\left[\omega t-\left(\sigma_{n-1,1}+\frac{x-x_{n-1}}{a_n}\right)\sqrt{\frac{\omega}{2}}\right]\\
&+(\beta-1)\exp\left[-\left(\sigma_{n-1,1}+\frac{x-x_{n-1}}{a_n}\right)\sqrt{\frac{\omega}{2}}\right]\cos\left[\omega t+\left(\sigma_{n-1,1}-\frac{x-x_{n-1}}{a_n}\right)\sqrt{\frac{\omega}{2}}\right]\Big\}\\
&-\frac{2\beta u_0}{\pi}\int_0^\infty\frac{\xi^3e^{-\xi^2t}}{\xi^4+\omega^2}\cdot\frac{\sin\sigma_{n-1,1}\xi\cos\frac{x-x_{n-1}}{a_n}\xi+\beta\cos\sigma_{n-1,1}\xi\sin\frac{x-x_{n-1}}{a_n}\xi}{\sin^2\sigma_{n-1,1}\xi+\beta^2\cos^2\sigma_{n-1,1}\xi}\,d\xi\\
&+\frac{2\beta u^{(0)}}{\pi}\int_0^\infty\frac{e^{-\xi^2t}}{\xi}\cdot\frac{\sin\sigma_{n-1,1}\xi\cos\frac{x-x_{n-1}}{a_n}\xi+\beta\cos\sigma_{n-1,1}\xi\sin\frac{x-x_{n-1}}{a_n}\xi}{\sin^2\sigma_{n-1,1}\xi+\beta^2\cos^2\sigma_{n-1,1}\xi}\,d\xi\,,\\
&\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad x>x_{n-1}\,;
\end{aligned}\right\}\qquad(27)$$

$$\varDelta=(\beta+1)^2\exp\left(2\sigma_{n-1,1}\sqrt{\frac{\omega}{2}}\right)+(\beta-1)^2\exp\left(-2\sigma_{n-1,1}\sqrt{\frac{\omega}{2}}\right)+2(\beta^2-1)\cos2\sigma_{n-1,1}\sqrt{\frac{\omega}{2}}\,,$$
$$\beta=\frac{A\lambda}{aA}\,,\quad\sigma_{01}=0\,.\qquad(27.1)$$

§ 9. Final Remark

Evidently, our preceding results can be immediately applied to the solution of the well-known advanced problems of theoretical electricity. The author of this paper hopes shortly to treat belonging questions is another paper.

Nuclear Magnetic Resonance of RbBr

By Junkichi ITOH and Yukio YAMAGATA

Department of Physics, Osaka University, Osaka

(Received November 28, 1958)

We have made nuclear magnetic resonance studies of alkali halides having alkali and halogen ions of similar electronic configurations. In these alkali halides, comparison with the theories[1,2] can be made with less ambiguity, because the masses of the ions are nearly equal. We measured spin-lattice relaxation time T_1 as well as paramagnetic chemical shift σ (referred to the resonance in dilute aqueous solution of the same salt*) for RbBr and KCl. In this note, we shall describe the results for RbBr.

The measured values of T_1 and σ at room temperature were as follows: T_1 (Rb^{87})=0.27 sec, T_1 (Br^{81})=0.16 sec, σ(Rb)$=1.6\times10^{-4}$, and σ(Br)$=1.05\times10^{-4}$.

First we shall compare the experimental results with the theory given by Yosida and Moriya[2], in which some small degree of covalency was assumed in the bond between alkali and halogen ions. According to their theory, the ratios of σ and $1/T_1$ for Rb and Br are simply given by the ratios of $\langle r^{-3}\rangle$ (average of r^{-3} over covalent p-orbital), s-p hybridization degree and nuclear quadrupole moments. On forming small covalent bond, one valence electron ($4p$-electron) of Br ion will transfer to the outer orbital of Rb ion. This orbital may be $5s$-$5p$ hybridized orbital, the weight of s-orbital being probably predominant. So, the calculated ratios of σ and $1/T_1$ for Rb and Br are very much smaller than the experimental one, though σ and T_1 for Br alone may be well interpreted by taking appropriate degree of covalency. Even if we assume a configurational interaction in Rb ion by which $4p$-orbital is partially mixed with $5p$-orbital, the experimental ratios may not be interpreted appropriately.

Next, we shall compare the experimental results with Kranendonk's theory[1], in which only the electrostatic effect of charges outside of the ion core is taken into account. The calculated ratio of $1/T_1$ for Rb and Br, with appropriate values of Sternheimer's antishielding factors,[3,4] gives much better approach to the experimental ratio than the covalency theory, but it is still smaller by a factor of 10 or so. However, ion core deformation by charges outside of it may not produce σ of the order which we have measured, in the framework of the original Sternheimer's theory.[3]

Also, we measured the relative intensities of Rb^{85} and Br^{81} resonances, from which it was concluded that $1/2\leftrightarrow-1/2$ transitions alone contribute to the observed resonance in these cases, while the width of the resonance lines was equal to the dipolar width. This indicates that imperfections of the crystal may produce static quadrupole energies of the same order of magnitude in Rb and Br.

These experimental results show that there seems no substantial difference in the nuclear magnetic resonance of Rb and Br in RbBr crystal, and that σ, T_1, and the quadrupole effects due to crystal imperfections may be determined, at least in their orders of magnitude, by the electronic configuration of the ion, regardless of the sign of ionic charge. To interpret the nuclear magnetic resonance of alkali halides, a more elaborate theory should be used, in which the overlapping of ion cores, the deformation of ion core by outside charges, possible covalent nature in the bond, etc. are taken into consideration.

We have made similar experiments on K and Cl nuclei in KCl. The details of the experiments will be published elsewhere.

---

* Concentration dependence of the shift in nuclear magnetic resonance of Rb or Br was found in aqueous solution of alkali halides containing Rb or Br ion, as in iodide ion in aqueous solution of alkali iodides.[5] So, the chemical shift σ of solid RbBr referred to dilute aqueous solution of RbBr might not be true shift σ_0 from corresponding free ion. σ_0 is necessary for the comparison with the theories. But, in the cases of Rb and Br, this concentration dependence was much less than that in I. Therefore, σ may be considered to be close to σ_0 and, since the values of σ_0 cannot be decided accurately, we used σ for the discussions of the experimental results.

Anisotropy of Ordinary Hall Effect in Silicon Iron

By Eiji TATSUMOTO and Tetsuhiko OKAMOTO
Department of Physics, Faculty of Science, Hiroshima University, Hiroshima

(Received December 12, 1958)

The observation of the Hall effect of ferromagnetic single crystals has not been made except on iron by Webster¹⁾ In his measurements the ordinary effect was not observed because of the insufficient intensity of the applied magnetic fields. In the present experiment, by using the single crystal strips of 1.23% silicon iron, and by applying the magnetic fields on them up to 30,500 gauss, not only the extraordinary but also the ordinary Hall effect was observed at room temperature. The single crystals were made by Fujiwara's method,²⁾ the size being about 0.5 mm × 9.5 mm × 35 mm and crystallographic orientations (001)−[100], (001)−[110] and $(\bar{1}\bar{1}0)$−[111].* The polycrystals were also measured. Some of the results of the preliminary measurements are presented here.

The Hall effects observed are satisfactorily represented by the empirical formula,³⁾ $E_H=(R_0H+R_1M)I/t$, where E_H is the Hall voltage measured directly, R_0 and R_1 the ordinary and the extraordinary Hall coefficient respectively, H the intensity of magnetizing field, M the mean intensity of magnetization, I the primary current and t the thickness of specimen. The extraordinary Hall coefficient observed in comparatively low fields is not anisotropic just as in the case of Webster,¹⁾ and the magnitude is 49.2 volt. cm/gauss. amp. The ordinary effect observed in the applied fields higher than about 26,000 gauss, however, is distinctly anisotropic, and moreover is affected by the tensions within the elastic range applied in the direction of the primary current; that is, the ordinary Hall coefficients sensitively vary according to the tensions, but their signs do not change in any case, as shown in Fig. 1. In the extraordinary Hall effect, the effect of tension was scarcely observed. Dependence of the ordinary Hall coefficients on the tensions is different among three kinds of the single crystals. Accordingly, the difference depends on the shapes of crystal lattice distorted by the tensions and seems to have some definite relation with the rate of the deformation of the crystal lattices. On the polycrystals, however, no effect of the tension has been observed. In the ferromagnetic cystals free from external tension, the crystal lattice has already been deformed by the spontaneous magnetostriction to the tetragonal lattice, the c axis of which is one of the easy axes <100>. Consequently, it should be considered that the ordinary Hall coefficients observed without tension have already been modified comparatively by the spontaneous deformation of the crystal lattice. There remains a question, however, whether they should still have anisotropy even if the crystal lattice were cubic. Because of the positive sign of the ordinary Hall coefficient in every cause, almost all or all the charge carriers are positive holes, so that the anisotropy and the effect of the tensions might be attributed to the nonspherical forms of the Fermi energy surface of the conduction band, which probably touches the boundary of Brillouin zone. It may be of interest to observe the Hall effect on the single crystals, such as nickel, the charge carriers of which are presumed to be electrons, in contradistinction from the case of hole conduction. In conclusion, one may expect that a complete investigation concerning these problems will give an essential information for understanding the structure of the conduction band in ferromagnetics.

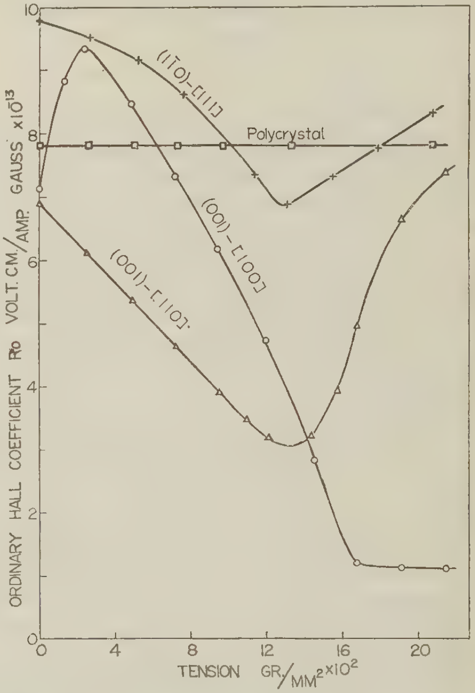

Fig. 1. Dependence of ordinary Hall coefficient on the tensions applied in the direction of primary current.

---

* For example, the notation (001)−[100] signifies that (001) and [100] coincide respectively with the surface plane and the longitudinal direction of a single crystal strip.

Electrostatic Transformer Type Particle Accelerator using Ceramic $BaTiO_3$ —Ferrostac—

By Toshikazu SHIBATA, Atsutomo TOI, Tokuo SUITA

Department of Nuclear Engineering, College of Engineering, Osaka University, Osaka

and

Shunkichi KISAKA

Matsushita Electric Industrial Corp. Ltd., Osaka

(Received December 15, 1958)

A particle accelerator for engineering use which utilizes the electrostatic transformer principle[1] has been constructed with ferroelectric materials such as ceramic $BaTiO_3$. The accelerator consists of a high voltage generator and an accelerating tube with an ion source and suitable accessories.[2] The essential feature of this accelerator is that the high voltage generator has rotating ferroelectric ceramic discs or capacitors which carry electric charges.

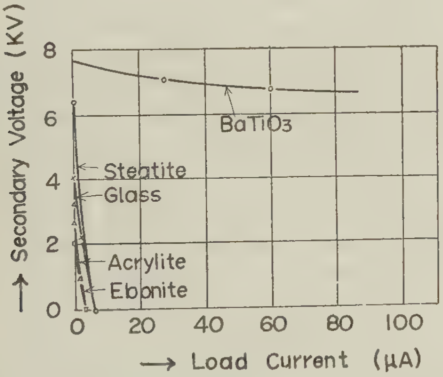

Fig. 1. Relations between the secondary voltages and the load currents at the constant primary voltage (8 kV) for various materials.

Various dielectric materials have been tried as the rotating discs and the results shown in Fig. 1 were obtained. In Fig. 1 some relations between the secondary currents and the secondary voltages for the 1:1 electrostatic transformers at a constant primary voltage of 8 kv are shown. It is clearly seen that much more secondary current or beam current can be obtained without marked voltage drop in the case of $BaTiO_3$ which is desirable for high beam current accelerator for engineering use like radiation source and nuclear fusion injector.

The constructed Ferrostac of 150 kv for neutron production is shown in Fig. 2. The ion source is of the rf type using 20 megacycles per second and kept at earth potential. The zirconium-tritium or titanium-tritium target is connected to the negative high potential terminal of the high voltage generator. Any potentials for the intermediate electrodes and focussing electrode may easily be obtainable through proper brushes of the generator. The deuteron beam current obtained so far is about 100 microamperes and the neutron intensity is about $10^9\, n$/sec. The beam current, however, will be increased by improving the ion source.

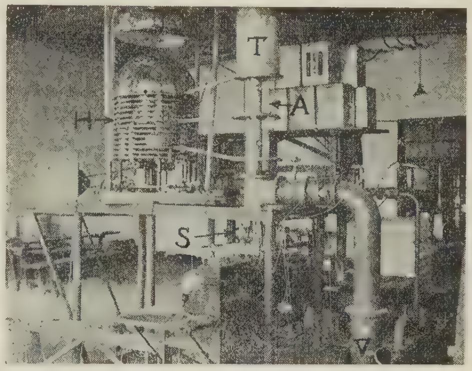

Fig. 2. 150 kV Ferrostac

H: High voltage generator (electrostatic transformer)
A: Accelerating tube
T: Target
S: Ion source
V: Vacuum pump

The accelerator of this type seems to combine several advantages of Van de Graaff and Cockcroft-Walton type accelerators in having (a) simple construction, (b) high beam current and (c) low cost per beam current. At the present stage, however, it has some problems such as mechanical vibration, secondary voltage fluctuation, surface discharge and brush contact. To improve these points, some fundamental researches are being done. And 400 kv Ferrostac, 1 mV Ferrostac and also an electrostatic accelerator which utilizes the electrostatic generator principle are being constructed.

Optical Properties of SiC in Infrared Region

By Masaharu NAMBA
Fuji Denki Seizo K.K., Research Dept., Kawasaki

(Received October 20, 1958)

It is well known that silicon carbide is the valence crystal and p- or n-type semiconductor. Unfortunately, unlike silicon, germanium and other semiconducting materials, it is impossible to get SiC single crystals thicker than about 0.5 mm for the present and is very difficult to polish the ones thinner than about 0.05 mm. Therefore the optical absorption of SiC in infra-red region described here may not be accurate quantitatively.

i) Transmission measurements

The transmission studies were carried out on a Perkin-Elmer double pass monochrometer in the range from 2.5μ to 16μ at room temperature.

As shown in Fig. 1 silicon carbides are found to have high transparency for infra-red radiation up to 5μ, although for p-type black SiC ($=10^{-1}\,\Omega$ cm) transparency is practically zero because of their high impurity contents ($5\times10^{19}\sim10^{20}$ cm^{-3}) and large free carrier concentrations ($n\sim5\times10^{18}$ cm^{-3}).

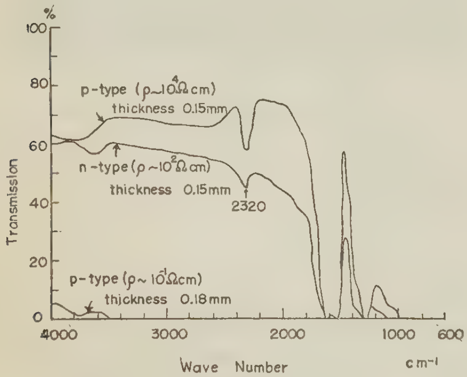

Fig. 1. Transmission of SiC.

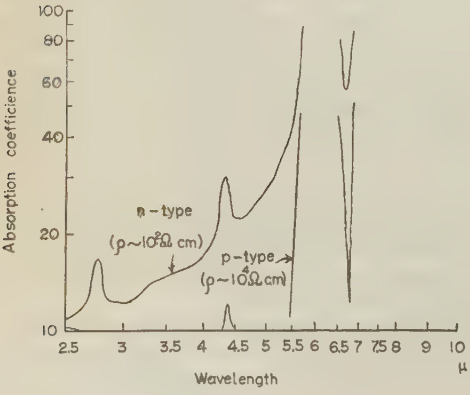

Fig. 2. Absorption coefficient of SiC.

ii) Absorption coefficient

Absorption coefficient at room temperature were determined by transmission measurements. From this method, owing to the thickness of our specimens used, it was impossible to measure absorption coefficients more than about 100 cm^{-1} and less than 10^{-1} cm. The experimental curve for n-type sample given in Fig. 2 roughly has the same slope as required by the Drude theory of free carrier absorption.

Besides this absorption there are absorption bands due to impurity and lattice vibration. The available thermal-ionization energy data for SiC indicate that the 1s state of the impurity level is explained in terms of a hydrogen-like model for the unionized impurity and is given by 0.275 e.v.[1]. Then, the corresponding optical absorption appears at $\nu=2320$ cm^{-1} ($h c\nu=0.288$ e.v.) for p- and n-type specimens. Now, since the tetrahedral bond length of sillicon carbide lies between those of sillicon and diamond, the lattice absorption frequency may be expected to exist between the ones of sillicon and diamond. Then, our measurement shows the existence of a principal transmission minimum ($\nu=1600$ cm^{-1}) and secondary minimum in the long wave side of the former. Although we can not discuss on this aspect in detail, the observed absorption is very strong compared with sillicon and diamond,[2] and resembles to the cases of some ionic crystals.

iii) Reflective power

The Coblentz's data on reflection[3], shown in Fig. 3, remind us of selective reflection of ionic crystals. If it is so, this experimental result will be understood in the same manner as the infra-red dispersion by ionic crystals.

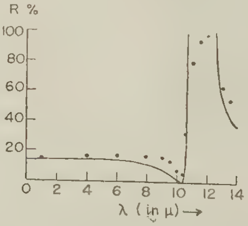

Fig. 3. Reflection of SiC.

Solid line=theoretical curve
Dotted line=Coblentz's experimental curve

Fig. 3 indicates that the wavelength at which the maximum reflection occurs is 12μ and ε_∞, the high frequency dielectric constant, 5.124, and then the dispersion frequency or wavelength λ_0 computed by Havelock's theorem is given by 12.415μ (assuming ε_0, static dielectric constant, $=7$).

If we write the dispersion formula as follows[4]:

$$\varepsilon=\varepsilon_\infty+\frac{\varepsilon_0-\varepsilon_\infty}{1-(\lambda_0/\lambda)^2}, \qquad (1)$$

then the reflective power R is given by the well-known formula

$$R=\left|\frac{n-1}{n+1}\right|^2, \qquad (2)$$

where n is the refractive index ($=\sqrt{\varepsilon}$). The theoretical curve based on Eqs. (1) and (2) is shown by solid line in Fig. 3. There is good agreement between theory and experiment, from which we have to conclude that the sillicon carbide may be classified between the valence and ionic type.

Note on the Spin of Excited States of Cadmium 110

By Mitsuo SAKAI*, Haruko OHMURA and Teruo MOMOTA**

Department of Physics, Faculty of Science, University of Tokyo

(Received November 28, 1958)

The spin of long-lived Ag^{110m} (253 day) was very recently determined as 6 by the atomic beam magnetic resonance method.[1] Since our analysis published in the last year[2] which concerned the angular correlation measurement of gamma rays from this nucleus was based upon the assumption of 5–or 4+ for the spin and parity of this level, it was considered worth while to examine our results once again.

The decay scheme is presented in Fig. 1. As the spin and parity of short-lived Ag^{110} is known to be 1+ by the information from beta disintegrations, the 116–KeV electromagnetic transition now should be of E5 or M5 character. Hence the K/L ratio of this gamma ray might be expected to be 0.185 or 1.05[3]. According to the experimental value of 1.3[4], the electromagnetic character can be concluded as M5. Consequently the parity of this isomeric level should be +. The low energy beta component decaying from this level to the 2.93 MeV level of the daughter nucleus of Cd^{110} has the log ft value of 4.2[5], which indicates the spin and parity of this level might be 7+, 6+ or 5+. These possibilities could not exist in our previous analysis in which the spin and parity of the third 1.541–MeV level was assumed to be either 2+ or 3+. Therefore the third alternative of 4+ should now be considered. In our preceding paper this possibility was rejected by reason of the rather big difference between the angular correlation patterns $\langle\gamma_3\gamma_4\rangle$ and $\langle\gamma_3\gamma_6\rangle$ even though we have got $\langle\gamma_4\gamma_6\rangle$ consistent with that of spin sequence of $0-2-4$. The similarity between $\langle\gamma_3\gamma_4\rangle$ and $\langle\gamma_3\gamma_6\rangle$ is a requisite for this spin sequence. But, to our regret, the accuracy of the experiment was not high enough to exclude this posibility complet-ly. Analyzing the data under the assumption of the third alternative for the spin of the 1.54–Mev level, we found that the spin 5 for the 2.930–Mev level with γ_2 of almost M1 character is the unique solution and that the spin 4 or 5 (less probably 6) of the 2.476–Mev level is only possible in case of γ_3 having the mixing ratio of about -0.2. The revised spin assignment is shown in Fig. 1.

Electronmicroscopic Observations on the KI Single Crystal

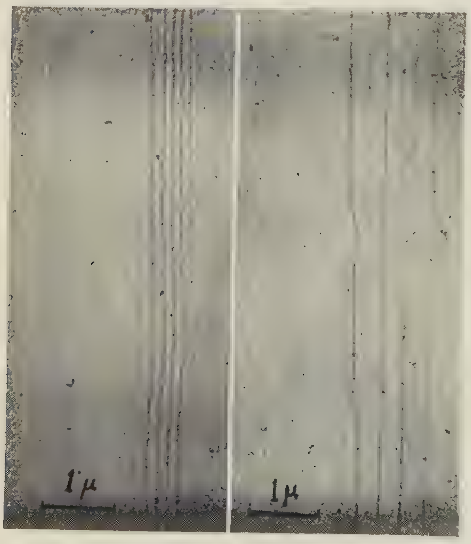
By Tetsuhiko TOMIKI*

The Research Institute for Steel, Iron
and other Metals,
Tohoku University, Sendai, Japan

(Received November 27, 1958)

During electronmicroscopic studies on alkali halides, it was found that KI single crystal has properties different from those observed hitherto on KCl, NaCl and KBr single crystals[1]. The experimental results obtained are summarized as follows:

(i) Fresh (100) cleavage surfaces of KI have a group of steps each of which is parallel to each other and is generally less than 0.1 microns in height (Fig. 1*a*). This step splits usually into two branches of cleavage steps, or vice versa (Fig. 1*b*). These properties have never been observed on the KCl, KBr and NaCl crystals.



(a) (b)

Fig. 1.

(ii) After evacuating the evaporation apparatus in which the freshly cleaved KI specimen was placed, this apparatus was filled with air to make the crystal expose to it. The crystallites came out on the (100) surface of this specimen, when the evaporation apparatus was evacuated again (Fig. 2). The similar phenomenon has already been reported on the KCl single crystal.[2]

(iii) When the KI single crystal was irradiated with x-ray (Cu target; applied potential=30 kv) on the (100) at the distance of 50 *cm* from the target for 60 minutes, the crystallites grew in a irregular shape as shown in Fig. 3. However, the crystallites did not grow on the KCl specimen x-rayed under the same conditions.

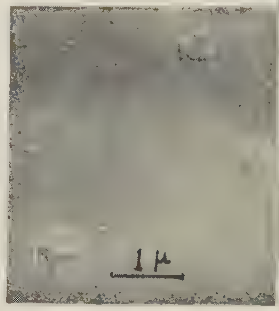


Fig. 2.

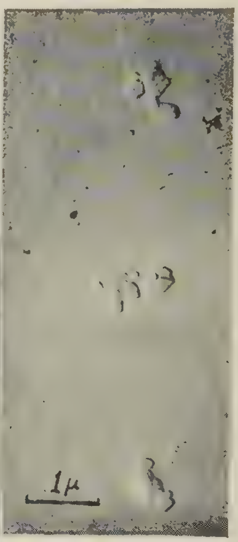

Fig. 3.

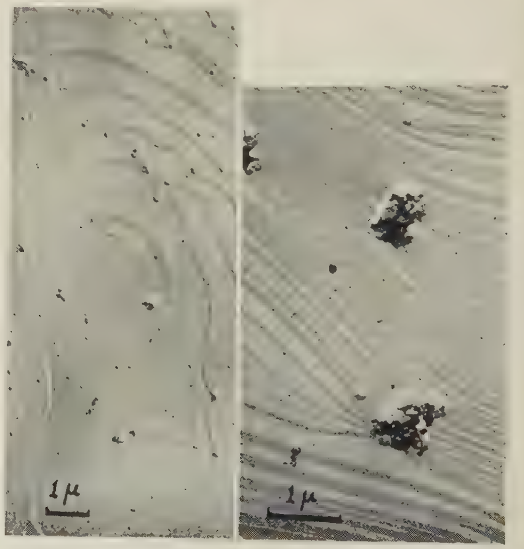

(a) (b)

Fig. 4.

(iv) When the KI single crystal was bombarded with electron beam of an electron microscope (Current=30μA; applied potential=50 kV) on its (100) surface, KI molecules evaporated from the surface and crystallites grew there at the same time. The surface area, where pits are produced by evaporation caused by bombardment with electrons for 15 minutes, is shown in Fig. 4a. The surface structures similar to contour lines in a map represent lamellae by which pits are formed. The grains on the (100) represent the grown-up crystallites. Fig. 4*b* shows another part of the surface where crystallites have grown at the convergent points of the stratified structures produced by evaporation. The shape of these crystallites resembles to those of crystallites on the x-rayed surface (*cf*. Fig. 3). Therefore, the crystallites will probably be composed of KI. The alkali halide single crystals bombarded with high speed electrons have been investigated only little.[3] Many problems are left unsolved.

---

* The present address: Department of Physics, The Faculty of Science, Tohoku University, Sendai, Japan.

It is planned to extend to electronmicroscopic observations on the KI single crystal.

The author would like to express his thanks to Prof. S. Ogawa who provided him an opportunity to achieve this experiment. His gratitudes are also due to Dr. M. Hirabayashi for his kind operations of x-ray apparatus.

Ferrimagnetic Resonance of Polycrystalline Nickel Ferrite-Chromites

By Hiroo YONEMITSU

Matsuda Research Laboratory,
Tokyo Shibaura Electric Co.,
Kawasaki-City, Japan

(Received December 5, 1958)

A series of dense mixed polycrystals $NiFe_{2-x}Cr_xO_4$ were prepared with $x=0$, 0.10, 0.20, 0.30, 0.40, 0.60, 0.80 and 1.20 by the usual ceramic techniques. The X-ray diffraction patterns obtained on a Norelco type diffractometer using FeK_α radiation, showed only spinel phase for all samples. Ferrimagnetic resonance absorption spectra showed no changes about the full half-width ΔH for all compositions below $x=0.60$, as shown in Fig. 1. Their absorption powers, however, were weakened with the increase of chromium contents x. Saturation magnetization at room temperature for the annealed samples are shown in Fig. 2.

This behavior resembles to the one for the nickel ferrite-aluminate series reported by Maxwell and Pickart[1)], except for the fact that in the latter case ΔH is increased with Al contents. Further investigations on the cation distribution of these mixed crystals and the constant ΔH characteristics are now in progress and the results will be published in this Journal.

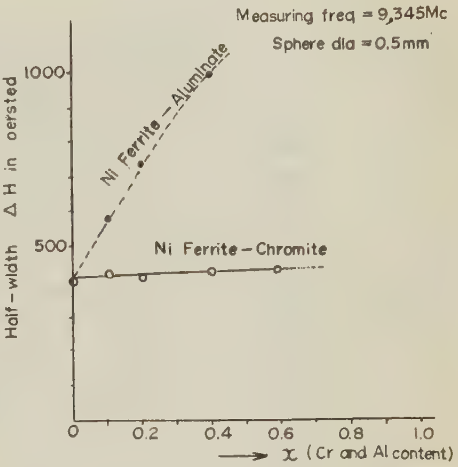

Fig. 1. Ferrimagnetic resonance half-width ΔH *vs*. x.

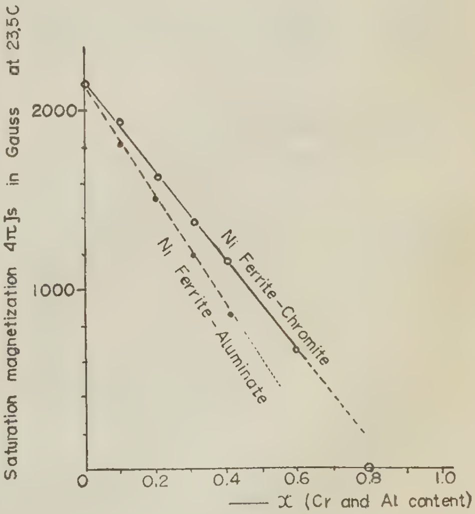

Fig. 2. Saturation magnetization $4\pi J_s$ *vs*. x at room temperature.

Barrier Temperature at Turnover in Germanium *p-n* Junction

By Jiro YAMAGUCHI and Yoshihiro HAMAKAWA
Faculty of Engineering, Osaka University, Osaka

(Received December 5, 1958)

In this note, the additional considerations are given for the barrier temperature at turnover in the reverse direction of germanium grown *p-n* junction, which has been previouly reported.[1]

The experimental procedures are the same as our previous publication.[1] Fig. 1(a) shows the experimental results of the barrier temperature of grown type junction at turnover, which is estimated from the saturation current in reverse direction. In this figure and the following ones, circles, crosses and dots express the results measured by the pulse of 160, 80 and 40 μs duration, respectively, in repetition frequency of 1000 c/s. It is found that the barrier temperature at turnover is nearly constant for a given specimen in the range of ambient temperature of (−180~20)°C.

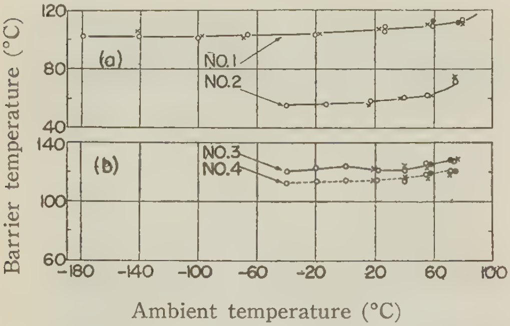

Fig. 1. Turnover barrier temperature estimated from saturation current at different ambient temperatures.

(a): grown junction, (b): point contact

On the other hand, the barrier temperature can be estimated by another means[2] which has been adopted to the point contact diode. Following this method, we can obtain the relation between turnover power and ambient temperature as Fig. 2 for specimens of No. 1 and No. 2 and the turnover barrier temperature can be indicated by the intersection of linear part of these plots to the abscissa. These results and physical properties of specimens are summarized in 1st and 2nd row of Table I and there is a discrepancy between the barrier temperatures obtained by the above two methods.

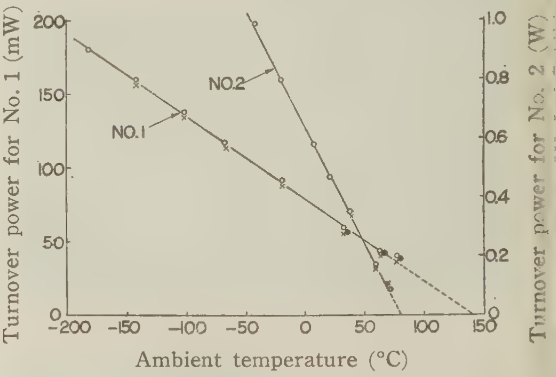

Fig. 2. Powers dissipated at turnovr versus ambient temperature in case of grown junctions.

Furtheremore, we take the same considerations for the specimens of point contact type. These results are shown in Fig. 1 (b) and also in the 3rd and 4th row of Table I. From these results, the difference of barrier temperature measured by above methods is rather small. Comparing the results of point contact type with those of junction type, we can confirm that there may be the non-uniformity or patch in the germanium junction,

Table I. Experimental results and physical properties of the specimens.

specimen No.	barrier temperature at turnover (°C)		type and size of specimen	property of high resistivity side	
	measured from saturation current	measured from turnover power		specific resistivity (Ω-cm)	intrinsic temperature (°C)
1	105~112	143± 5	grown junction (collector-base of 2T52)	1	148
2	56~ 62	82± 3	grown junction (3×3×10 mm)	6	83
3	120~130	118± 8	point contact (IN34)	3~5	90~115
4	114~123	119±11	point contact (INA4)	3~6	83~115

like as in the sillicon p-n junction,[3-4] and the turnover occurs, when the barrier temperature reaches the intrinsic temperature at any spot in junction.

The authors are indebted to Sony, Corp., Kobe Kogyo, Corp. and Nippon Electric Company Ltd. for the supply of the specimens.

Interaction of Water Vapour with Germanium Real Surface

By Koji KAWASAKI, Kyoichi KANOU and Yoshiyasu SEKITA

Electrotechnical Laboratory, Nagatacho, Chiyodaku, Tokyo, Japan

(Received December 6, 1958)

The adsorption isotherm of water vapour and the surface conduction current in the atmospheres of various relative humidities were measured for germanium treated by CP4 etching solution.

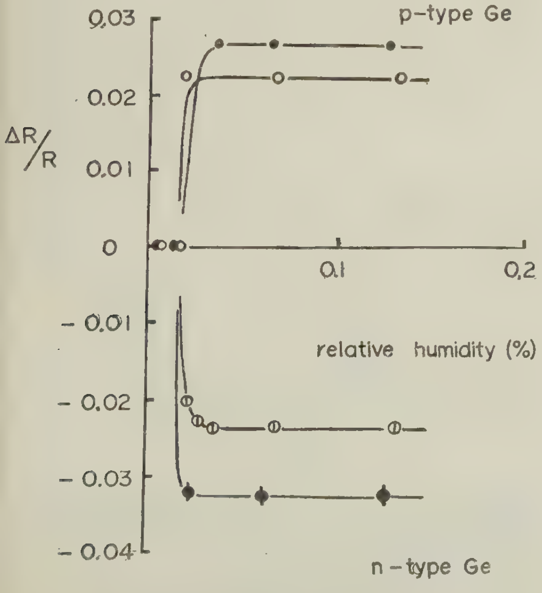

Fig. 1. Relative variation of resistance, $\Delta R/R$, as a function of relative humidity.

It was found that in general, the resistance R of n-type germanium decreases with the adsorption of water vapour, while that of p type sample increases with the adsorption.

The relative variation of resistance, $\Delta R/R$, of

Table I.

Samples	Specific Resistivity ($\Omega\cdot$cm)	$\Delta R/R$	ΔN_R (no./cm^2)
p-type			
1	6.0	0.0038	1.6×10^{11}
2	1.2	0.0080	4.9×10^{11}
3	0.6	0.028	4.1×10^{12}
4	0.8	0.009	6.2×10^{11}
5	6.0	0.0026	1.1×10^{11}
6	1.2	0.0058	5.9×10^{11}
7	6.0	0.028	5.6×10^{11}
8	0.9	0.041	1.6×10^{12}
N-type			
1	9.1	-0.0014	1.5×10^{10}
2	0.9	-0.012	8.4×10^{11}
3	2.5	-0.0195	6.5×10^{11}
4	8.3	-0.023	1.3×10^{11}
5	47	-0.0089	1.2×10^{10}
6	0.9	-0.014	9.5×10^{11}
7	3.1	-0.043	7.2×10^{11}

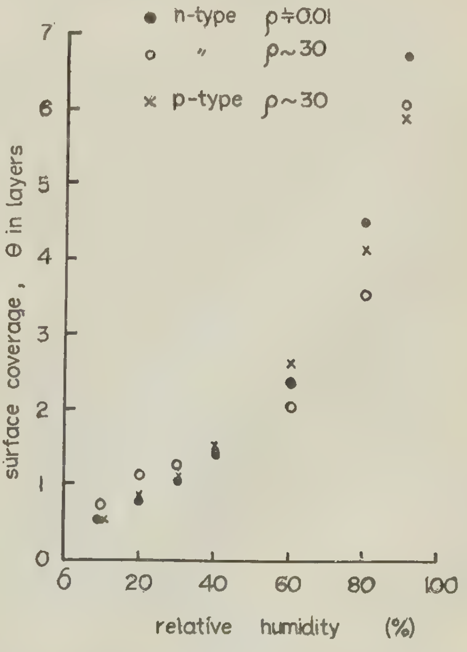

Fig. 2. Adsorption isotherms of water vapour on germanium at 25°C.

n- and *p*-type germanium in the atmospheres of very low relative humidities are shown in Fig. 1. $\Delta R/R$ seems to be saturated at such low humidities. Saturation values of $\Delta R/R$ and the number ΔN_R of charge carriers per unit area which must be introduced into the samples to produce the observed change in resistance with the adsorption of water vapour are shown in Table I for several samples. In the table, the values of ΔN_R range between 10^{11} and 10^{12} for both *n*- and *p*-type. These values are larger than those obtained by S. R. Morrison.1)

Next, the adsorption isotherms of water vapour on germanium surfaces were obtained by the gravimetric method using powdered specimens, i.e., by suspending the sample on the end of a sensitive quartz spring in a glass vacuum vessel and measuring the spring elongation with a cathetometer. Typical adsorption isotherms on the samples outgassed at 25°C are shown in Fig. 2, where θ is the surface coverage as determined by the B.T.E. method. These isotherms are nearly in accordance with Law's data.2)

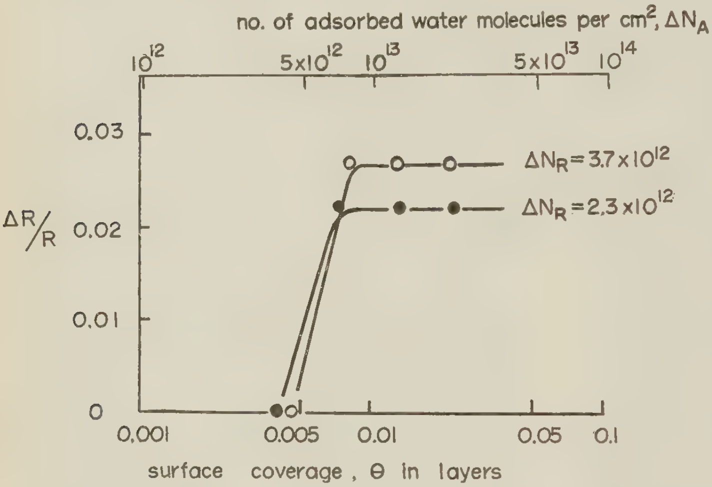

Fig. 3. $\Delta R/R$ with number of the adsorbed water molecules or surface coverage.

From Fig. 1 and the logarithmic expression of adsorption isotherm given in Fig. 2, $\Delta R/R$ for *p*-type germanium is plotted in Fig. 3 versus the surface coverage θ. It can be seen that $\Delta R/R$ increases with θ and is saturated at a certain critical value of θ. This critical value of the surface coverage θ lies between 5×10^{-3} and 8×10^{-3}. The number ΔN_A of the adsorbed water molecules per unit area at this critical values of θ is about $(5\sim8)\times10^{12}$.

Size Distribution of Radioactivity of the Natural Radioactive Dust

By Koji Kawasaki and Keiji Kato
Electrotechnical Laboratory, Nagatacho Chiyodaku, Tokyo, Japan

(Received October 7, 1958)

In order to provide further information on the particle size distribution of the radioactivity of the natural radioactive dust in the atmosphere near ground, an apparatus has been designed and the distribution of radioactivity has been measured.

A copper wire was set as shown in Fig. 1 and the radioactivity captured by the wire was measured by a G.M. counter. According to this measurement, the radioactivity of the dusts captured by the wire was almost zero when the wire was maintained at a high positive potential, but was measurable when the wire was at a negative potential. These results indicate that the polarity of radioactive dust particles captured is positive, although there may exist in the atmosphere neutral particles that have not been detected by this experiment. Furthermore, the radioactive substances were identified as RaB, RaC and ThB by the decay rate curve, as already reported.1),2)

Based on these facts, an apparatus for the determination of the size distribution of the natural radioactive dust was designed as shown in Fig. 2. The air that is taken in by the blower flows into the cylindrical ion separator. The separator captures the charged particles or the "ions", as they are called in the atmospheric electricity, that have mobilities higher than the cut off mobility determined by the equation

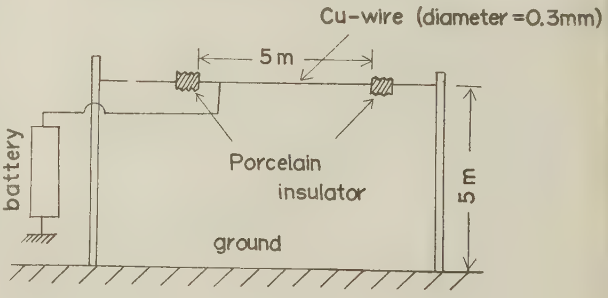

Fig. 1.

$$k=Q\ln\frac{D}{d}\Big/2\pi lV. \qquad (1)$$

where k is the cut off mobility, D and d are the diameters of the outer and the inner cylinder respectively, l is the length of the cylinder, Q is the airflow, and V is the applied voltage. The charged particles having the mobilities lower than the cut off mobility pass through the ion separator, flow into the electric precipitator and are captured by the precipitator effectively.[2] After the ions have been collected, the chamber of the electric precipitator is closed by the glass valves A_1 and A_2, and the d.c. high voltage applied on the tungsten wire of the precipitator is removed. This chamber is then used as a G.M. counter, commercial methane being introduced into the chamber through the glass valve B_1 and exhausted through B_2, at slightly above atmospheric pressure. From this measurement, the fraction of total radioactivity can be plotted versus the cut off mobility. Particle size is related to mobility by

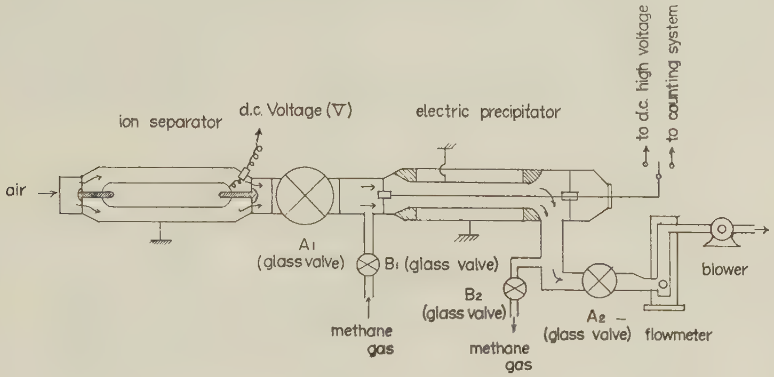

Fig. 2.

$$k=e\{1+(b/pr)\}/6\pi\eta r \qquad (2)$$

where e is the charge of particle, η the viscosity of the air, r the radius of dust particle, p the pressure and b a constant.

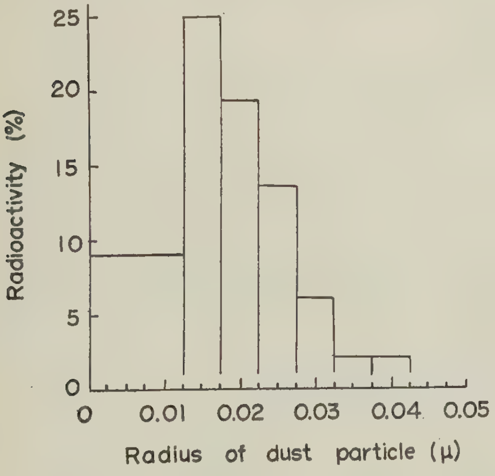

Fig. 3.

A typical result of the particle size distribution of radioactivity is shown in Fig. 3. It is found out that most of the natural radioactivity in the atmosphere attaches itself to particles having radii in the range 0.01 to 0.04 micron and predominance of the activity is in the vicinity of 0.0175 micron. These results are nearly in accordance with the data given by Wilkening.[3]

Zeeman Study of Nuclear Quadrupole Resonance Spectrum in *p*-Dibromobenzene

By Kenji Shimomura

Minami Bunkô, Hiroshima University, Hiroshima

(Received November 27, 1958)

The Zeeman analysis[1] of bromine quadrupole resonance spectrum in p-dibromobenzene was performed employing the Zeeman analyzer which has been described previously.[1] The single crystal was obtained by descending slowly a cylindrical glass container with a bottom tapered to a point, through a vertical furnace having a large temperature gradient.

The experimental results of the Zeeman analysis are shown in Fig. 1, which shows two nonequivalent directions[2] of z-axes of field gradient tensor. The angle between them was found to be $71°59'\pm12'$, which is in fairly good agreement with the angle between the two Br–Br directions $71°11'$

which has been obtained from the X-ray analysis.[3]

The points representing the zerosplitting angles are plotted in Fig. 1 together with the zerosplitting loci. The point D is plotted on the line AC connecting the point C which specifies the zerosplitting direction with the center A of the zerosplitting locus so that AD represents the angle $\theta-53°$, where θ is the zerosplitting angle at C, and 53° is arbitrarily chosen in order to clearly locate the maximum and minimum directions of the zerosplitting angles about A. From the maximum or minimum value of zerosplitting angle one obtains[1] $\eta=0.05\pm0.01$ for the asymmetry parameter of field gradient tensor at the bromine nucleus. On the other hand, from the study of Zeeman splitting Kojima et al[4] have obtained $\eta=0.12\pm0.01$, which is larger than our value. Our value seems to be more reasonable since it is nearly the same as those of p-diiodobenzene $4.77\pm0.40\%$, $3.65\pm0.50\%$[5] which have been definitely obtained from the frequency measurements of iodine resonances.

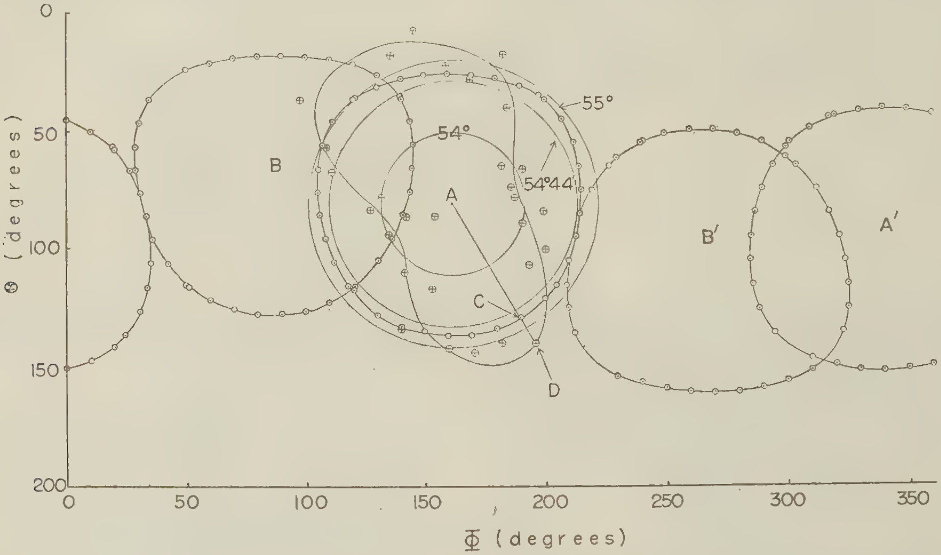

Fig. 1. Zerosplitting-direction patterns of Zeeman lines of bromine in p-dibromobenzene. Θ, Φ are polar angles specifying zerosplitting-direction with respect to the axes fixed to the sample.

○ represents the direction of zerosplitting.

⊕ represents the zerosplitting angle.

Three circles around A designate the 54°, 54°44′, and 55° zerosplitting angles. A′ and B′ are the equivalent directions of A and B, respectively.

From the value of η and the resonance frequency[6] of pure quadrupole resonance spectrum of bromine we may obtain[7] 80.9%, 2.0%, and 17.1% for the amount of single, double, and ionic character for C–Br bond, respectively.

(Received November 24, 1958)

The gamma-rays following the inelastic scattering of protons by ^{24}Mg, ^{25}Mg and ^{26}Mg were investigated at proton energies up to 5.7 MeV.

The energy spectra of the gamma-rays at several proton energies have been obtained for each isotopes.

2^+ was assigned to the second, third and fourth excited level of ^{26}Mg considering the gamma-ray branching ratios for those levels.

The yields of gamma-rays from the first excited levels were found to have peaks at proton energies of 4.0, 4.6 and 5.05 MeV for ^{24}Mg$(p, p'\gamma)$ reaction, 4.9 and 5.4 MeV for ^{26}Mg$(p, p'\gamma)$ reaction respectively. These resonances correspond to the levels at 6.1, 6.7 and 7.14 MeV for ^{25}Al, and 13.0 and 13.5 MeV for ^{27}Al.

To determine the spins for those levels, angular distributions were measured at resonance energies. Spin values of 3/2 and 5/2 are probable for 7.14 MeV level in ^{25}Al and 13.0 MeV level in ^{27}Al respectively.

For the 13.5 MeV level in ^{27}Al, the spin of 3/2 is also probable, but 5/2 can not be excluded because of the presence of the cascade gamma-rays from higher levels.

The total cross sections for the gamma-ray emission are estimated to be about 700 mb at 5.05 MeV resonance for ^{24}Mg and a few hundreds mb for the 4.9 and 5.4 MeV resonances for ^{26}Mg.

§ 1. Introduction

Inelastically scattered protons by magnesium have been observed by numerous workers at proton energies between 2.4 and 15.3 MeV[1].

The 1st excited state of ^{24}Mg was determined as 1.371±0.002 MeV by electro-static analysis[2]. The 2nd and 3rd excited state of ^{24}Mg proved to be a doublet of 4.13±0.02 and 4.24±0.02 MeV using magnetic analysis[3].

On the other hand in the study of beta-decay of ^{24}Na, the energies of gamma-rays from the excited levels of ^{24}Mg were determined by magnetic spectrometer as 2.7535±0.0010 (2nd → 1st) and 1.3680±0.0010 MeV (1st → gnd)[4], and the spins and parities of the gnd, 1st and 2nd state were assigned 0^+, 2^+ and 4^+ respectively.

Recently a large amount of informations has become available on ^{23}Na+P reactions, and the 3rd excited state of ^{24}Mg was assigned $J=2^+$, and the level at 5.26 MeV was observed with $J=3$ and probably negative parity[5].

The angular distribution measurements of inelastically scattered alpha particles to 1.37 and 4.2 MeV level also agree with direct surface interaction for $(0^+) \to (2^+)$ transition and the level at 4.12 MeV (4^+ state) is not excited[6]. These results are consistent with the above spin assignments.

As the excited states of ^{25}Mg, the magnetic analysis of inelastic scattering of 8-MeV protons by natural magnesium have revealed levels at 0.61, 1.62, 1.98, 2.56, 2.76, 3.41 and 3.91 MeV, all ±0.02 MeV[3]. In the study of gamma-rays in ^{25}Mg$(p, p'\gamma)$ reaction, the branching ratios of the levels at 0.98, 1.61 and 1.96 MeV were obtained[7]. From these results, the spins and parities of lower levels can be assigned as shown in Fig. 7. These assignments are also consistent with those from (d, p) angular distributions, log ft value in decay of ^{25}Na and ^{25}Al, shell model predictions and classifications of corresponding levels in the mirror nucleus ^{25}Al. The energy levels in ^{25}Mg were determined more accurately from ^{24}Mg$(d, p)^{25}$Mg reaction at deutron energy 1.8 MeV[8] and ^{27}Al$(d, \alpha)^{25}$Mg at 2.1 MeV[8] as also shown in Fig. 7.

The level energies of ^{26}Mg were found very accurately from the ^{25}Mg(d, p)^{26}Mg reaction⁹⁾ using enriched targets as shown in Fig. 9. The magnetic analysis of inelastically scattered protons in ^{26}Mg(p, p')^{26}Mg* reaction at proton energy 8 MeV gives levels at 1.83±0.02 and 2.96±0.02 MeV³⁾.

The shape of the β^+ spectrum determined the spin of the 1st level of ^{26}Mg as 2^{+}¹⁰⁾. The angular distribution study in ^{25}Mg(d, p)^{26}Mg reaction indicates for the 2nd, 3rd and 4th excited states to have $J=2^+$ or 3^+¹¹⁾, but 2^+ assignments are more probable for the 2nd and 4th excited states from the analogy to the levels of ^{26}Al¹²⁾.

In this paper we report the study of the gamma-rays produced in ^{24}Mg(p, $p'\gamma$), ^{25}Mg(p, $p'\gamma$) and ^{26}Mg(p, $p'\gamma$) reactions, and discuss the properties of these levels. From the angular distributions of these gamma-rays the properties of the levels of the compound nuclei are also discussed.

§ 2. Experimental Methods

Experimental arrangement was the same as previously described¹³⁾. The 5.7 MeV proton beam from 44 inch cyclotron was used and the energy was degarded at 0.1 MeV intervals down to 2.5 MeV by aluminum absorbers. The proton beam current was a few hundredths of a microampere.

The targets used were magnetically separated isotopes of a few tenths of a mg/cm² in thickness on gold backings. In the present experiment we intended principally to investigate ^{26}Mg(p, $p'\gamma$) reaction. The mass separator was arranged to get the ^{26}Mg target as purely as possible. There was, therefore, some impurity of ^{24}Mg in the target of ^{25}Mg.

The detector was a scintillation spectrometer consisting of a NaI(Tl) crystal 3″ in diameter and in length, viewed by a Dumont 6364 photomultiplier. For the pulse height analysis 20 channel analyser was used.

§ 3. Results and Discussions

1. ^{24}Mg

The level scheme is shown in Fig. 1. The yield of the 1.37 MeV radiation by the deexcitation of the 1st excited state of ^{24}Mg was measured at right angles to the beam as a function of the incident proton bombarding energy. The results is shown in Fig. 2 and in Table I.

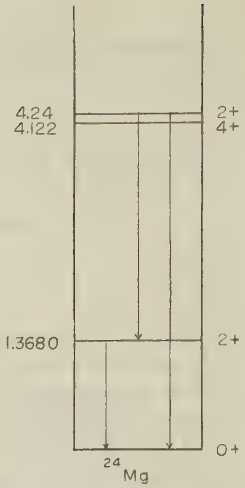

Fig. 1. The level scheme of ^{24}Mg, and the gamma-rays observed in our work.

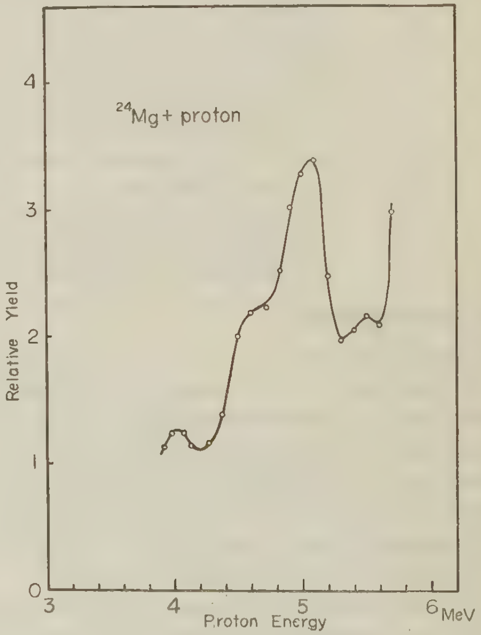

Fig. 2. The yield of the 1.37 MeV radiation by deexcitation of the 1st excited state of ^{24}Mg measured at right angles to the beam as a function of the proton energy.

Table I. Resonances in ^{24}Mg(p, $p'\gamma$).

Resonance energy (MeV)	Corresponding level energy in ^{25}Al (MeV)
4.0	6.1
4.6	6.7
5.05	7.14
~5.4	~7.5

The peak at 4.0 MeV agrees with the previous experimental data[19)], and peak at 4.6 MeV is newly found resonance. The large resonance peak at 5.05 MeV agrees with the experiment by Greenless[14)], and the uncertain small resonance is observed at 5.4 MeV. The total cross section for the excitation of the 1st excited state at 5.05 MeV proton energy is about 700 mb.

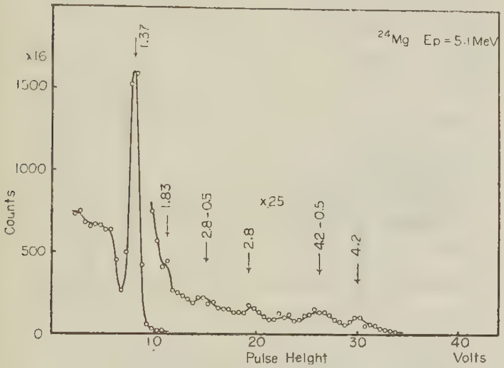

Fig. 3. The gamma-ray spectrum: ^{24}Mg+proton at 5.1 MeV and 90° with respect to the proton beam.

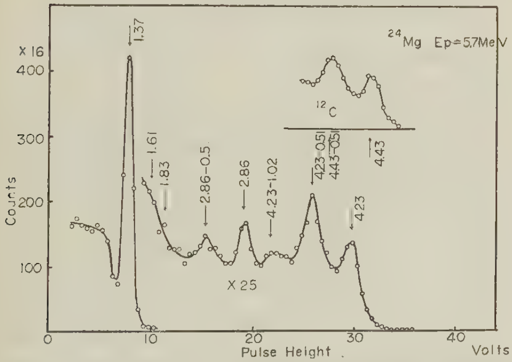

Fig. 4. The gamma-ray spectrum: ^{24}Mg+proton at 5.7 MeV and 90° with respect to the proton beam.

Table II. Gamma-rays in ^{24}Mg$(p, p'\gamma)$ reaction at proton energy 5.7 MeV.

Gamma-ray energy (MeV)	Relative intensity	Origin of the gamma-ray
4.23	7.0	3rd-gnd in ^{24}Mg
2.86	2.5	3rd-1st in ^{24}Mg
(2.75)		(2nd-1st in ^{24}Mg)
1.83	0.5	1st-gnd in ^{26}Mg
1.61	0.5	3rd-gnd in ^{25}Mg
1.37	100	1st-gnd in ^{24}Mg

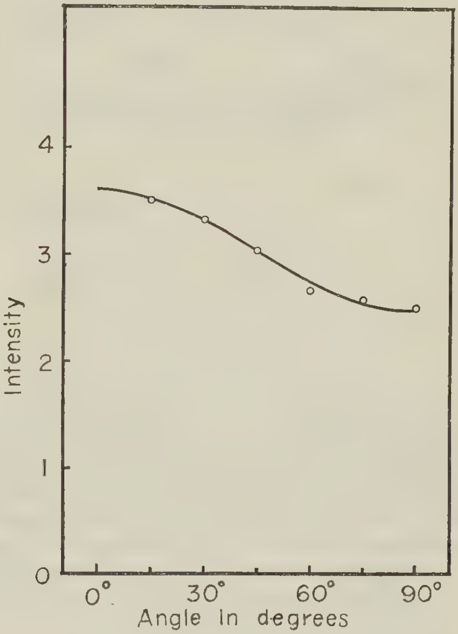

Fig. 5. Angular distribution of the 1.37 MeV gamma-ray in ^{24}Mg$(p, p'\gamma)$ reaction at proton energy 5.1 MeV.

The gamma-ray spectra are shown in Fig. 3 and 4. The arrows indicate the positions of the peaks and the numbers show the corresponding gamma-ray energies calibrated by the 4.43 MeV gamma-ray in ^{12}C$(p, p'\gamma)$ and 1.33 and 1.17 MeV gamma-ray of ^{60}Co.

The relative intensities of those gamma-rays are calculated using the shapes of the 4.43 MeV gamma-ray of ^{12}C$(p, p'\gamma)$, 2.75 and 1.37 MeV gamma-ray of ^{24}Na, and 1.33 and 1.17 MeV gamma-ray of ^{60}Co, and the known efficiences for those energies. The origins of the gamma-rays and their relative intensities at proton energy of 5.7 MeV are shown in Table II.

The branching ratio of those gamma-rays agrees with the previous experiment[16)].

Next, to determine the spin of the resonance level at proton energy of 5.05 MeV, the angular distribution of the 1.37 MeV gamma-ray was measured. The result of this measurement is shown in Fig. 5. The solid line in this figure represents are least squares fit to the data, using even Legendre polynomials up to P_4, and is given by

$$W(\theta)=1+(0.259\pm0.013)P_2+(0.012\pm0.023)P_4$$

Fig. 6 shows the results of the calculation using the theory by Biedenharn et al[16],[17]. The results of the present experiment is also shown in this figure. This result shows that the angular distribution can be represented by P_0 and P_2 only, and therefore the spin of the compound state at 7.1 MeV of ^{26}Al is probably 3/2.

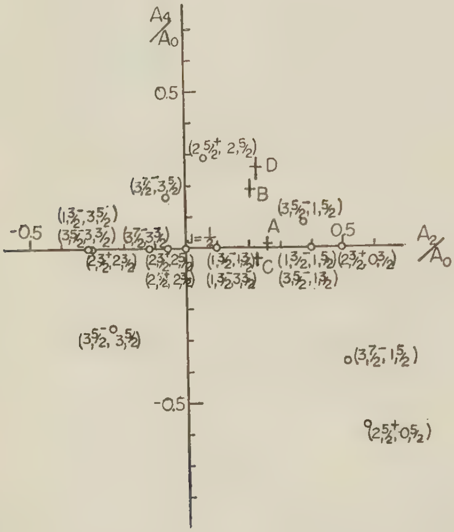

Fig. 6. The results of the calculation using the theory by Bienharn et al. Open points indicate A_2/A_0 and A_4/A_0 for various $(1, J^{\pi}, 1', s')$, where $W(\theta)=A_0+A_2P_2(\cos\theta)+A_4P_4(\cos\theta)$ is the angular distribution of the gamma-ray of the $(2^+)\rightarrow(0^+)$ and state transition in $(p, p'\gamma)$ reaction, 1 and 1′ are the orbital angular momenta of incoming and outgoing proton respectively, J^{π} is the spin and parity of the compound state, and s' is the channel spin of the outgoing channel.

Cross A, B, C and D indicate the experimental results of the 1.37 MeV gamma-ray angular distribution in ^{24}Mg$(p, p'\gamma)$ reaction at proton energy 5.1 MeV and the 1.83 MeV gamma-ray angular distributions in ^{26}Mg$(p, p'\gamma)$ reaction at proton energy 4.9, 5.4, and 5.7 MeV respectively.

The angular distribution measurement of the inelastically scattered protons by magnesium[18] shows that the corresponding compound state seems to have the spin 3/2. From the energy dependence of this angular distribution it is probable that the reaction proceeds mainly through the compound nucleus. These results are consistent with the present experiment.

2. ^{25}Mg

The low lying levels of ^{25}Mg are studied by many workers, as is shown in Fig. 7. The present results are also consistent with these informations. The gamma-ray spectrum at proton energy 5.7 MeV is shown in Fig. 8.

The arrows indicate the positions of the peaks and the numbers show the corresponding gamma-ray energies. The results are tabulated in Table III.

The yield curve of the most intense gamma-ray of 1.37 MeV was measured as a function

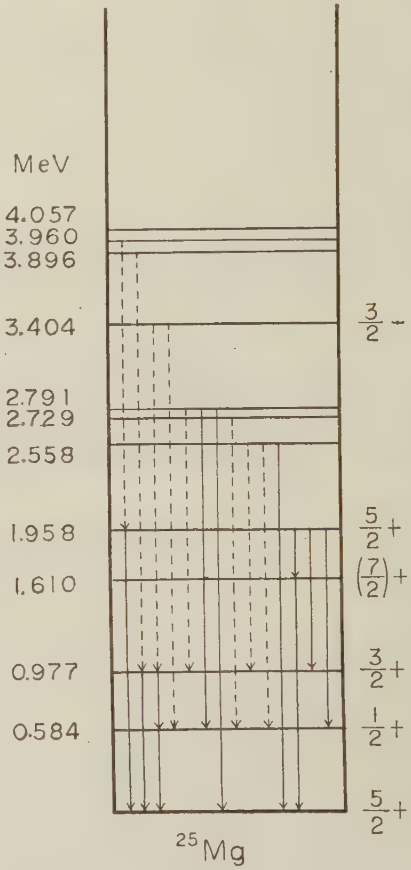

Fig. 7. The level scheme of ^{25}Mg. and the gamma-rays observed in our work.

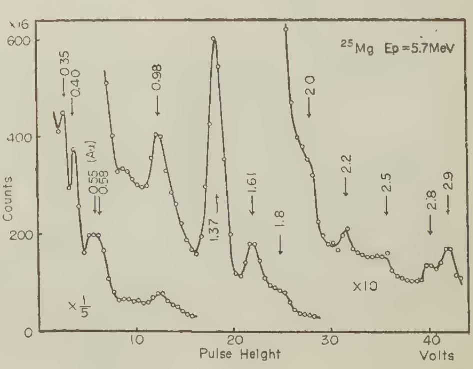

Fig. 8. The gamma-ray spectrum: ^{25}Mg+proton at 5.7 MeV and 90° with respect to proton ceam.

Table III. Gamma-rays in ^{25}Mg(p, $p'\gamma$) reaction at proton energy 5.7 MeV.

Gamma-ray energy (MeV)	Relative intensity	Origin of the gamma-ray
2.9	1	3rd–1st in ^{24}Mg (9th–2nd in ^{25}Mg)
2.8	0.3	7th–gnd in ^{25}Mg (2nd–1st in ^{24}Mg) (8th–1st in ^{25}Mg)
2.5	0.3	5th–gnd in ^{25}Mg (8th–2nd in ^{25}Mg)
2.2	0.5	7th–1st in ^{25}Mg (6th–1st in ^{25}Mg)
2.0	1	4th–gnd in ^{25}Mg (5th–1st in ^{25}Mg) (10th–4th in ^{25}Mg)
1.8	4	1st–gnd in ^{26}Mg (7th–2nd in ^{25}Mg)
1.61	10	3rd–gnd in ^{25}Mg (5th–2nd in ^{25}Mg)
1.37	30	1st–gnd in ^{24}Mg (4th–1st in ^{25}Mg)
0.98	7	2nd–gnd in ^{25}Mg (4th–2nd in ^{25}Mg)
0.58		1st–gnd in ^{25}Mg
0.55		Au
0.40		2nd–1st in ^{25}Mg
0.35		4th–3rd in ^{25}Mg

of incident proton energy and proved to have the same shape as that of the 1.37 MeV gamma-ray from ^{24}Mg(p, $p'\gamma$) reaction described above, while the yield curve of 1.61 MeV gamma-ray, which is certainly due to the deexcitation from the 3rd to the ground state, shows the quite different form from it. It is, therefore, concluded that the most part of this intense gamma-ray is due to the impurity of ^{24}Mg in the target of ^{25}Mg. The other results in Table III agree with the data of the other experiments$^{7)}$.

3. ^{26}Mg

The yield of the 1.83 MeV radiation by the deexcitation of the 1st excited state ef ^{26}Mg was measured at right angles to the beam as a function of the proton bombarding energy. The result is shown in Fig. 10 and Table IV.

The total cross section for the excitation of the 1st excited state at 4.9 and 5.4 MeV proton energy are estimated to be a few tenths of a barn.

The gamma-ray spectra at these resonances are shown in Fig. 11–14, and tabulated in Table V. The gamma-ray energies and their relative intensities were calculated using the same method as above described.

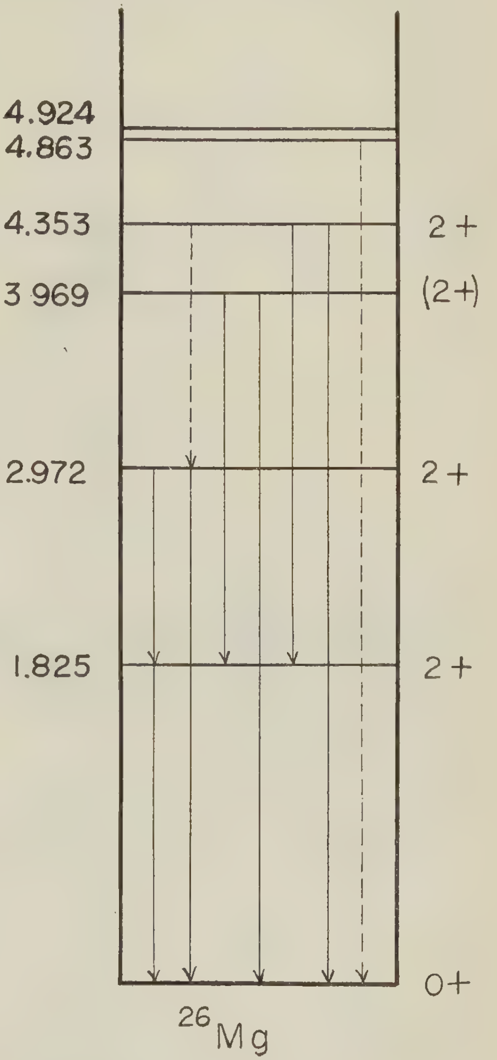

Fig. 9. The level scheme of ^{26}Mg, and the gamma-rays observed in our work.

As previously described, the 1st state has been assigned 2$^+$ from ^{26}Al(β^+), and the 2nd, 3rd and 4th state are assigned 2$^+$ or 3$^+$ from ^{25}Mg(d, p)^{26}Mg. In the present experiment, from the gamma-ray intensity ratios in Table V we may discussed the spins and parities for these states by the use of the Moszkowski's formula based on the single particle model.

Considering the results of ^{25}Mg(d, p)^{26}Mg reaction, we may consider only 2$^+$ or 3$^+$ for these states, If the spin and parity of the 2nd state at 2.97 MeV is 2^+, the transition to the gnd state is $E2$, and the transition probability is, therefore, $2.8\times10^{12}\,\mathrm{sec}^{-1}$.

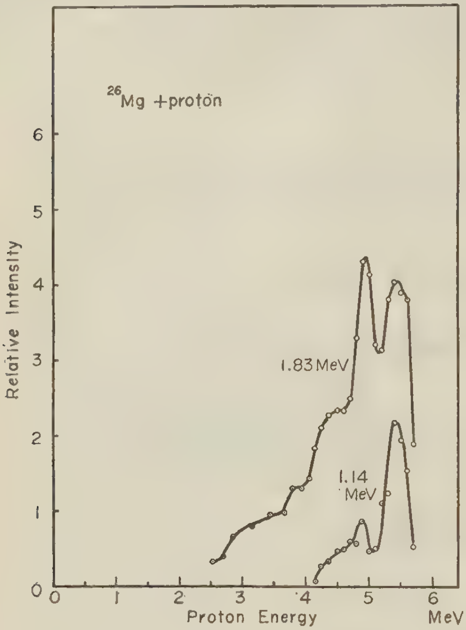

Fig. 10. The yield of the 1.83 MeV radiation by the deexcitation of the 1st excited state of ^{26}Mg and the yield of the 1.14 MeV radiation by the transition to the 1st state from the 2nd state, measured at right angles to the beam as a function of the proton energy.

Table IV. Resonances in ^{26}Mg$(p, p'\gamma)$ reaction.

Resonances energy (Mev)	Corresponding level energy (MeV) in ^{27}Al
2.9	11.0
3.8	11.9
4.4	12.5
4.95	13.02
5.45	13.50

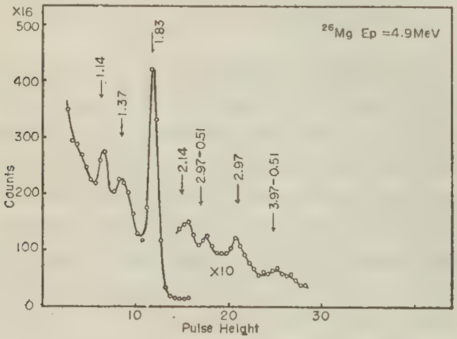

Fig. 11. The gamma-ray spectrum: ^{26}Mg+proton at 4.9 MeV and 90° with respect the beam.

If that is 3^+, the transition is $M3$, and the transition probability is, therefore, 2.8×10^{7} sec^{-1}.

For both cases, the cascade transition to the 1st state is $M1$, and the transition probability is $4.2\times10^{13}\,\mathrm{sec}^{-1}$.

From the experimental data in Table V, the intensity ratios of these gamma-rays, $I(2.97\,\mathrm{MeV})/I(1.14\,\mathrm{MeV})$, are both 0.12 at 5.7 and 5.4 MeV of proton energy. Then it is conculded that the spin and parity of the 2nd state at 2.97 MeV is 2^+.

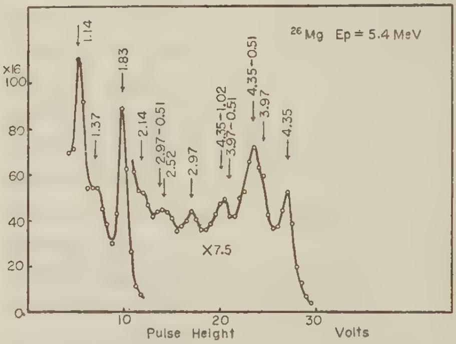

Fig. 12. The gamma-ray spectrum: ^{26}Mg+proton at 5.4 MeV and 90° with respect to the beam.

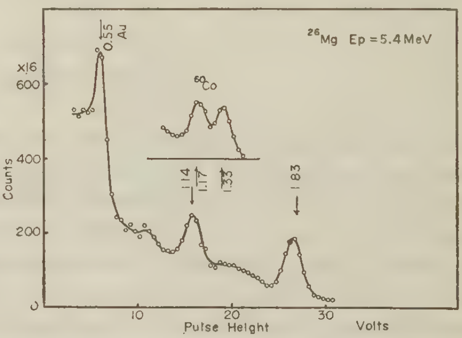

Fig. 13. The gamma-ray spectrum: ^{26}Mg+proton at 5.4 MeV and 90° with respect to the beam.

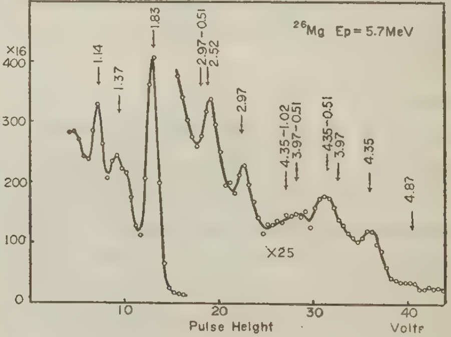

Fig. 14. The gamma-ray spectrum: ^{26}Mg+proton at 5.7 MeV and 90° with respect to the beam.

Next we consider the 3rd state at 3.97 MeV. In this case also the state has the spin of 2^+ or 3^+ only, and then the transition to the gnd state is $E2$ or $M3$, respectively, and the transion probability is, therefore, 1.2×10^{14} sec^{-1} or 2.2×10^{8} sec^{-1}, respectively.

The two cascade transitions to the 1st and 2nd state are both $M1$, and these transition probabilities are 2.8×10^{14} sec^{-1} and 2.8×10^{13} sec^{-1}, respectively.

Trble V. Gamma-rays in ^{26}Mg(p, $p'\gamma$) reaction.

Gamma-ray energy (MeV)	Relative intensity Ep=5.7	5.4	4.9 (MeV)	Origin of the gamma-ray
4.87	0.7			5th-gnd in ^{26}Mg
4.35	4	40		4th-gnd in ^{26}Mg
3.97	1	3		3rd-gnd in ^{26}Mg
2.97	2	6	4	2nd-gnd in ^{26}Mg
(3.06)				(5th-1st in ^{26}Mg)
2.52	1.5	2.5		4th-1st in ^{26}Mg
2.14		1.5		3rd-1st in ^{26}Mg
1.83	100	100	100	1st-gnd in ^{26}Mg
1.37	14	13		1st-gnd in ^{24}Mg
(1.38)				(4th-2nd in ^{26}Mg)
1.14	20	45	16	2nd-1st in ^{26}Mg
0.5		8		An
				(5th-4th in ^{24}Mg)

From the experimental data, these gamma-ray intensities are found to be of the same order. Then, it is concluded that the 3rd state at 3.97 MeV has probably the spin of 2^+.

The 4th state at 4.35 MeV has also 2^+ or 3^+, and the transition to the gnd state is $E2$ or $M3$, respectively, and then the transition probability is 2.0×10^{13} sec^{-1} or 3.7×10^{8} sec^{-1}, respectively.

The cascade transitions to the 1st, 2nd and 3rd state are all $M1$ and these transition probabilities are 4.5×10^{14} sec^{-1}, 7.3×10^{13} sec^{-1}, and 1.5×10^{12} sec^{-1}, respectively.

From the experimental data, the intensity ratios, I(4.35 MeV)/I(2.52 MeV) etc., are found to be 2 or 3, or larger. In this case, as the energy of gamma-ray 4.35 MeV is very close to 4.43 MeV gamma-ray from ^{12}C(p, $p'\gamma$) reaction, we must take precaution against carbon which may deposit on the target during preparation or bombardment. But we took good care of the target preparations and the energy calibrations of the gamma-ray spectra, and then the intensity of the 4.43 MeV gamma-ray was found to be negligible compared to that of the 4.35 MeV gamma-ray. It is, therefore, concluded that the spin and parity of the 4th

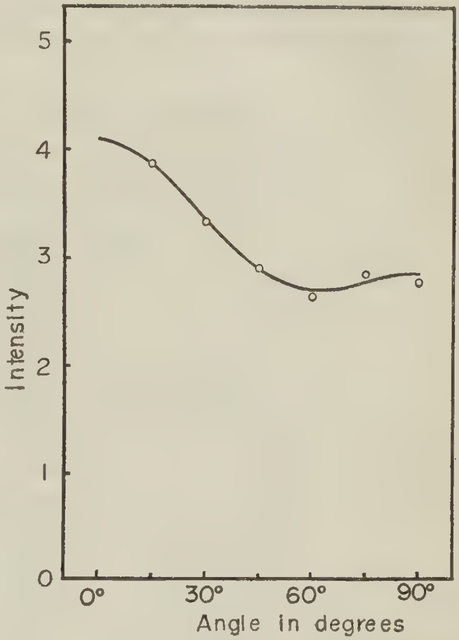

Fig. 15. Angular distribution of the 1.83 MeV gamma-ray in ^{26}Mg(p, $p'\gamma$) reaction at proton energy 4.9 MeV.

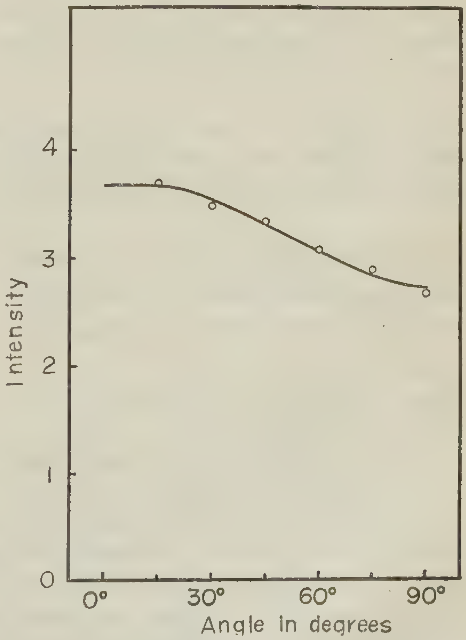

Fig. 16. Angular distribution of the 1.83 MeV gamma-ray in ^{26}Mg(p, $p'\gamma$) reaction at proton energy 5.4 MeV.

state at 4.35 MeV is also probably 2^+. These results show good agreement with the spins and parities of $T=1$ isotopic spin triplet levels in ^{26}Al[12].

The angular distributions of 1.83 MeV gamma-ray at proton energy 4.9 MeV, 5.4 MeV and 5.7 MeV are shown in Fig. 15, 16 and 17 respectively.

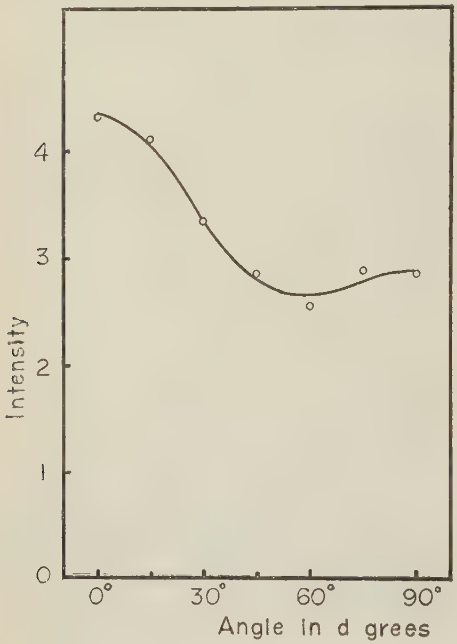

Fig. 17. Angular distribution of the 1.83 MeV gamma-ray in $^{26}Mg(p, p'\gamma)$ reaction at proton energy 5.7 MeV.

The solid lines in these figures represent the least squares fit to the data using even Legendre polynominals up to P_4 and are given by

$$W(\theta)=1+(0.206\pm0.015)P_2+(0.187\pm0.028)P_4$$

$$W(\theta)=1+(0.229\pm0.013)P_2-(0.036\pm0.023)P_4$$

$$W(\theta)=1+(0.227\pm0.018)P_2+(0.255\pm0.034)P_4$$

respectively.

These results and the calculations from the theory are shown in Fig. 6.

At proton energy 4.9 MeV, about 20% of the intensity of the 1.83 MeV gamma-rays is due to the cascade transitions from the 2.97 MeV and higher levels. At proton energy 5.4 and 5.7 MeV, these amount to about 50% and 20% respectively. Therefore, the expansion coefficients of the angular distributions of the 1.83 MeV gamma-ray by the direct excitation of this level by proton may be somewhat larger than these experimental results. At proton enengy 4.9 MeV, in spite of these circumstances, the coefficient of P_4 is too large to be neglected. Therefore, the level at 13.0 MeV in ^{27}Al have probably the spin of 5/2, considering the barrier penetrabilily. At proton energy 5.4 MeV, the angular dirtribution can be fairly represented by P_0 and P_2, and the spin of the level at 13.5 MeV in ^{27}Al is probably 3/2, but the possibility of 5/2 can not be excluded on account of the presence of the cascade gamma-rays as described above.

Both the angular distributions at proton energy 4.9 and 5.7 MeV can be represented by P_0, P_2 and P_4. This fact indicates that the spin of the 1st state of ^{26}Mg is 2 or larger, and is consistent with the result of β^+ decay.

Acknowledgment

The authors wish to thank Prof. K. Ogata and Mr. J. Okano for the preparation of the targets.

Convex-Core Model of Molecules in Crystalline State

By Taro KIHARA and Saburo KOBA

Department of Physics, Faculty of Science, University of Tokyo

(Received December 4, 1958)

The convex-core model of nonspherical molecules, introduced for the sake of treating the second virial coefficients of nonpolar gases (T. Kihara: Revs. Modern Phys. **25** (1953) 831), is applied to crystals of methane, carbon dioxide, and nitrogen. By use of model parameters determined from the second virial coefficients, lattice constants and cohesive energies are calculated. For methane, results of the calculations agree with observed values when the zero-point energy and the effect of potential non-additivity are taken into account. The crystal structure, the lattice constant and the cohesive energy of carbon dioxide are explained by use of a convex-core model with an embedded electric quadrupole.

§ 1. Introduction

The structure, the lattice constant, and the cohesive energy of a molecular crystal at absolute zero temperature can, in principle, be explained in terms of the potential energy between the constituent molecules. In the case of spherical molecules (i.e. inert-gas atoms) we can use, to a good approximation, the intermolecular potential

$$U(r)=U_0\left[\left(\frac{r_0}{r}\right)^{12}-2\left(\frac{r_0}{r}\right)^{6}\right] \qquad (1.1)$$

depending only on the distance r between centers of molecules. Here r_0 and U_0 are two parameters, which can be determined from the second virial coefficients of the corresponding gas. There are several theoretical investigations on inert-gas crystals$^{1)-7)}$.

Few investigations have been made, however, for crystals of polyatomic molecules. The present article is an application of a nonspherical molecular model, which has been introduced by one of the authors$^{8)}$ in order to treat the second virial coefficients of nonpolar gases. The model will be explained in the next section.

20	24	41	48	64	12
21	48	42	48	65	48

In this article crystals of methane, carbon dioxide, and nitrogen are treated. These molecules are nonpolar and almost convex in shape; hence they can be approximated by our model. The crystal structures of these three are all cubic; moreover they are modifications of the face-centered cubic structure of spherical molecules. For the face-centered cubic lattice, the number n_i of ith neighbors of a lattice point and the distance r_i to the ith neighbors (divided by the nearest neighbor distance a) have been calculated in detail[4)]; the results are given in Table I, a part of which will be used in the following.

§ 2. The Convex-Core Model of Molecules

We assume an appropriate convex body called core inside each molecule. The core of a (free) carbon dioxide molecule CO_2 is defined by a thin rod connecting the two O's, the length l of the core being $l=2.30$ A. The core of a nitrogen molecule N_2 is also a thin rod connecting the two N's, the length of the core being $l=1.094$ A. Let us define the core of a methane molecule CH_4 by a regular tetrahedron connecting the midmost points of C–H bonds. The distance of a vertex from the centered carbon atom will be denoted by l; then $2l=1.093$ A, the C–H bond length. (There is no definite reason for this particular choice of the core of a methane molecule. However, for other hydrocarbon molecules in gaseous states, the choice of midpoints of C–H bonds as vertexes of a core is known to be adequate[8)].)

The shortest distance between two cores will be called "intercore distance" and denoted by ρ. The potential energy U between two molecules is assumed to be a function of ρ only, and moreover

$$U(\rho)=U_0\left[\left(\frac{\rho_0}{\rho}\right)^{12}-2\left(\frac{\rho_0}{\rho}\right)^{6}\right], \qquad (2.1)$$

which is a generalization of (1.1). Here ρ_0 and U_0 are model constants determined from the second virial coefficients of the corresponding gas. Thus,

$\rho_0=3.15$ A, $U_0/k=226$°K for methane,
$\rho_0=3.36$ A, $U_0/k=309$°K for carbon dioxide,
$\rho_0=3.47$ A, $U_0/k=124$°K for nitrogen,

k being the Boltzmann constant. The cores and their parallel bodies at distance $\rho_0/2$ are shown in Fig. 1.

The model can be applied only to nonpolar molecules which are nearly convex in shape. In gaseous state the model is also applicable to molecules with electric quadrupole moment, because the quadrupole interaction is mostly cancelled there[9),10)]. In crystalline state, however, this interaction must be taken into account, for CO_2 in particular.

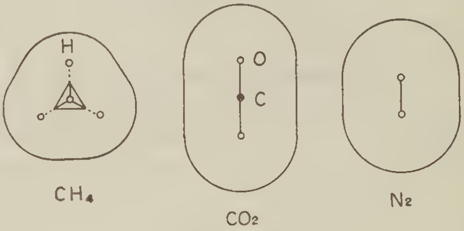

Fig. 1.

§ 3. Methane CH_4

(a) *Core-model interaction*

The carbon atoms in a methane crystal occupy the lattice points of a face-centered cubic structure. At temperatures below 20.4° K, the molecules do not freely rotate and seem to be parallel to each other with all the C–H bonds directed towards the body diagonals[11)]. The distance between nearest neighboring carbon atoms will be called "nearest neighbor distance" and denoted by a (so that the lattice constant by $\sqrt{2}\,a$).

A methane molecule has 12 nearest neighbor molecules at the intercore distance $a-2\sqrt{2/3}\,l$. In general, the square of the intercore distance ρ_i^2 to ith neighbors is given in Table II, where n_i is the number of ith neighbors.

Now, if the potential additivity is assumed and the zero-point energy is neglected, the cohesive energy per molecule is given by the minimum of

$$\frac{1}{2}U_0\sum_{i=1}^{\infty}n_i\left[\left(\frac{\rho_0}{\rho_i}\right)^{12}-2\left(\frac{\rho_0}{\rho_i}\right)^{6}\right] \qquad (3.1)$$

as a function of the nearest neighbor distance a. The expression (3.1) can be evaluated by use of Table II and, for farther molecules, Table I. It takes its minimum

$$-3.29 \text{ kcal/mol} \quad \text{at} \quad a=4.00 \text{ A}.$$

Observed values of the cohesive energy and the nearest neighbor distance are, respectively[12)],

$$-2.51 \text{ kcal/mol} \quad \text{and} \quad a=4.16 \text{ A}.$$

The discrepancy may be partly due to the zero-point energy and partly due to non-additivity of the intermolecular potential. In fact, according to our calculations to be mentioned in (b), the zero-point energy is about 0.48 kcal/mol and the effect of potential non-additivity is about 0.23 kcal/mol. These two effects slightly increase the nearest neighbor distance a.

Table II.

i	ρ_i^2	n_i
1	$\left(a-2\sqrt{\frac{2}{3}}l\right)^2$	12
2	$\left(\sqrt{2}a-\frac{2}{\sqrt{3}}l\right)^2$	6
3	$(\sqrt{3}a-\sqrt{2}l)^2$	24
4	$\left(2a-2\sqrt{\frac{2}{3}}l\right)^2$	12
5	$5a^2-8\sqrt{\frac{2}{3}}al+\frac{8}{3}l^2$	24

(b) *Zero-point energy and non-additive van der Waals interaction*

For methane crystal, the zero-point energy of rotational vibration must be taken into account besides that of the translational vibration. We assume for the rotational vibration the Einstein theory of specific heat, according to which the specific heat of the rotational vibration is

$$C_{V,\mathrm{rot}}=3k\left(\frac{\Theta_E}{T}\right)^2\exp\frac{\Theta_E}{T}\left[\exp\frac{\Theta_E}{T}-1\right]^{-2}$$

per molecule. Here $\Theta_E=h\nu_E/k$; and $h\nu_E$ is the frequency of the rotational vibration times Planck's constant. Then the zero-point energy of the rotational vibration is given by $(3/2)k\Theta_E$ per molecule; that of the translational vibration is given by $(9/8)k\Theta_D$ as usual, Θ_D being the Debye characteristic temperature. By use of observed values of the specific heat due to Clusius[13], Θ_D and Θ_E for methane are determined as

$$\Theta_D=78°\mathrm{K} \quad \text{and} \quad \Theta_E=102°\mathrm{K}\,.$$

Hence the total zero-point energy is calculated to be 0.48 kcal/mol.

The potential energy of the van der Waals attraction between three spherically symmetric atoms at large separation is of the form

$$-\mu(r_{12}^{-6}+r_{23}^{-6}+r_{31}^{-6})$$
$$+\nu(r_{12}r_{23}r_{31})^{-3}(3\cos\theta_1\cos\theta_2\cos\theta_3+1)\,.$$

Here r_{ij} is the distance between ith and jth atoms; θ_i's are inner angles of a triangle formed by the three atoms. Between μ and ν holds the approximate relation[14]

$$4\nu=3\alpha\mu$$

with the polarizability α. The μ is given by

$$\mu=3m_ec^2\alpha|\chi_{\mathrm{mol}}|/L\,,$$

in which m_e is the electron mass, c the light velocity, $L=6.025\times10^{23}$, and χ_{mol} is the molar diamagnetic susceptibility. The relations hold also for molecules with isotropic polarizability and susceptibility. Using[15]

$$\alpha=2.60\ \mathrm{A}^3\,,\qquad \chi_{\mathrm{mol}}=-12.2\times10^{-6}\ \mathrm{cm}^3$$

we have

$$\mu=12.9\times10^{-11}\ \mathrm{erg\ A}^6 \quad \text{for methane.}$$

According to Axilrod[16] contribution of the non-additive ν-term to the cohesive energy is $18.9\nu a^{-9}$ per molecule, which is 0.23 kcal/mol.

§ 4. Carbon Dioxide CO_2

(a) *Core-model interaction*

The carbon atoms in a carbon dioxide crystal form a face-centered cubic lattice, which is composed of four simple cubic lattices. On each simple cubic lattice the CO_2 molecules are in the same direction towards the body diagonals, the direction being different on different simple lattices[17] (Fig. 2). The distance between nearest neighboring carbon atoms will again be denoted by a.

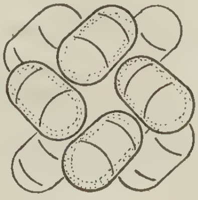

Fig. 2.

A carbon atom has 12 nearest neighboring carbon atoms at the distance a; the intercore distance to any of the 12 nearest neighbors is

$$\left(a^2-\sqrt{\frac{2}{3}}al+\frac{2}{9}l^2\right)^{1/2} \quad \text{if} \quad l\leqq\frac{3}{2}\sqrt{\frac{3}{2}}a\,.$$

A carbon atom has 6 second neighboring carbon atoms at the distance $\sqrt{2}a$; the intercore distance to any of the 6 second neighbors is

Table III.

i	j	ρ_{ij}^2	n_{ij}
1	1	$a^2-\sqrt{\frac{2}{3}}al+\frac{2}{9}l^2$	12
2	1	$2a^2-2\sqrt{\frac{2}{3}}al+l^2$	6
3	1	$3a^2-\sqrt{6}\,al+\frac{2}{3}l^2$	12
3	2	$3a^2-\sqrt{\frac{2}{3}}al+\frac{2}{9}l^2$	12
4	1	$4a^2-4\sqrt{\frac{2}{3}}al+l^2$	6
4	2	$4a^2$	6
5	1	$5a^2-\sqrt{6}\,al+\frac{1}{3}l^2$	12
5	2	$5a^2-\sqrt{6}\,al+\frac{2}{3}l^2$	12
6	1	$6a^2-2\sqrt{6}\,al+l^2$	2
6	2	$6a^2-\sqrt{6}\,al+\frac{3}{4}l^2$	6
7	1	$7a^2-5\sqrt{\frac{2}{3}}al+\frac{2}{3}l^2$	12
7	2	$7a^2-\sqrt{6}\,al+\frac{2}{9}l^2$	12
7	3	$7a^2-\sqrt{6}\,al+\frac{1}{3}l^2$	12
7	4	$7a^2-\sqrt{\frac{2}{3}}al+\frac{2}{9}l^2$	12
8	1	$8a^2-4\sqrt{\frac{2}{3}}al+l^2$	6
9	1	$9a^2-5\sqrt{\frac{2}{3}}al+\frac{2}{3}l^2$	12
9	2	$9a^2-\sqrt{6}\,al+\frac{2}{9}l^2$	12
9	3	$9a^2-\sqrt{6}\,al+\frac{2}{3}l^2$	12
10	1	$10a^2-2\sqrt{6}\,al+l^2$	12
10	2	$10a^2-2\sqrt{\frac{2}{3}}al+l^2$	12
11	1	$11a^2-5\sqrt{\frac{2}{3}}al+\frac{2}{3}l^2$	12
11	2	$11a^2-\sqrt{6}\,al+\frac{1}{3}l^2$	12
12	1	$12a^2-8\sqrt{\frac{2}{3}}al+l^2$	6
12	2	$12a^2-4\sqrt{\frac{2}{3}}al+l^2$	12
12	3	$12a^2$	6
13	1	$13a^2-7\sqrt{\frac{2}{3}}al+\frac{2}{3}l^2$	12
13	2	$13a^2-5\sqrt{\frac{2}{3}}al+\frac{1}{3}l^2$	12
13	3	$13a^2-5\sqrt{\frac{2}{3}}al+\frac{2}{3}l^2$	24
13	4	$13a^2-\sqrt{6}\,al+\frac{2}{9}l^2$	12
13	5	$13a^2-\sqrt{\frac{2}{3}}al+\frac{2}{9}l^2$	12
14	1	$15a^2-7\sqrt{\frac{2}{3}}al+\frac{2}{3}l^2$	12
14	2	$15a^2-5\sqrt{\frac{2}{3}}al+\frac{1}{3}l^2$	24
14	3	$15a^2-\sqrt{6}\,al+\frac{2}{3}l^2$	12
15	1	$16a^2-8\sqrt{\frac{2}{3}}al+l^2$	6
15	2	$16a^2$	6
16	1	$17a^2-7\sqrt{\frac{2}{3}}al+\frac{2}{3}l^2$	12
16	2	$17a^2-5\sqrt{\frac{2}{3}}al+\frac{1}{3}l^2$	12
16	3	$17a^2-5\sqrt{\frac{2}{3}}al+\frac{2}{3}l^2$	12
16	4	$17a^2-\sqrt{6}\,al+\frac{1}{3}l^2$	12
17	1	$18a^2-10\sqrt{\frac{2}{3}}al+l^2$	6
17	2	$18a^2-2\sqrt{6}\,al+l^2$	12
17	3	$18a^2-2\sqrt{\frac{2}{3}}al+l^2$	12

$$\left(2a^2-2\sqrt{\frac{2}{3}}\,al+l^2\right)^{1/2} \quad \text{if} \quad l\leqq\sqrt{\frac{2}{3}}\,a\,.$$

A carbon atom has 24 third neighboring carbon atoms at the distance $\sqrt{3}\,a$; the intercore distance to a half of the third neighbors are

$$\left(3a^2-\sqrt{6}\,al+\frac{2}{3}l^2\right)^{1/2} \quad \text{if} \quad l\leqq\sqrt{\frac{3}{2}}\,a\,,$$

and those to the others are

$$\left(3a^2-\sqrt{\frac{2}{3}}\,al+\frac{2}{9}l^2\right)^{1/2} \quad \text{if} \quad l\leqq\frac{3}{2}\sqrt{\frac{3}{2}}\,a\,.$$

In general, when $l\leqq\sqrt{2/3}\,a$, we denote by ρ_{ij} the intercore distance to n_{ij} cores of ith neighbors, $\sum_j n_{ij}$ being the total number n_i of the ith neighbors. Values of ρ_{ij}^2 and n_{ij} are given in Table III.

If the potential additivity is assumed and the zero-point energy is neglected, the cohesive energy per molecule is given by the minimum of

$$\frac{1}{2}U_0\sum_{i,j}n_{ij}\left[\left(\frac{\rho_0}{\rho_{ij}}\right)^{12}-2\left(\frac{\rho_0}{\rho_{ij}}\right)^{6}\right] \tag{4.1}$$

as a function of the nearest neighbor distance a. The expression (4.1) can be evaluated by use of Table III and, for farther molecules, Table I. It takes its minimum

$$-4.72\ \text{kcal/mol} \quad \text{at} \quad a=4.19\ \text{A}\,.$$

Observed values of the cohesive energy and the nearest neighbor distance are, respectively[9],[18],

$$-6.44\ \text{kcal/mol} \quad \text{and} \quad a=3.94\ \text{A}\,.$$

The discrepancy cannot be explained by the zero-point energy or by the potential non-additivity. In fact, electrostatic interactions are dominant, as shown in the following.

(b) *Electric quadrupole interaction*

The CO_2 molecule has an electric quadrupole[19]

$$Q\equiv\sum_i e_i(z_i^2-x_i^2)=3.12\times10^{-26}\ \text{e.s.u.}\,,$$

where (x_i, y_i, z_i) are coordinates of an electric charge e_i, z_i being in the direction of the molecular axis.

The potential energy between the two quadrupoles at the distance r is given by

$$\frac{3}{4}\frac{Q^2}{r^5}f(\theta_1,\varphi_1;\theta_2,\varphi_2)$$

in which

$$\begin{aligned}&f(\theta_1,\varphi_1;\theta_2,\varphi_2)\\&\quad=1-5\cos^2\theta_1-5\cos^2\theta_2-15\cos^2\theta_1\cos^2\theta_2\\&\quad+2[4\cos\theta_1\cos\theta_2-\sin\theta_1\sin\theta_2\cos(\varphi_1-\varphi_2)]^2\,.\end{aligned}$$

Here θ_1, φ_1 are polar angles of the axis of one quadrupole with respect to the line connecting the both, and θ_2, φ_2 are those of the other. For the CO_2 crystal, the function f is given in Table IV, which is due to Jansen, Michels, and Lupton[20]. It is important to note that the sign of f is negative for first and second neighbors.

Table IV.

Shell No. i	Shell No. j	Distance from center	Number of molecules	$f(\theta_1,\varphi_1;\theta_2,\varphi_2)$
1	1	a	12	$-\frac{19}{9}$
2	1	$\sqrt{2}\,a$	6	$-\frac{28}{9}$
3	1	$\sqrt{3}\,a$	12	$-\frac{31}{81}$
3	2	$\sqrt{3}\,a$	12	$+\frac{1}{9}$
4	1	$2a$	6	$+3$
4	2	$2a$	6	$-\frac{13}{9}$

Contribution of the quadrupole interaction to the cohesive energy is

$$-\frac{1}{2}\times21.4\,Q^2/a^5 \tag{4.2}$$

per molecule. The sum of (4.1) and (4.2) takes its minimum

$$-5.90\ \text{kcal/mol} \quad \text{at} \quad a=4.16\ \text{A}\,.$$

These values are close to the corresponding observed values written in the foregoing.

(c) *Crystal stability*

The crystal which we have treated is not a structure of closest packing. For the core-model of CO_2 there are two closest packing structures in which the molecules are parallel; they correspond to cubic and hexagonal closest packings of spheres. The cohesive energies of these two are almost the same.

In fact, if we consider the core-model interaction only and do not take account of the quadrupole interaction, then the closest packing structures become more stable, the cohesive energy being −5.26 kcal/mol in comparison with −4.72 kcal/mol for the face-centered cubic structure treated in (a).

However, the electric quadrupole interaction decreases the stability of the closest packing structures; they are less stable than the cubic structure when the quadrupole moment is larger than 1.2×10^{-26} e.s.u.

Thus we draw our conclusion. The core-model of molecules with an embedded quadrupole can be applied to the CO_2 crystal and explains its cohesive energy, lattice constant, and crystal stability.

§ 5. Nitrogen N_2

Below 35°K nitrogen crystallizes into a cubic structure which is somewhat similar to the structure of carbon dioxide. In detail, however, the midmost point of the N–N bond is not on the face-centered cubic lattice. It is somewhat shifted along the molecular axis; and the point dividing the bond in the ratio 4 to 7 is on the lattice[17]. This shift cannot be explained by our convex-core model of molecules.

If we neglect the shift, we obtain, for our core-model of molecules, the cohesive energy

$$-1.99\ \text{kcal/mol}\,, \qquad a \text{ being } 3.83\ \text{A}\,.$$

Here the potential additivity has been assumed, and the zero-point energy has been neglected. These results agree rather well with observed values[12),20)]

$$-1.65\ \text{kcal/mol} \quad \text{and} \quad a=4.00\ \text{A}\,.$$

(A nitrogen molecules has an electric quadrupole $Q=1.29\times10^{-26}$ e.s.u.[19], whose interaction energy is -0.30 kcal/mol. Sum of the zero-point energy and the effect of potential non-additivity is about 0.6 kcal/mol.)

Interaction of Exciton with Electron Trapping Centers in Alkali Halide Crystals

1. *F* and *U* Centers in KCl and KBr Crystals

By Masayasu UETA, Masamitsu HIRAI
and Hiroyuki WATANABE

*Department of Physics, The Faculty of Science,
University of Tohoku, Sendai*

(Received September 24, 1958)

The quantum efficiency for the bleaching of *F* centers in the KCl crystal with incident ultra violet lights in the region of the fundamental absorption band was obtained to have five times larger value than that with the visible light in *F*-absorption region. With the estimation of the absorption coefficient of the crystal at the fundamental absorption tail, it is infered that one exciton can bleach at least six *F* centers. From the similar experiments to measure the quantum efficiency for the process of $U \rightarrow F$ transformation using monochromatic lights, it is concluded that one exciton is able to transform about three *U* centers. Dependence of the quantum efficiency on the wavelength of exciting light was determined in the KBr crystal.

§I. Introduction

It is well known that exciton is formed in alkali halide crystal with the irradiation of ultra violet light in the region of characteristic absorption band. The investigation of exciton has been developed by many authors¹⁾ from both theoretical and experimental view point, and much knowledges of its fine structure, fluorescence and photoemission have been accumulated.

On the interaction of excitons with electron-trapping centers, there are two important experiments of the external photoelectric effect by Apker and Taft²⁾ and photoconductivity measurements by Inchauspé³⁾. Both experiments suggest that the exciton can migrate through crystal and is captured by *F* center which is an electron trapped by a negative ion vacancy and transfer its large energy to *F* center and ionize it effectively. From the photoconductivity measurements of KBr containing *F* centers, Inchauspé has obtained the curve giving $\eta\omega_0$ versus wavelength of the irradiation light as shown in Fig. 1. Here η is the number of photoelectrons produced per *incident* quantum on the crystal surface and ω_0 is the displacement of a photoelectron in the field direction by unit electric field. Therefore, η is not the true quantum yield giving the number of photoelectrons per quantum *absorbed* in crystal.

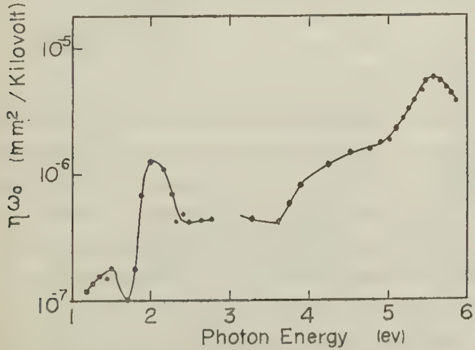

Fig. 1. The Photoconductivity measurement in KBr crystal containing *F* centers at −80°C (by Inchauspé).

We found that ultra violet lights from the high intensity hydrogen discharge tube through LiF window can bleach *F* centers very easily in KCl crystals. A KCl crystal containing *F* centers of density of 5×10^{17}/cc was set in front of the window of hydrogen lamp to be irradiated by light. One half of irradiated surface was covered with potassium iodide or glass plate to cut off the ultra violet light in the fundamental absorption band—we call it for brevity as extiton light—because, the exciton absorption band of KCl crystal starts at the wavelength shorter than 200 mμ and the ultra violet cutoffs are 250 mμ and 290 mμ for the KI and glass plates, respectively. After a short irradiation period of 30 seconds or so, the portion of the crystal which was irradiated by unfiltered light changes its red purple coloration due to F center to bluish color with more rapid rate compared to the another filtered portion, in spite of larger photon numbers in F-absorption region than ultra violet region.

Absorption spectra show that F band was bleached in part and M band enhanced, however, after a continued irradiation, the relative height of M-bands was reversed. This fact shows that M centers are more easily bleached than F centers by the exciton light.

These observation suggested the possibilities of quantum yield determinations for the ionization process of F centers and $U\rightarrow F$ transformation by the exciton, from both measurements of light quanta absorbed by the crystal and the number of F centers destroyed (in the case of $F\rightarrow M$) or increased (in the case of $U\rightarrow F$). These principles are the main logic of experiments described in the present report.

Through this report, all experiments and measurements were carried out at room temperature and KCl and KBr crystals obtained from Harshaw Chemical Company were used.

§ 2. Bleaching of F Centers by the Exciton in KCl Crystal

F centers were prepared additively by the conventional method with heating crystals with potassium metal at 560°C for 12 hours in a pyrex glass tube. The potassium metal was carefully distilled to take off the trace of hydrogen gas. Crystals thus treated contain only F centers and there is no trace of U centers due to the hydrogen atom in ultra violet region.

Concentrations of F centers n_0 were determined optically as 5×10^{17} per cubic centimeters using Smakula's formula[4].

$$n_0 f=1.31\times10^{17}\frac{n}{(n^2+2)^2}\cdot\alpha_m\cdot H\,,$$

where n is the index of refraction of the crystal at the wavelength of F-absorption peak; α_m is the absorption coefficient in cm^{-1} at the maximum of the F-band; H is the half width of the F-band in electron volts; f is the oscillator strength. Putting $n=1.49$, $H=0.38$, $f=0.81$ for the KCl crystal, we get the simplified equation: $n_0=1.19\times10^{16}(-\log_{10} I/I_0)$, I/I_0: transmission at F-band peak.

The number of light quanta from hydrogen discharge tube in exciton region (shorter wavelength region than 200 mμ) was determined by the proper set of filters as follows.

Very crose to the window of the hydrogen discharge tube a pure uncolored KCl crystal of 0.5 mm thickness and a KCl+F crystal of 3 mm thickness were set at position of 1 and 2 as shown schematically in Fig. 2 and the

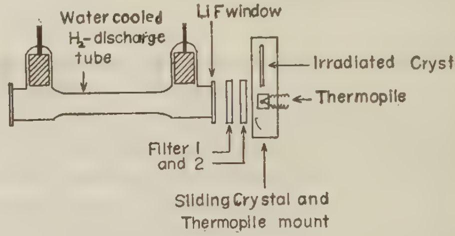

Fig. 2. Schematic arrangement of filters and thermopile to measure the light quanta.

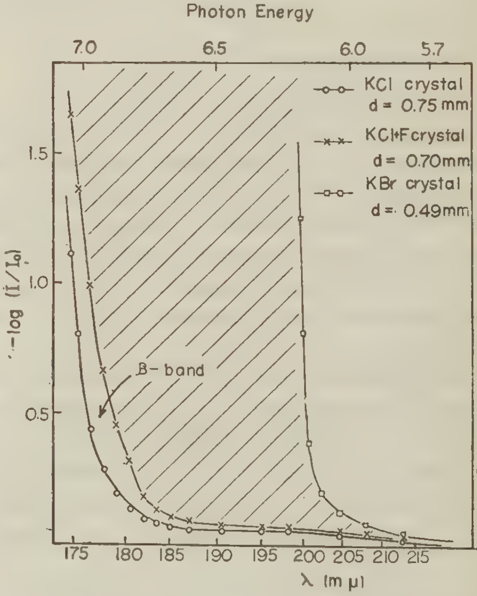

Fig. 3. Absorption curves of KCl, KBr and KCl +F crystals.

photon energy transmitted through these filters was measured with the thermopile made by Kipp. KCl+F crystal means the KCl crystal containing only F centers. Sensitivity* of our thermopile is 115 mV/W/cm². Thermopile was set always at a constant place of 14 mm distance from the window of hydrogen discharge tube. Next, only filter 1 was replaced by a cleaved pure KBr crystal of 0.5 mm thickness and measured the photon energy. The difference of these two quantities gives the energy of ultra violet light contained between wavelengths of the characteristic absorption edges of KCl and KBr crystals i.e. from 200 mμ to 180 mμ as shown by the shadowed area in Fig. 3. The number of photon was thus measured as $9.3\times10^{13}/\mathrm{cm}^2\,\mathrm{sec}$ averaged to the light of 190 mμ when the hydrogen lamp was discharging with 2 KW powers. Fig. 3 are the absorption curves of KCl, KBr filter and KCl+*F* crystal. These absorption curves were measured with the vacuum monochromator constructed in this Laboratory, having a concave grating of which diameter of Rowland circle is 998 mm.

---

* The writers are deeply indebted to Dr. H. Sadone, Electro-technical Laboratory, Osaka, who has determined the absolute sensititivity of the thermopile.

Samples of KCl+*F* ($d\sim$ 0.3 mm) crystals were alternatively placed at the position of thermopile and irradiated with the lights filtered by the KCl+*F* crystal of 3 mm thickness. As visible *F*-lights from the hydrogen lamp are filtered by the *F* centers in this crystal, samples are irradiated mainly with ultra violet light in the region of 205 mμ–180 mμ, because the tail of the exciton band extends to 210 mμ as shown in Fig. 3. At several stages of irradiation period, decreases of absorption maximum of *F* band were measured. The number of decreased *F* centers is calculated simply according to the equation:

$$\Delta n = 1.19\times10^{16}\cdot\Delta(\log_{10} I_0/I)$$

Here $\Delta(\log_{10} I_0/I)$ is the decrease of the absorption coefficient at absorption peak of the *F*-band. A constant factor p greater than 1 must be multiplied to the equation to obtain the real decrease, because the bleaching of *F* centers enhances the *M*-band simultaneously and the second *M*-absorption band superposes to the *F*-band[5]. However the quantum efficiency for the case of exciton-light irradiation is discussed with comparison to the case for visible light irradiation, and in both case the constant is common. Therefore, the factor can be omitted. Another factor *S* which gives the illuminated area of the crystal surface must be multiplied to the equation too, but for the uniform irradiation it is canceled out in the expression of quantum efficiency.

Lower scale is for curve b

Fig. 4. The relations between light quanta and bleached *F* centers in KCl+*F* crystals when they are irradiated by the ultraviolet light (curve a) and *F* light (curve b).

Fig. 4a shows the relations between the number of decreased *F* centers and the total *incident* light-quanta in the tail of exciton bands for two samples.

§ 3. Quantum Efficiency for the Bleaching of *F* Centers by *F*-light in KCl Crystal

The difference of energies measured with the thermopile in two cases, where one case has a glass plate and a pure KCl crystal of 0.3 mm thickness interposed respectively at positions 1 and 2 in Fig. 2 and another case has a glass and a KCl+*F* crystal of 0.3 mm thickness as filter 1 and 2 respectively, gives the energy of lights absorbed in *F*-band. When the hydrogen lamp was operated with the same condition as before, the number of photon (averaged to the wavelength of *F*-band peak) was calculated to $6.3\times10^{14}/\mathrm{cm}^2\,\mathrm{sec}$.

KCl+*F* crystals of about 0.3 mm thickness were placed at the position of filter 2 and they were irradiated by the light from the hydrogen lamp through the same glass filter. The number of decreased *F* centers are obtained as before and are plotted as a function of *absorbed* total quanta in Fig. 4b. The concentration of *F* center is very large, therefore, through the course of bleaching experiment, the absorbed light quanta remained to the constant value.

From Fig. 4a and 4b it is shown that the quantum efficiency for the destruction of F centers by the *incident* exciton-light is 0.15 and it is five times greater than that due to the *absorbed* F-light, compared the tangents of slopes at zero irradiation.

§ 4. Quantum Efficiency for the $U \rightarrow F$ Transformation by U-light and Exciton-light in KCl Crystal

The U center is considered a negatively charged hydrogen ion H-occupying substitutionally halogen ion site. U centers display a bell shaped absorption band in ultra violet region and its absorption maximum situates at 216 mμ and 228 mμ in KCl and KBr crystal, respectively. When the crystal containing U centers is irradiated by the U-light, $U \rightarrow F$ transformation occurs. There is no enhanced centers other than F center in this conversion process.

Hilsch[6)] has measured the quantum efficiency for the $U \rightarrow F$ transformation in KBr crystal and obtained 0.30 at room temperature. However, the effect of exciton lights on U centers has not been investigated so far as we know.

High concentration of U centers is prepared as follows. KCl crystal containing high density of F centers colored additively was heated with hydrogen gas of 100 atomospheric pressure in Ni–Cr bomb at 540°C for several hours. All F centers initially existed are converted to U centers without any loss.

A. *Quantum efficiency with the light including both exciton and U-light*

The photon energy absorbed by KCl+U crystals in the region of U-absorption band and exciton absorption tail was measured as follows. Two pure KCl crystal plates were set at positions of filter 1 and 2 in Fig. 2 and transmitted photon energy from the hydrogen discharge tube was measured with thermopile. Next, filter 2 was replaced by the KCl+U crystal and transmitted photon energy was measured. The difference of these two energies gives the photon energy which is absorbed in the KCl+U crystal at the region of U band and exciton tail, corrected the reflection loss on the surface.

KCl+U crystals were irradiated at the position of filter 2 and the increase of F centers were measured. The number of enhanced F centers is plotted in Fig. 5a versus total absorbed photon numbers averaged at 200 mμ.

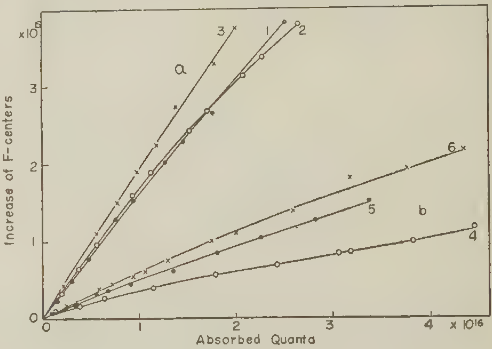

Fig. 5. The relations between total absorbed light quanta and numbers of enhanced F centers in KCl+U crystals when they are irradiated with U+exciton light (curve a) and U light only (curve b).

The thickness of pure KCl filters and irradiated KCl+U crystals and absorbed light quanta are shown in Table I for three samples.

From the slope of Fig. 5a the number of enhanced F centers per sec at zero irradiation time was obtained as given in the fifth column. The quantum efficiency was then calculated and is given in the sixth column of Table I.

B. *Quantum efficiency with the U-light only*

The energy difference between the photon energies transmitted two sets of filters, one set has a pure KBr and a pure KCl crystal as the filter 1 and 2 and the another set has the same KBr and a KCl+U crystal at the

Table I. Quantum efficiency for the $U \rightarrow F$ transformation with U-light including exciton light.

KCl+U crystal No.	Crystal thickness (mm)	KCl crystal-filter thickness (mm)	Absorbed quanta/cm² sec	Increase of F-centers per sec	Quantum efficiency
1	0.59	0.89	7.9×10^{14}	1.27×10^{14}	16%
2	0.56	0.56	4.7×10^{14}	8.1×10^{13}	17%
3	0.88	0.80	5.4×10^{14}	9.9×10^{13}	18%

position of filter 1 and 2, gives the photon energy absorbed in U-band only, as shown in the shadowed area in Fig. 6. Fig. 6 is a group of absorption curves of the pure KCl, KBr and KCl+U crystals of about 0.7 mm thickness.

KCl+U crystals were set at position of filter 2 and irradiated with the light filtered by the KBr crystal.

Fig. 5b shows the relation between the absorbed total light quanta and the number of F centers formed from U centers. Description of samples, filter thickness, number of absorbed quanta, enhanced F centers and quantum efficiency are given in Table II.

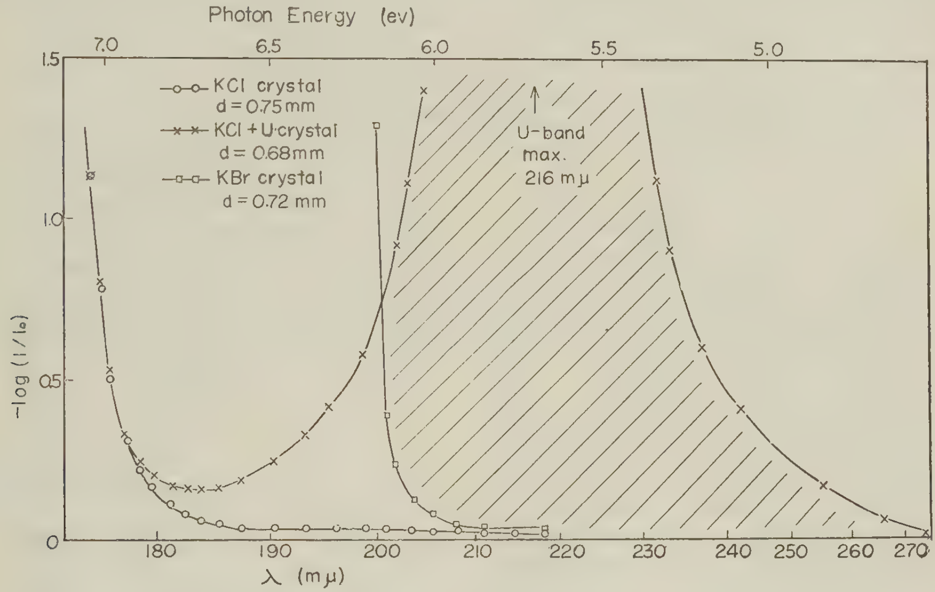

Fig. 6. Absorption curves of KCl, KBr and KCl+U crystals.

Table II. Quantum efficiency for the $U\rightarrow F$ transformation with U-light only.

KCl+U crystal No.	Crystal thickness (mm)	KBr crystal-filter thickness (mm)	Absorbed quanta/cm² sec	Increase of F-centers per sec	Quantum efficiency
4	0.88	0.80	3.2×10^{14}	1.8×10^{13}	5.6%
5	0.59	0.62	5.6×10^{14}	3.0×10^{13}	5.4%
6	0.58	0.60	2.9×10^{14}	1.8×10^{13}	6.2%

From Table I and II it is shown that the quantum efficiency of the $U\rightarrow F$ transformation with U-light including the exciton tail is three times larger than that with U-light only. From these facts, we can conclude that the ultra violet light in the exciton absorption tail has a large quantum efficiency for the transformation of U centers to F centers, because of the very small absorption coefficient in the tail.

From the preliminary experiment it was observed that when the KCl+U crystal of 3.75 mm thickness was irradiated with the monochromatic light of 190 mμ, the quantum efficiency has a large value as much as four.

§ 5. Quantum Efficiency of the $U\rightarrow F$ Transformation and its Dependence on Photon Energy in KBr Crystal

U centers were prepared in the KBr crystal as described before. The Concentration of U centers $[U]$ are calculated with the following equation given by Hilsch[7].

$$[U]=5.1\times10^{16}\cdot f_\lambda\cdot K_\lambda: \quad \text{at room temperature.}$$

Where K_λ is the absorption coefficient measured in mm^{-1} and f_λ's are constants depending on the wavelength of light with which the absorption coefficient is measured, and have the following values.

$\lambda(m\mu)$	absorp. peak 228	Hg 245	Hg 254	Cd 257	Hg 265
f_λ	1	8	21.2	43.2	235

The value of 7.3×10^{17}/cc was determined to the concentration of U centers in our crystals.

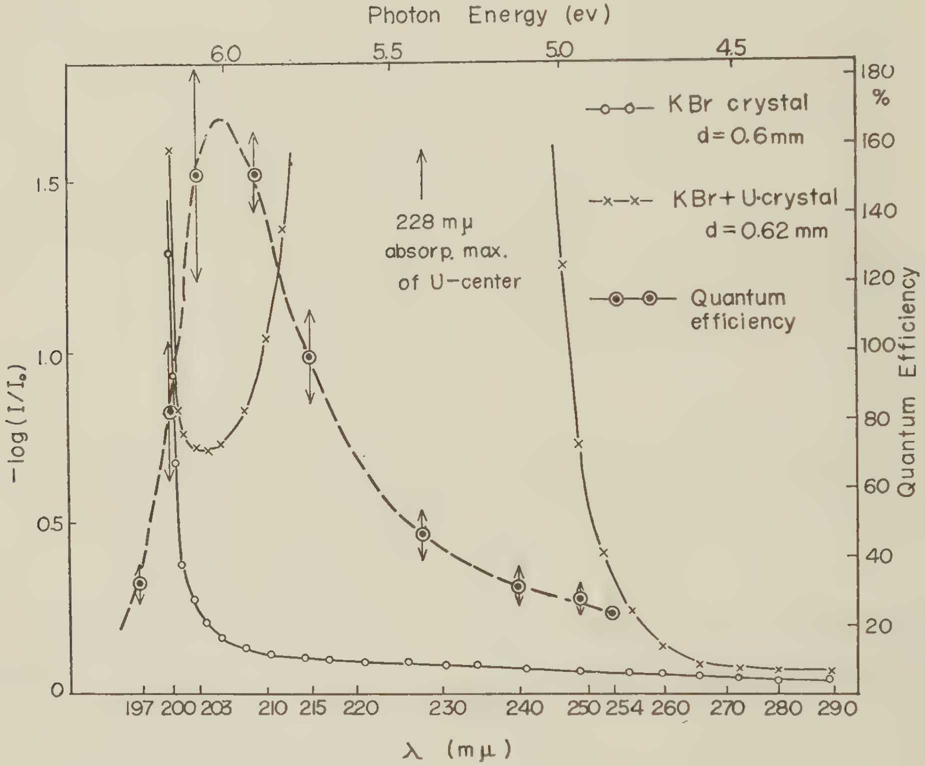

Fig. 7. Absorption curves of KBr, KBr+U crystals and the dependence of the quantum efficiency for the process of $U\rightarrow F$ transformation on the wavelength of the exciting light.

In KBr+U crystals U-absorption and the exciton bands situate closer with each other compared to the KCl crystal as shown in Fig. 7 and there are no proper filters to separate two absorption bands, therefore, the similar method performed in the case of KCl crystal can not be applied to KBr crystal. However the monochromatic lights in the region of 250 mμ–190 mμ are obtained with high intensity using a vacuum monochromator constructed for the irradiation purpose. Optical system of the vacuum monochromator is shown in Fig. 8. M_1 and M_2 are off axial parabolic mirror[*] of 130×130 mm dimension, 360 mm focal length, and G is a plane replica grating which was purchased from Bausch and Lomb Optical Company having a dimension of 102 ×102 mm as a ruled area. The blaze wavelength of the grating is 200 mμ. When the hydrogen lamp are discharging with 2 KW power the photon intensity from the monochromator are 1×10^{13}, 4×10^{12}, 2×10^{12} and 1.8×10^{12} quanta per cm² per sec at 249 mμ, 230 mμ, 200 mμ and 190 mμ respectively. Each monochromatic light has a band pass of 6 mμ.

Quantum efficiency of the $U\rightarrow F$ transformation with the monochromatic light of Hg 253.7 mμ was measured as 18%. This value are determined with relatively high accuracy, because, the monochromatic light of 253.7 mμ from a mercury lamp is very intense and the response of the thermopile to this light is large. We have chosen this value of 18% as a standard, and obtained the absolute quantum efficiency for the monochromatic light with measuring the relative photon intensity and the relative numbers of enhanced F centers by the monochromatic light against for the standard 253.7 mμ light.

---

[*] By the courtesy of Professor T. Sakurai, Institute of Scientific measurements, Tohoku University, these parabolic mirrors were polished in his Laboratory.

KBr+U crystals of about 3 mm thickness was irradiated at first with a monochromatic light, say 203 mμ, for ten minutes and measured the number of enhanced F centers using the Smakula's equation, putting $n=1.53$, $H=0.36$ (ev) and $f=0.85$. For the successive ten minutes the crystal in turn was irradiated with light of 253.7 mμ and the increment of F centers was measured. Thus, alternative ten mitutes' irradiation with 203 mμ and 253.7 mμ lights are repeated three times on the same crystal, and the numbe of F centers created independently with two monochromatic lights were averaged respectively.

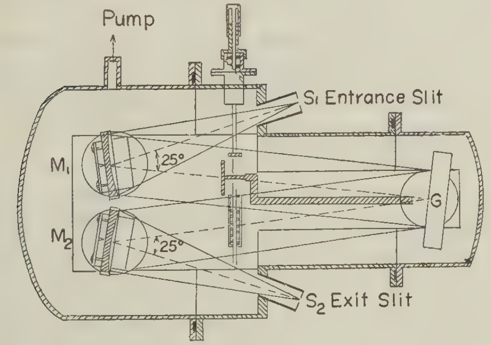

Fig. 8. The optical system of the vacuum monochromator.

The relative intensity of the two monochromatic lights at the surface of crystal was obtained with measuring the fluorescence impressed on the sensitive flourescent film placed at the position of the crystal. A pump oil and sodium salicylate film were used for the fluorescent film. Both films are confirmed to have the same quantum efficiency to the monochromatic ultra violet lights from 300 mμ down to 100 mμ[8]. The relative intensities of monochromatic lights measured using two films coincided with each other within 10%.

The absorption spectra of KBr+U and pure KBr crystal of 0.6 mm thickness are shown in Fig. 7. It is clear that the exciton tail is not affected by the existence of U centers, i.e. there is no band corresponding to β-band in the existence of F centers. The same conclusion can be said to the KCl crystals (c.f. Fig. 6).

Quantum efficiencies of the $U\rightarrow F$ transformation thus obtained in KBr crystal with monochromatic lights are shown in Fig. 7. Crystals used have the thickness of more than 3 mm and transmissions of crystals at all monochromatic lights were lower than 5%. Therefore, the correction for the differences of absorption coefficients was unnecessary.

At 203 mμ and 209 mμ, the quantum efficiency has the maximum value and drops rapidly towards the exciton band which has a large absorption coefficient.

§ 6. Discussions

A. *Bleaching of F centers by the exciton*

The quantum efficiency for the bleaching of F centers with the incident light in the exciton band was determined as 0.20 from Fig. 4a. To obtain the real quantum efficiency η_0 which gives the number of F centers bleached per absorbed quantum, we have to estimate the fraction of the energy absorbed in the crystal.

KCl+F crystals were irradiated by the ultra violet light from the hydrogen lamp through the thick crystal containg F centers of high density and so, ultra violet lights in shorter wavelength region than the β-band are filtered. On the other hand, the exciton band extends to the 210 mμ as shown in Fig. 3. Therefore, the effective ultra violet light for the bleaching of F centers is limited mainly in the region between 180 mμ to 205 mμ of which total light quanta were determined as 9.3×10^{13} per cm^2 per sec. In these wavelength region, the spectral intensity distribution[9] of light from the hydrogen lamp is measured to have nearly the uniform intensity.

Absorption curve of the exciton band in the tail shows that the light quanta which are absorbed in the crystal will be at most 3% of the total incident quanta. From these facts, it may be concluded that the quantum efficiency η_0 for the bleaching of F centers per one exciton is at least six.

It is unknown whether or not the mechanism of the bleaching of F centers by the exciton is the same to the process of F-light illumination, though the absorption spectra of the crystal after a short irradiation show the enhancement of M band and with continued irradiations, R band become to appear. Now let us assume the same mechanism for both cases.

When the F center absorbs F-light, it should be ionized in the first step with quantum efficiency 1 at room temperature, because Pick[10] has obtained it at even low temperature in his observation of the photochemical reaction of $F \rightarrow F'$. At room temperature F' center is unstable and the back reaction of $F' \rightarrow F$ occurs. This back reaction explains the apparent small quantum efficiency for the bleaching of F centers by the F-light that we obtained as 0.04.

The efficiency of the F center bleaching by the incident ultra violet light is obtained to have 0.20 as shown in Fig. 4 and it is five times larger than that with the F-light. Therefore, if the assumption is correct that the effect of excitons on F centers is the same as in the case of F-light irradiation, we have to conclude that one incident photon of ultra violet light ionizes five F centers. If we calculate the real quantum efficiency η_0: the number of ionized F centers per one absorbed quantum or exciton: it will reach a quite large value. On the other hand, the thermal dissociation energy of F center was calculated as 1.95 ev for the KCl crystal by Mott and Gurney[11] and the energy of an exciton is about 6 ev, and so, even in the case that all energy of the exciton is used to ionize the F centers, the maximum value of F centers destroyed should be at most three. Therefore, the action of excitons on F centers which we observed can not be explained from the ionization process only and the thermal effect which produce the reaction of such as $F \rightarrow$ colloid must be considered to happen simultaneously.

Theisen and Scott[12] has discovered the easy thermal bleaching of F centers in KCl crystal when the crystal containing F centers was kept in dark at above 150°C. They plotted the number of F centers bleached thermally as a function of time and obtained the activation energy of 10.5 ± 1.5 kg cal/mol for the process of $F \rightarrow$ colloid. Though the mechanism by which the F centers coagulate is unclear at the present time, if the exciton energy is given in full to the thermal process for the formation of colloid, one exciton can bleach more than ten F centers. Therefore, the observed quantum efficiency of six for the bleaching of F centers by an exciton will be reasonable value.

As mentioned before, at the initial state of the irradiation with the exciton light, the crystal shows the enhancement of M band as in the case of F-light irradiation. From this fact it may be concluded that the energy of an exciton is shared to both processes for the ionization of an F center and for the thermal bleaching of F centers to the formation of colloids.

B. *Excitation of U center*

In KBr crystrl, η_0 for the process of $U \rightarrow F$ transformation with U-light was determined as 0.46 at the U-band peak, which nearly coincides with the result measured by Hilsch.

On the conversion of $U \rightarrow F$, Mott and Gurney[13] concluded that the excited state of the U center is metastable as a result of crossing of the crystalline Franck-Condon curves and that a hydrogen atom escapes from the center in the metastable state. By this mechanism the increases of efficiencies we obtained when the crystal are irradiated with lights of higher photon energies will be explained.

With the photon energies of 209 mμ and 203 mμ, η_0 has the value larger than 1. Here the absorption coefficients of the crystal are the superposition of the absorptions due to the U-band and exciton band. Therefore, the total light quanta is shared to both absorption bands in proportion to the absorption coefficients. From Fig. 7 it is estimated that the light quanta absorbed in the exciton tail are 1/7 and 1/2.5 of the total quanta, respectively. From these facts η_0 for the ionization of U centers are calculated to have the values of five and three with the exciton lights of 209 mμ and 203 mμ, respectively.

With the lights of shorter wavelength than 203 mμ decreased rapidly. This fact might be explained as due to the destruction of excitons by the mutual interaction, because at these wavelength region the absorption coefficient of the crystal is large and almost of all incident exciton lights are absorbed in a thin layer of the crystal and the density of excitons is large.

This drop of the quantum efficiency is also observed at shorter wavelength than $h\nu = 5.5$ ev by Inchauspé in his photoconductivity measurements shown in Fig. 1.

§ 7. Conclusion

The large quantum efficiency for the bleaching of color centers with the ultra violet light in the region of the fundamental absorption tail was observed. It has to be considered that the effect of the exciton is mainly the thermal action, and that the color centers *F* and *U* are not uniformly distributed even in the case of the additive coloration but exist locally as the aggregations of atomic centers and receive the exciton energy with a good efficiency.

To obtain the definite conclusion, more detailed experiments have being carried out at the lower temperatures.

The authors wish to express our cordial thanks to Professor T. Muto for his kind interests. This work was aided by the Scientific Research Fund of the Ministry of Education.

Electrical Resistivity and Superstructure of $CuAu_3$

By Makoto HIRABAYASHI

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai

(Received October 14, 1958)

The superlattice formation in the alloy $CuAu_3$ containing 75.0_6 atomic per cent gold was studied by measurements of electrical resistivity and by means of X-ray diffraction with a single crystal. After the alloy was quenched from 450°C, the isothermal change in resistivity was measured at various temperatures between 100° and 220°C. In most of the isothermal measurements, the resistivity increased monotonously with the time of annealing, possessing an activation energy of 25 ± 2 Kcal/mol. It was found, however, that after prolonged annealing at 162 and 175°C sluggish decrease in resistivity took place following initial increase. The transition point of this alloy was determined as 200 ± 5°C.

Corresponding to the resistivity measurement, X-ray diffraction patterns were taken at various states of ordering at 100°, 150° and 180°C as well as at the states quenched from 210° and 450°C. It was confirmed that nucleation and growth of small anti-phase domains in the disordered lattice take place in accordance with the rise in resistivity, and that the development of order within the domains plays an important role in the reduction of resistivity. Then even after three months annealing at 180° and 100°C, the ordered alloy $CuAu_3$ has a two-dimensional, rather than one-dimensional, anti-phase domain superstructure with the linear dimension of nearly 11 times the fundamental face-centered cubic cells. In every stage examined, the main lattice reflections were surrounded by fairly strong diffuse scatterings, which is considered to be caused by the thermal motion of atoms, not by the lattice distortion due to ordering. Finally, comparing with the alloy Cu_3Au, the change in resistivity due to ordering was discussed in connection with the result of X-ray study.

§ 1. Introduction

According to the statistical theories of order-disorder phenomena in binary alloys, one can expect three superlattices at the compositions of the atomic ratios 3:1, 1:1 and 1:3 for alloys of a face-centered cubic structure forming an isomorphous series in the disordered solid solutions. The copper-gold alloy is a representative of such alloys. In addition to the superlattices Cu_3Au and CuAu, which have been investigated in detail since the earliest works on the order-disorder transition in alloys, the superlattice at the composition 1 Cu and 3 Au was confirmed by X-ray diffraction and measurements of several physical properties1) as well as by electron diffraction2). For the alloy $CuAu_3$, it was previously reported that the electrical resistivity increases as the ordering proceeds below the transition point1), but the residual resistance of the highly ordered state is slightly lower than that of the disordered one3),4). On the other hand, for the alloy Cu_3Au, as well known, the ordered state possesses a remarkably lower resistivity than that of the disordered state. It was recently found5), however, that the resistivity of Cu_3Au increases during the initial process of ordering immediately below the transition point, and suggested that such increase may be due to the formation of small ordered nuclei. Since there seems an analogy with regard to the electrical resistivity between $CuAu_3$ and Cu_3Au, we attempted to clarify the correlation between the resistometric and structural change due to ordering of $CuAu_3$.

In the course of the present work, two papers concerning with $CuAu_3$ were published by Wright and Goddard6) and by Batterman7). Wright and Goddard found that the resistivity of $CuAu_3$ increases initially and then decreases slowly during isothermal annealing at 167°C, and supposed that the presence of small ordered domains may be attributed to the resistivity increase. Batterman made an X-ray work in order to determine the degree of order as well as the transition point of this alloy, and found the presence of anti-phase domains of size about 50 A in the well annealed state. These works are closely related to the present paper, so that they will be often refered later. In this paper, we will show the results of isothermal measurement of resistivity and X-ray diffraction study using a single crystal of $CuAu_3$, and then show the presence of anti-phase ordered domains as well as its contribution to the anomalous resistivity.

§ 2. Experimental Procedures

The $CuAu_3$ alloy was prepared by melting together weighed amounts of electrolytic copper (99.9%) and gold (99.99%). Chemical analysis showed the composition to be 75.0_6 atomic per cent gold, which agreed well with the result obtained by X-ray measurement of the lattice parameter in the disordered state, as will be given later. The ingot, about 4 gr in weight, was homogenized for several hours at 850°C in vacuum, and then in part swaged and drawn into wire of about 0.4 mm in diameter. A single crystal was grown from the residual ingot in a thin ceramic tube by means of the Tammann-Bridgman method in vacuum. Both the wire and the single crystal were again annealed at 750°C for several hours. In all cases, to attain the disordered state, the specimens sealed in evacuated glass tubes were heated at 450°C for two hours, and then quenched into ice water. The isothermal annealing was done in either vacuum or an oil bath.

The electrical resistivity was measured by the potentiometric method. The leads were spot-welded to the wire of about 8 cm in length. This specimen had been used to measure the resistivity at low temperatures[4].

All X-ray diffraction patterns were taken by Cu $K\alpha$ radiation. The diameter of the single crystal was reduced to about 0.2 mm by etching in aqua regia. At each stage of ordering the crystal was mounted on an X-ray goniometer with either the [001] or the [$\bar{1}$10] direction set accurately along the axis of rotation. Then stationary and oscillation photographs were taken, using cylindrical film cassettes of 10 and 7 cm in diameter. A 114.6 mm Debye-Scherrer camera was also used to determine the lattice parameters in both the annealed and the quenched states.

§ 3. Experimental Results

(A) *Electrical resistivity*

The electrical resistivity of the alloy quenched from 450°C was measured during isothermal annealing at various temperatures from 100° to 220°C. Typical results are shown in Fig. 1, where the change of the specific resistivity is plotted for the initial period of annealing. A monotonous increase in resistivity takes place at each temperature. However, by successive measurements at 162° and

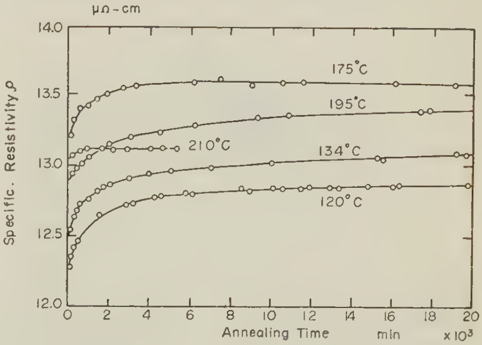

Fig. 1. Specific resistivity as a function of annealing time at various temperatures.

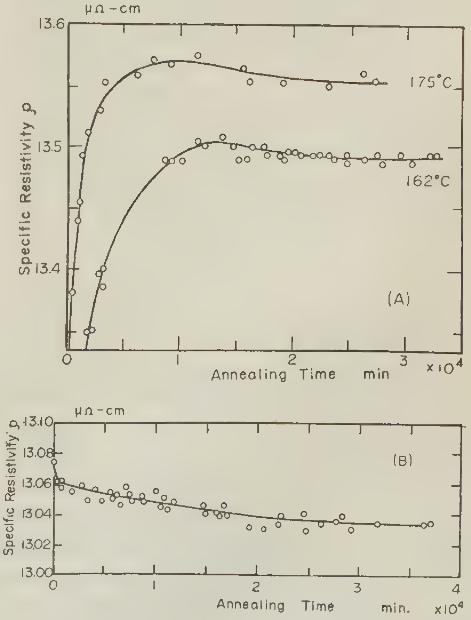

Fig. 2. Specific resistivity plotted against annealing time at 162° and 175°C (A), and at 100°C (B). In the latter, the specimen was previously annealed at 162°C for 3.5×10^4 min.

175°C, it was found that the resistivity decreased gradually over the maximum near 1×10^4 min, as shown in Fig. 2 (A). Furthermore, at 100°C annealing following 162°C annealing of 3.5×10^4 min, the resistivity decreased with increasing time of annealing as shown in Fig. 2 (B), though even after 3.5×10^4 min at 100°C the decrement was only about 0.2% of the initial value. Accordingly it is reasonably suggested that the ordering reaction of this alloy proceeds through a multistage rather than a single-stage process.

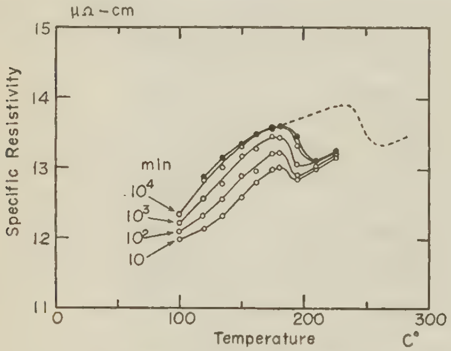

Fig. 3. Isochronous curves of resistivity against temperature. Each closed circle shows the resistivity finally reached at each temperature, and a dotted line shows a curve obtained when the specimen was reheated from 180°C at a rate of about 2 deg/min.

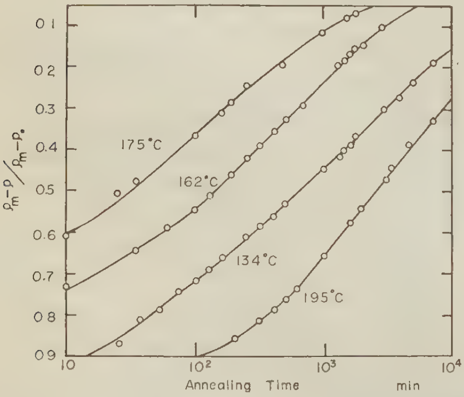

Fig. 4. $\rho_m-\rho/\rho_m-\rho_0$ plotted against annealing time.

Fig. 3 shows the specific resistivity at the annealing times 10, 10^2, 10^3 and 10^4 minutes, in addition to terminal value finally reached at each temperature. The transition temperature is determined as 200±5°C from the maximum negative temperature coefficient of the resistivity corresponding to the finally reached states, which may approximately be thought as thermal equilibrium. The increase in resistivity at 210° and 220°C is probably due to the formation of the short range order. If the alloy is heated at the rate of about 2 deg/min, after the resistivity has reached the maximum at 180°C, the transition from order to disorder occurs near 240°C, as depicted by the dotted line in Fig. 3. This fact agrees well with our previous report[1)], and the heating curve is entirely different from thermal equilibrium since the heating rate is too large to maintain the equilibrium state.

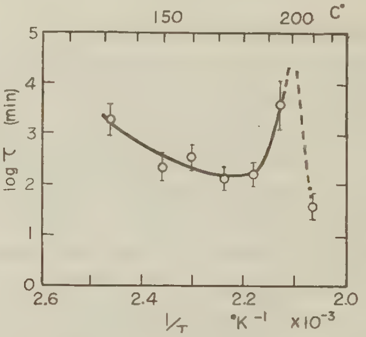

Fig. 5. Relaxation time $\log\tau$ *versus* reciprocal temperature $1/T$.

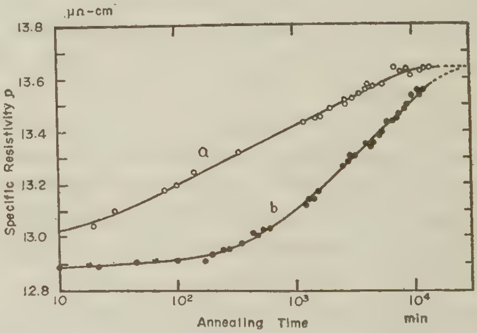

Fig. 6. Resistivity change at 180°C annealing. The meaning of curves (a) and (b) is stated in the text.

Next, in order to obtain an activation energy in the first stage of ordering process, the function $\rho_m-\rho/\rho_m-\rho_0$ was plotted against $\log t$. Here ρ_m and ρ_0 are the maximum and initial resistivity respectively, and t is the annealing time. Typical curves of this function are given in Fig. 4, from which one may obtain the relaxation time τ at each temperature. In Fig. 5 the values of $\log\tau$ are plotted as a function of the reciprocal of the absolute temperatures. The value τ corresponding to the first stage of ordering is appreciably longer than that of Cu_3Au[8], and one may expect much longer value of τ for the second stage of ordering, which corresponds to the decreasing resistivity. If the ordering of atoms is a diffusion process, the relaxation time should approximately satisfy the equation, $\tau=\tau_0\exp(-W/kT)$, where τ_0 is a constant, W the activation energy necessary for ordering and T the absolute temperature. Thus the activation energy 25±2 Kcal/mol is evaluated from the slope of the curve in the temperature range below 165°C. It appears from Fig. 5 that the transition rate is highest around 180°C and is rather lower near the critical temperature. Such a behavior was already reported for other ordered alloys, such as Cu_3Au[8] and CuAu[9], and coincides with the theoretical predictions[10].

Fig. 6 shows the change in specific resistivity at 180°C plotted against annealing time. Curves (a) and (b), marked with open and closed circles, correspond to ordering processes immediately after quenching from 450°C to ice water and immediately after annealing at 210°C for 30 hr, respectively. Here it is noted that the initial ordering rate of the alloy quenched from the higher temperature is higher than that of the alloy having fairly high degree of short range order.

(B) *X-ray diffraction study*

(1) Polycrystalline specimen

The polycrystalline specimen was used to determine the lattice parameteres in both the ordered and disordered states and also to detect the superstructure lines. The lattice constants of the alloy quenched from 450°C and annealed at about 150°C for four months were 3.9764 and 3.9730 kX respectively, which were determined by means of the Nelson-Riley graphical-extrapolation method using Cu $K\alpha$ radiation*. Accordingly the linear contraction due to ordering is about 0.085%, which agrees well with the dilatometric study[1]. Many superlattice lines were clearly observed on the powder pattern of the highly ordered alloy, as shown in Photo. 1. Here it should be pointed out that the line breadths of the superlattice reflections vary with their indices. This photograph was taken by using a LiF monochromator and a 90 mm-camera of Burger-type, in which the film was tightly held against the inner cylindrical surface.

(2) Single crystal specimen

After the single crystal was quenched from 450°C into ice water and was annealed at 100°, 150°, 180° and 210°C for various durations, X-ray diffraction photographs were taken of the superlattice reflections and of the diffuse scattering around the main lattice reflections. At first the series of 180°C annealing after quenching from 450°C will be described. In this course the diffraction patterns were taken at each stage of annealing for 30 min, 100 min, 5 hr, 10 hr, 37 hr, 108 hr, 219 hr and one month. After keeping for 30 min at this temperature, any superlattice reflections could not yet be observed. They became faintly visible from the stage of 100 min annealing and grew intense with time of annealing. Photos. 2 and 3 show examples of superlattice reflections at the annealing states for 5 and 10 hr, respectively. In Photo. 2 two superlattice reflections appear very faintly and broad, while in Photo. 3 one can clearly see the cross-like spot of the 210 reflection. After 37 hr annealing at this temperature, such cross-like superlattice reflections became more definite, as shown in Photo. 4 (A) and (B). The former corresponds to the sections passing through such superlattice spots as 100, 110 and 221 in reciprocal space, and the latter corresponds to a series of the successive sections passing through 001, 012, 123 and 223. The diffuse scatterings around the main lattice spots 113 and 133 are observed in these photographs. Similar diffraction patterns were obtained in both the states of 108 and 219 hr annealing.

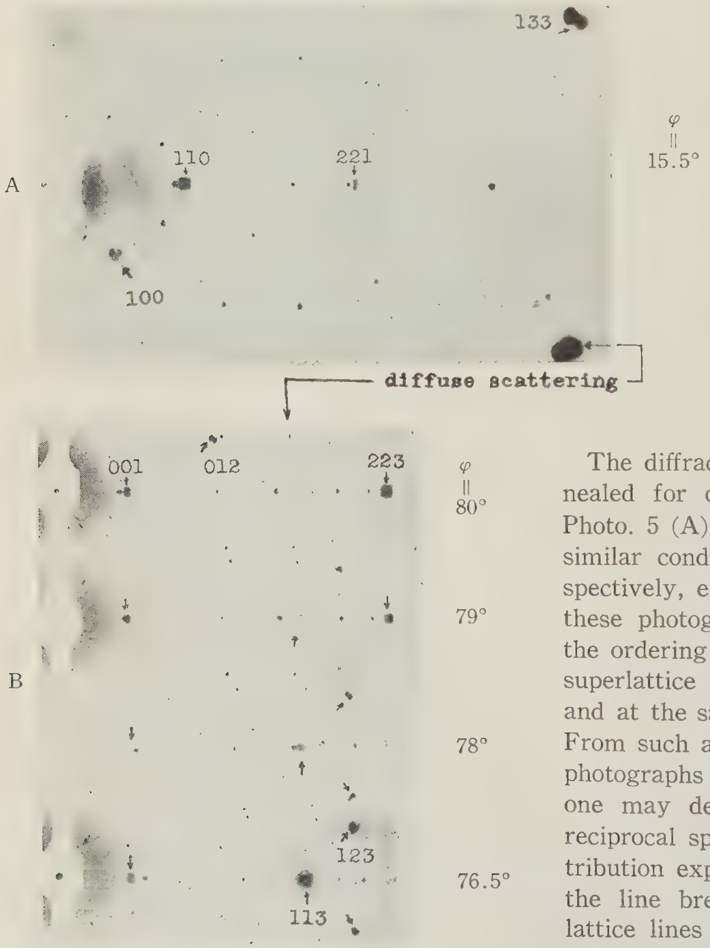

Photo. 4 (A) and (B). Stationary crystal photographs of CuAu$_3$ annealed for 37 hr at 180°C. [$\bar{1}$10] is vertical. In addition to many superlattice reflections, main lattice reflections surrounded by diffuse scattering are observed.

The diffraction patterns of the crystal annealed for one month at 180°C are given in Photo. 5 (A) and (B), which are taken under similar conditions to Photos. 4 (A) and 3 respectively, except annealing durations. From these photographs, it will be noticed that, as the ordering advances, the splitting points of superlattice reflections approach each other and at the same time their intensity increases. From such a number of successive stationary photographs for many superlattice reflections, one may deduce the intensity distribution in reciprocal space as given in Fig. 7. This distribution explains reasonably the variation of the line breadth with indices of the superlattice lines seen in Photo. 1. From Fig. 7 it is suggested that the highly ordered alloy CuAu$_3$ has such an anti-phase domain structure as observed in the partially ordered state of Cu$_3$Au[11,12], or in the ordered alloy Ag$_3$Mg[13,14], Cu$_3$Pd[13,15] and others. The size of anti-phase domain, which can be determined from the separation of splitting superlattice reflections, increases with time of annealing. The result is given in Fig. 8. After one month annealing at 180°C, the domain size reaches about 11 times the lattice constant. Comparing Fig. 8 with the curve (a) in Fig. 6, one can find fairly good correspondence between the increase in the domain size and that in the electrical resistivity.

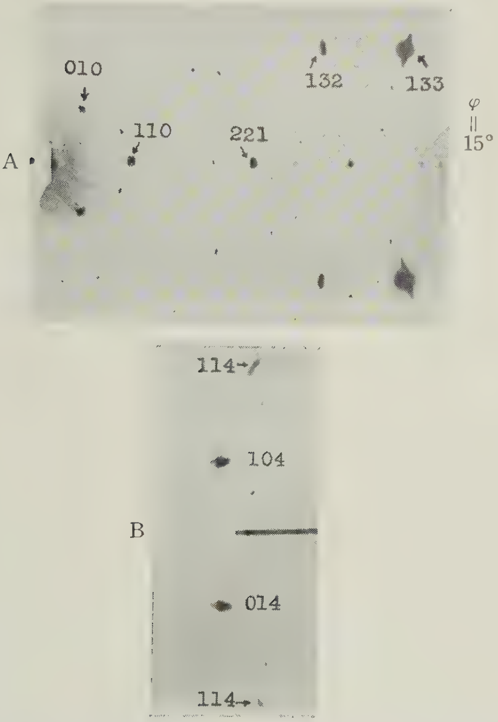

Photo. 5 (A) and (B). Stationary and oscillation photographs of $CuAu_3$ annealed for one month at 180°C. $[\bar{1}10]$ is vertical.

X-ray photographs were also taken at various annealing states between 2 hr and 45 days at 150°C after being quenched from 450°C. In the diffraction patterns the general appearance seems almost similar to that at 180°C annealing mentioned above. The superlattice reflections begin to appear from about 5 hr annealing, and the diffuse scattering surrounding the main lattice reflections is observed from the initial period of annealing. Even after 45 days annealing, however, the splitting superlattice spots are comparatively broad, and on the average the size of anti-phase domains is nearly 10 times the fundamental cell.

After the alloy was annealed for one month at 180°C, it was subsequently heated at 100°C, in order to examine how far this heating affected the ordered structure, because the resistivity decreases continuously during a similar heat treatment as shown in Fig. 2 (B). Photo. 6 gives the diffraction patterns of the alloy annealed for two months at 100°C. The

separation of splitting superlattice reflections does not change from the stage reached after one month annealing at 180°C, but the intensity of them becomes stronger. It means that in this course the domain growth takes little place but the degree of order within the domains increases. Here it is noticeable that the diffuse scattering around the main lattice points such as 133 and 224 remains with considerably large intensity, and, especially that, the anomaly of intensity is seen in 221 as well as in 321 in Photo. 6 (C). The former reflection seems to consist of a pair of splits, and the component in the side of lower diffraction angle is fairly weaker than that in the side of higher angle. The latter consists of two pairs of splits, and the components in the side of lower angle are also weaker than those in the side of higher angle. From the microphotometry of 321 reflection in this photograph, it was found that each component of lower angle side had only almost half the intensity of that of higher angle side. Such an asymmetry in intensity is also seen in Photo. 5 (B). But it appears to increase with the advance of ordering at 100°C. The discussion on this fact will be given in the following section.

The diffuse scattering around the main lattice reflections was examined in detail in the short-range ordered state quenched from 210°C after keeping for 30 hr. In this stage the main lattice reflections were certainly surrounded by the diffuse scattering, while very diffuse super-

ing kinetics[18]. In terms of this effect it is reasonably interpreted that the ordering rate varies appreciably, even at the same temperature of annealing, by the initial condition with or without local order as shown in Fig. 6.

The present X-ray diffraction study in the course of annealing at 150° and 180°C shows that the development of order is made not through homogeneous increase in short-range order throughout the crystal, but essentially through a nucleation and growth of small ordered domains in the disordered lattice. From Figs. 6 and 8, it is conclusively said that the growth of the anti-phase domains takes place in the first stage of ordering, where the resistivity increases. At the early period of this stage only a few domains exist in the lattice, while prolonged annealing causes a large number of domains with a fairly definite size of about 44 A to occur. In the second stage of ordering, corresponding to the decrease in resistivity, the domain growth takes little place but the degree of order within domains increases progressively.

Now we shall consider the increase in resistivity at the initial stage of the ordering process in the light of the present X-ray diffraction study. Such inverse change of resistivity is not so unusual but is already found in such ordered alloys as Cu_3Au[5], Cu_3Pd[19] and Ag_3Mg[14], all of which form anti-phase domain structures. Rise in resistivity of these alloys has been qualitatively explained by the presence of anti-phase ordered nuclei, of which the linear dimension is smaller than the mean free path of conduction electrons. The latter is given in monovalent metals by the formula $\lambda = h/\rho e^2(3/\pi N^2)^{1/3}$, where ρ is the specific resistivity, e the electronic charge and N the number of conduction electrons per unit volume[20]. Assuming that there is one conduction electron per atom for $CuAu_3$, the value of λ is about 100 A for the annealing state at 180°C. This value is larger than the size of the anti-phase domain, 44 A, existing at 180°C, so that such domains may act as scattering centers for electrons. Therefore, as the ordering proceeds, the inhomogeneity enhanced by the formation of small anti-phase domains induces the increase in resistivity, but the growth of domains intends to decrease the resistivity. Thus the rise of resistivity in the initial stage of ordering is probably caused by the fact that the effect of formation of domain boundaries overcomes that of domain growth. Formation and growth of domains is stopped when the lattice is closely filled with domains, and then the subsequent reduction of resistivity is reasonably thought to be produced with the development of order in the domains. Successive coalescence of the anti-phase domains, which may likewise induce the decrease of resistivity, is not observed in the present X-ray study of the isothermal ordering.

Next we shall discuss the superstructure of the ordered alloy $CuAu_3$. Even at the final state of annealing above 100°C, $CuAu_3$ possesses the anti-phase domain structure with about 44 A in length, which accords well with the value estimated by Batterman[7]. At the present time, as described above, we know a number of the ordered alloys of A_3B type with various anti-phase domain structures, i.e. as the one-dimensional anti-phase domain Ag_3Mg[13),14], Au_3Cd[13], Au_3Zn[21] and so on, and as the two-dimensional one Cu_3Pd[15], Au_4Zn[21] and Au_3Mn[22]. From the intensity distribution of superlattice reflections in reciprocal space given in Fig. 7, it is probable that the highly ordered state of $CuAu_3$ has the two-dimensional anti-phase domain structure rather than the one-dimensional one. The reason is given in the following. If the latter would be the case, every original superlattice spot should be flanked by four satellites in reciprocal space. On the other hand, if the former would be the case, the central spot at every superlattice reflection position should vanish leaving only satellites, because the central spot would also be split, as previously reported in our paper[15]. In the highly ordered state of $CuAu_3$, the central spot of every superlattice reflection position is hardly observable or much weaker than the satellite splits as shown in many photographs*. It is not clear from the diffraction patterns to which satellites the central spot is split and what kind of two-dimensional domain is realized, but any other origin than described above can hardly be conceivable for the vanishment of the central spot. It remains unsolved whether such an anti-phase domain structure exists in the stable state as in several ordered alloys mentioned above or in the intermediate one as in Cu_3Au[11),12)], because it takes extremely long duration to attain the ordered state in an equilibrium below the transition point as low as 200°C. In order to answer this question, however, it seems necessary to obtain a more highly ordered state of the alloy by any other means than a prolonged heating, e.g. by irradiation of high energy particles. It is of some interest to note, here, that the anti-phase domain in $CuAu_3$ has, roughly speaking, similar size to that in Cu_3Au. The latter sizes are 7, 10~11 and 18~19 times the fundamental face-centered cubic cell at 300°, 320° and 330°C, respectively[12)].

---

* The superlattice reflections of Cu_3Au reported in the references 11) and 12) also seem to show the disappearance of the central spot of superlattice reflection similarly to the present patterns of $CuAu_3$.

The remarkably asymmetrical intensity of splitting superlattice reflections seems somewhat complicated but is interesting*. Some possible explanations may be considered. One of them is the effect of diffuse intensity due to difference in size of the component atoms in alloys proposed by Warren, Averbach and Roberts[23)]. This effect has actually been observed in the short-range ordered state of $CuAu_3$[7)] as well as of Cu_3Au[23)] and CuAu[24)]. It is hardly expected, however, that the contribution of the size effect gives rise to highly asymmetrical intensities of splits in superlattice reflections, as these splits are very close to each other. An alternative explanation of this phenomenon is probable on the analogy of X-ray pattern observed in precipitation process of an Al-Cu alloy[25)]. X-ray diffraction photographs of the alloy containing 4 weight per cent copper showed diffuse streaks emerging from diffraction spot on one side only. It was qualitatively explained[26)] by a combination of varying lattice parameter and varying structure amplitude owing to the segregation of solute copper atoms on to particular atmic planes in the matrix. The asymmetrical splittings shown in the present X-ray photographs of $CuAu_3$ may be interpreted in the same way. It may reasonably be supposed in the anti-phase domain structure of this alloy that out-of-step boundaries differ in the lattice spacing as well as in the structure amplitude from the inside of domains. Therefore the spacing and the structure amplitude vary periodically with the same period as that of out-of-step. If both of the modulations synchronize in such a way that the maximum spacing coincides with the minimum structure amplitude, the split spot of the superlattice reflection on the lower diffraction angle side becomes weaker than that on the opposite side. Of course, this is only a qualitative explanation, and the knowledge on amplitudes of both of the modulations is necessary to explain this phenomenon quantitatively.

Finally the diffuse scattering will be discussed. The characteristic diffuse streaks, which are directed along ⟨110⟩ directions, have also been observed in early stages of ordering in CoPt[27)] and CuAu[28)], and in these cases qualitatively explained by the lattice distortion associated with the ordering process. The fact that the unit cells of both the ordered and disordered structures of these alloys differ considerably from each other in the crystal symmetry as well as in the lattice spacing has been considered to be a main cause of such a lattice distortion. In $CuAu_3$, however, the circumstances are not the same, i.e. no change in the crystal symmetry takes place and the change in the lattice spacing is far less than in these alloys. Therefore, the diffuse diffraction due to a lattice distortion could not be expected in the present case. In fact, it was concluded from the low temperature diffraction patterns that the diffuse diffraction observed in $CuAu_3$ is caused by the thermal scattering. This conclusion is also supported by the considerably low Debye temperature[29)] and the diffuse intensity distribution in reciprocal space shown in Fig. 9. The diffuse diffractions in this figure have the same sectional shapes of equal diffusion surfaces caused by thermal vibration of certain cubic crystals with the elastic anisotropic factor $2c_{44}/c_{11}-c_{12}$ of more than unity.

In conclusion the author wishes to express his sincere thanks to Professor S. Ogawa for his kind guidance throughout the work. His thanks are also due to Mr. D. Watanabe for his valuable discussions, and to Mr. K. Fujiwara for his helpful assistance in measurement of the resistivity. This work was supported in part by the fund of the Ministry of Education in Aid of Scientific Researches.

---

* Such a phenomenon has been pointed out in Cu_3Pd by Wilkens and Schubert[21)].

Electrical Resistivity of Arc-evaporated Carbon Film

By Hiroo TOYODA,

Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation,

and Masahisa NAGASHIMA

Faculty of Technology, Waseda University

(Received November 14, 1958)

The electrical resistivities of arc-evaporated carbon films were studied. The resistance has a large negative temperature coefficient. The annealing diminishes remarkably both the resistance and its temperature dependency. The specific resistivity depends on the film thickness and increases rapidly below 500Å. It seems that the lattice imperfections play the most important role, and then from the annealing curve, their distributions are discussed. The aging effect on the resistance were also measured.

§1. Introduction

Several years ago, Bradley has invented an useful method of preparing the relica for electron microscope by arc-evaporated carbon film1). The evaporated film has a very amorphous structure and therefore can reproduce a faithful replica of the specimen. Since his invention, this technique became one of the most important and usual methods for electron microscopy2), but the various properties of the carbon film were not fully studied. Blue and Danielson3) have measured its electrical resistivities, while Agar4) and Cosslett5) have studied the relation between the optical densities and the film thickness. Kakinoki et al.6) have studied the structure by electron diffraction and discussed its singularity.

Carbon films are produced under several conditions, for example, thermal decomposition of organic compounds (pyrolytic carbon)7)–10), painting with colloidal carbon11), decomposition from carbon brush12), and so on. But, in most cases, these products lack the uniformity or contain some volatile matters, whose driving-off requires the heat-treatment at higher temperature. On the contrary, the arc-evaporated carbon film has a uniform thickness and homogeneous composition over the whole area, and furthermore, the evaporation can be made on substrates maintained at desired temperature, hence making possible to study the annealing of lattice imperfections in carbon.

As consequences of measuring the properties of the film, believed as the most amorphous carbonaceous solids, we have obtained some interesting results about the aging effects of electrical resistances, the relation between the conductivities or their temperature coefficients and the film thickness, and the annealing effects on them.

§2. Experimental Methods

Carbon rod for carbon replica, 0.5 cm in diameter, of Tokai Electrode Co. was used as the evaporating material. The sharpening contact was heated by alternating current. The substrates were photographic glass plate or transparent fused quartz, 0.5 cm × 1.5 cm in sizes. These substrates were arranged in a bell-jar, about 12 cm apart from the carbon source. The vacuum was maintained below 10^{-4} mmHg and the evaporating are was about 50Å/sec.

The film thickness was measured by a multiple-beam-interferometer13) using the light of 5461Å of Hg lamp. We measured also the optical density against the incandescent tungsten light by a microphotometer.

Gold film electrodes were evaporated on the carbon film at the two ends, leaving the naked carbon film 0.5 cm in breadth and 1 cm in length. The electrical resistance was measured potentiometrically or by micro-micro-ammeter under vacuum or in argon or air. In the case of glass substrates, the annealing was achieved under 400°C, while the quratz substrates were heated to 900°C in various atmospheres.

§ 3. Results

Optical densities were defined as $D = \log_{10}(I_0/I)$, where I is the light intensity transmitted through the film, while I_0 the one without film. If the films have the same absorption coefficient and the reflection at the surface is neglected, following relation should hold.

$$I = I_0 e^{-\alpha\tau},$$

where α is absorption coefficient and τ is thickness. I and I_0 were measured by a microphotometer.

There holds an approximately linear relation between the film thickness determined by multiple-beam-interferometer and the optical densities (Fig. 1). Cosslett has pointed out that the proportional constant has depended on the process of evaporation and that for thinner films than 200Å, the relation has deviated from the linearity. Thorn and Winslow[14)] have found two straight lines with different gradients according to the temperature of heated carbon source. Also in our cases, there exist some random variances from the straight line, but the relation is useful to deduce the thickness of thinner samples from its optical density, as it cannot be determined by the interferometry.

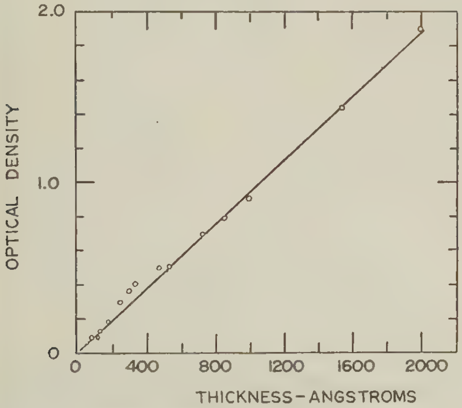

Fig. 1. Optical density versus film thickness.

Heat treatment of films always brings the optical density to increase. About 30 per cent increase was observed by 400°C annealing. The increase, however, is very small compared with the rise of electrical conductivities.

Though the coefficients of thermal expansion differ between glass and fused quartz about ten times, there is no difference between the temperature coefficients of electrical resistances of carbon films evaporated on both substrates. But when the thinner films were heated above 250°C, the carbon evaporated on glass was more easily annealed than the one on fused quartz. The annealing of carbon, 200Å thick, at 380°C brought 20 per cent difference of resistance between two substrates, though for the film thicker than 400Å this was not the case. The following results are concerned with quartz substrates.

Annealing was performed in atmospheres of argon or air of atmospheric pressure below 400°C, there being found no differences between them, and above it, the heat treatment in vacuum of 10^{-5} mmHg was used.

Fig. 2 shows an example of resistance change with temperature and annealing effects on it. The annealing begins at once above the evaporated temperature and brings a rapid decrease of resistance. Below the annealing temperature, the resistance changes with temperature reversibly. The curves of $\log R$ versus $1/T$ are concave downwards for all specimens and for all temperature ranges. As it is, however, known that the expression $R = R_\infty \exp(\Delta E/2kT)$ holds for carbonace-

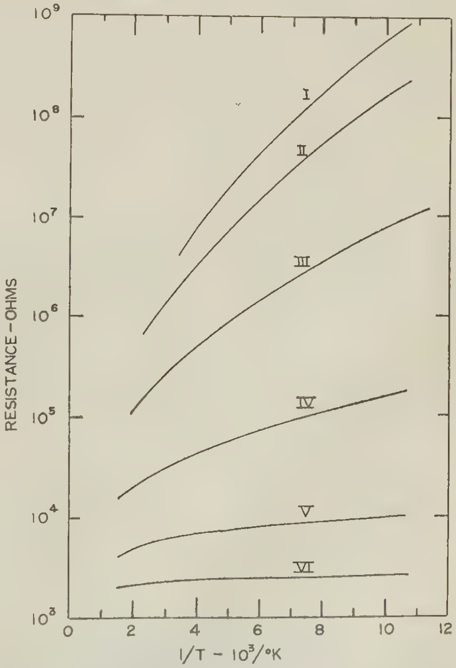

Fig. 2. Temperature dependence and annealing effect of resistance. Thickness is 380 Å. Annealing temperature: I, Unannealed; II, 140°C; III, 245°C; IV, 380°C; V, 500°C; VI, 900°C.

ous solids having the conjugate double bond[15)-17)], we will adopt this representation frequently. Fig. 2 suggests that ΔE for each film is not a constant, but it may have a continuous distribution over a certain region.

Blue pointed out that the curve of $\log R$ versus $\log T$ was linear and we also found it true, namely, $R=aT^{-b}$. b decreases with the film thickness and the annealing temperaperature. We have found $b=9$ for the 100Å film without annealing.

The thicker becomes the film, the less rapidly the resistance changes with temperature in the reversible region, while the more easily the annealing takes place. In Fig. 3, one can see the dependence of annealing effect on the film thickness. It shows the specific resistivity changes at 0°C accompanied with annealing.

The electrical resistivities at 0°C of the unannealed films change with film thickness. Below 500Å, the specific resistivity increases rapidly with the decrease in thickness. Above 500Å, it is almost constant and equals to 0.5 to 1 ohm-cm (Fig. 4).

Though the relation $R=R_\infty \exp(\Delta E/2kT)$ does not strictly hold, we have calculated the energy gap ΔE as an indicator of temperature coefficient, combining the value at

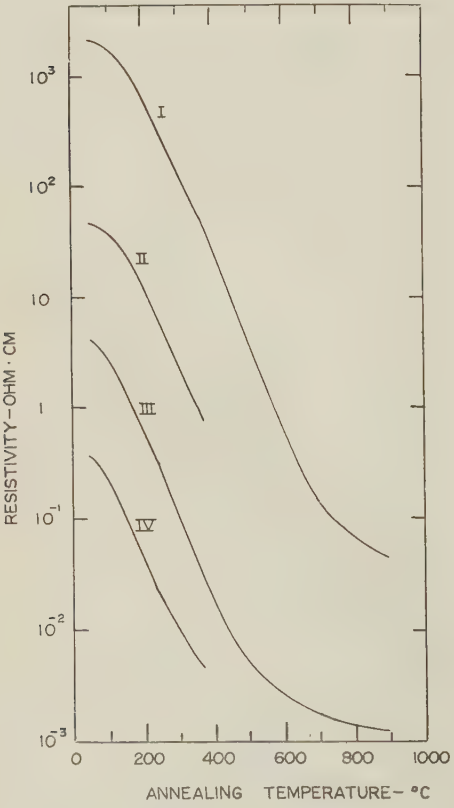

Fig. 3. Annealing effects on the specific resistivity at 0°C, for four films. Thickness: I, 110 Å; II, 200 Å; III, 380 Å; IV, 2000 Å.

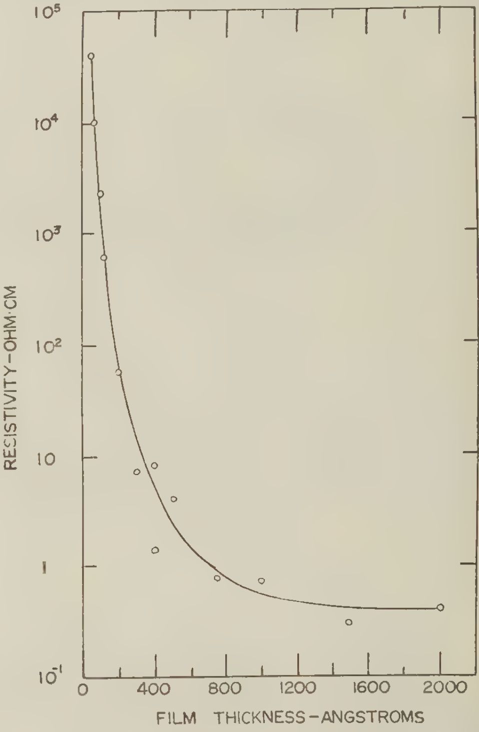

Fig. 4. Specific resistivity at 0°C versus film thickness.

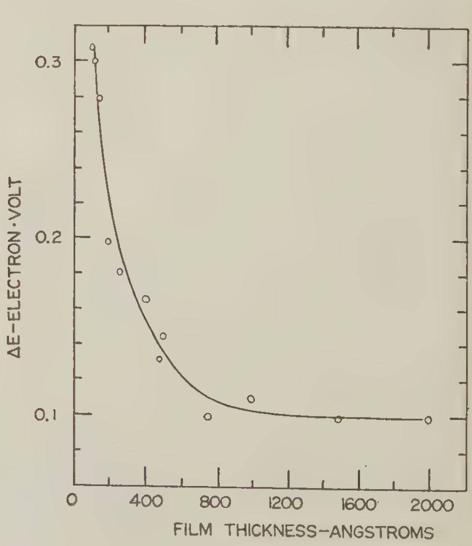

Fig. 5. ΔE versus film thickness. ΔE is calculated from the straight line combining the values at 0° and −73°C in Fig. 2.

−73°C with the value at 0°C by a straight line. ΔE depends also on the film thickness and is larger for thinner film. (Fig. 5) With the rise of annealing temperature, ΔE falls as well as resistivity (Fig. 6)

Fig. 7 shows the relation between the specific resistivity at 0°C and ΔE. It includes the values of ten films of different thickness ranging from 100 to 2000Å, unannealed and annealed at various temperatures under 900°C. There is a clear dependency, and in spite of different thickness or of annealing temperature, the carbon films of definite specific resistivity have the same temperature coefficient of resistivity. The result suggests the following fact; the carbon films with different thickness have different structures before annealing and the annealing rates for them are also different, but even though there are these varieties, when the specific resistivities become the same order, the carbon film have the resembling microscopic structure. It is, however, expected that this simple relation might not hold, when the thickness is extremely small.

In all experiments described above, the films were taken off after evaporation from the vacuum into the air and replaced in the resistance measuring vessel. The time exposed to the air was so long that the gas adsorption, if occurred, would reach the saturated state. Then, we intended to measure

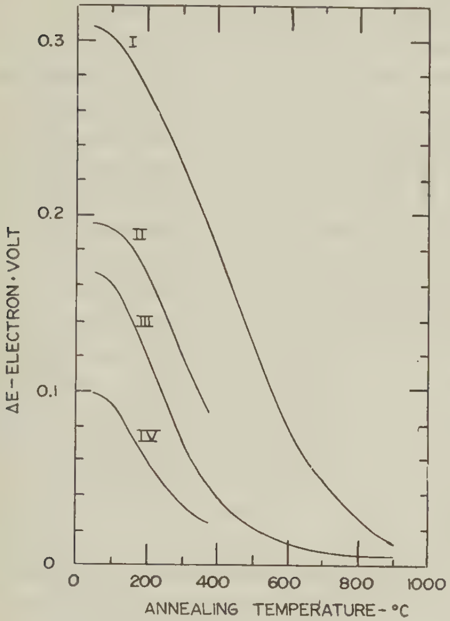

Fig. 6. Annealing effects on ΔE of four films. Thickness: I, 110 Å; II, 200 Å; III, 380 Å; IV, 2000 Å.

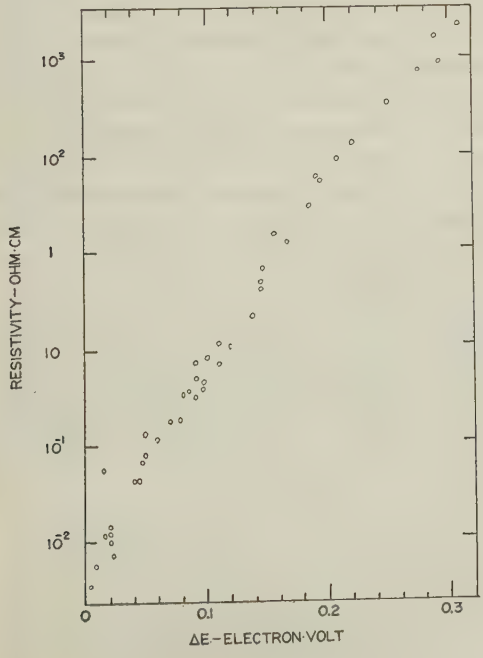

Fig. 7. Specific resistivity at 0°C versus ΔE.

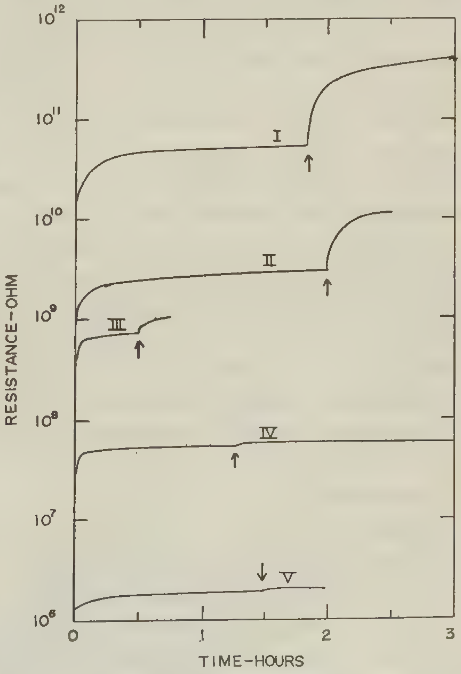

Fig. 8. Aging effects on resistance in vacuum and in air. Thickness: I, 40 Å; II, 50 Å; III, 80 Å; IV, 290 Å; V, 450 Å. Arrow shows the introduction of air of atomospheric pressure. Note; for I, full time scale is six hours.

the aging effect of resistance just after the evaporation.

Quartz substrates were preliminarily gold-evaporated at both ends, leaving bare space of $0.5\times0.5\,\mathrm{cm}^2$. D.C. 100 volt was given between the electrodes during and after the evaporation, and we observed the changes of electric resistances by micro-micro-ammeter. During the evaporation, the current indication could not be defined, presumably by disturbance of A.C. induction or ion current.

Fig. 8 shows the resistance variation after the deposition for several specimens of different thickness. Electric resistances for all films increased with time, and the smaller the thickness, the more remarkable the change. Though there seemed to be some differences according to the evaporation rate, they could not be made clear. Introduction of air brought further irreversible resistance increase for some thinner films.

The aging of silver or other metal film strongly depends on the evaporating condition and the thickness[18)-20)]. Aggregation makes the resistance higher, while the diffusion of Frenkel type doublet imperfections to the regular sites makes the resistance lower. For carbon film, however, the resistance always increases, more or less, whatever the thickness is. It is known that the evaporated carbon rather hardly aggregates in island, and our vacuum is not so good that it is inevitably influenced by oxygen. Furthermore, the irreversible increase after the air introduction suggests the possibility of oxidation. However, if the gas adsorption is a principal cause, it is questionable why the time constants of resistance increase are comparable for all thickness. There may be some effects of cooling of substrate after the evaporation and we are now clarifing them.

§ 4. Discussion

Carbonaceous solid is a general name for the extensive materials spreading over the range of aromatic compounds to graphite as two limiting cases. It is specified as having the π-electron network[21)-23)], and one can find a continuous characteristic change in the sequence, though the magnitude varies over some tens order. On the other hand, carbon atoms construct the tetravalent large crystal, namely, diamond. This has also some varieties in electric conduction and optical absorption or other properties[24,25], but these depend principally on the impurities or mosaic structure, in other words, on extrinsic causes[26)]. Kakinoki et al. have discussed the probable existence of diamond structure in carbon film, and if so, it might play some important roles in electric conduction. From the fact that the carbon film is black and subjected to the continuous annealing effect, we will, here exclude the contribution of diamond structure.

In organic compounds, when thermally decomposed, there develops progressively the π-electron network and carbonized materials become more and more conductive with the treatment temperature. The effective size of π-electron network determines the conduction electron density and the forbidden energy gap[27)]. It is not equal to the crystallite size, but depends on lattice imperfections, volatile impurities, and the electronic configuration on the periphery carbon atoms. The last one serves as surface acceptor level in some cases[28)]. The carbon film has as large number of lattice imperfections as other evaporated metals. These imperfections not only play the role of scattering for conduction, but also destroy the π-electron network and so diminish the effective size.

Vand has given a good analyzing method to investigate the decay of scattering centers[29)], and it is effective for studing the resistance annealing of neutron-irradiated polycrystalline graphite[30)]. For the carbon film which has very small crystallites, one can not, however, apply Vand's method in its original form. Vand's thought are as following; lattice defects decay in mutually independent process and the rate of decay is expressed by a relation,

$$dN/N=-c\cdot\exp(-\mathcal{E}/kT)\cdot dt,$$

where N is number of defects, c is a frequency factor, and $\mathcal{E}$ is a decay activation energy. Using an appropriate approximation, he has found a distribution of defects as function of $\mathcal{E}$. For materials with larger crystallites, one can put

$$R_i=R-TdR_T/dT=\int_{-\infty}^{\infty} r(\mathcal{E})\cdot N(\mathcal{E})\cdot d\mathcal{E},$$

where R: total resistance,

R_T: resistance caused by thermal oscillation of lattice,

R_i: resistance caused by lattice imperfections.

From the annealing curve, one can not obtain $r(\mathcal{E})$ and $N(\mathcal{E})$ separately, but their product.

For the carbon film, it is obvious that R_i is not proportional to the number of imperfections, but we have assumed that ΔE might be proportional to N. The assumption is not strictly well-founded. It is, however, well known that the forbidden band energy gap become progressively small in the sequence from aromatic compound to graphite with the increase of crystallite size. If ΔE is proportional to N, it turns into the assumption, from the relation seen in Fig. 7, that N would be proportional to $\log R$. Several years ago, we have studied the oxidation effect on the carbon contact resistance. Oxidation increases the resistance considerably and also augments the adsorption power of alkali$^{31),32)}$. adsorption gives the activity of carbon, which is considered as singularity of electronic configuration on the peryphery carbon atom. As a result, we have found that the adsorption was proportional to the logarithm of contact resistance. Though the two cases are not always parallel, linear dependency of ΔE on N is one of the simplest and probable thoughts.

Blue has found that there happened no development of long-range-order in the film by the annealing below 900°C. And furthermore, from a correlation, as seen in Fig. 7, among all the thickness which we have measured, it is not unreasonable to apply a common model of same crystallite size to all the films.

According to these assumptions and using Vand's tempering method, we have calculated the function, $F_0(\mathcal{E})=\Delta e(\mathcal{E})\cdot N(\mathcal{E})$, which belongs to the imperfection distribution before annealing. Δe is the contribution to ΔE of one imperfection. Fig. 9 shows $F_0(\mathcal{E})$ for three thickness. The ordinate is in arbitrary unit, but the curves are normalized under the condition that

$$\int_{\mathcal{E}_0}^{\infty} \Delta e(\mathcal{E}) N(\mathcal{E}) d\mathcal{E}$$

is proportional to ΔE. $\mathcal{E}_0$ corresponds to the evaporated temperature and the appropriate forms are assumed for the curves above the highest annealing temperature. It is clear that when the film thickness becomes smaller the peak rises and the distribution spreads over the wider region of activation energy. The distributions are not so different from the one for displaced atoms in neutron-irradiated polycrystalline graphite, but somewhat shift to higher energy.

When annealed at 900°C, the specific resistivities of films reach the same order as the carbonized organic compounds. Accordingly, the evaporated carbon has enormous number of lattice imperfections and the annealing brings them into regular sites without much larger crystallite growth. Extinction of imperfections increases the effective size of π-electron system and diminishes ΔE and the resistivity.

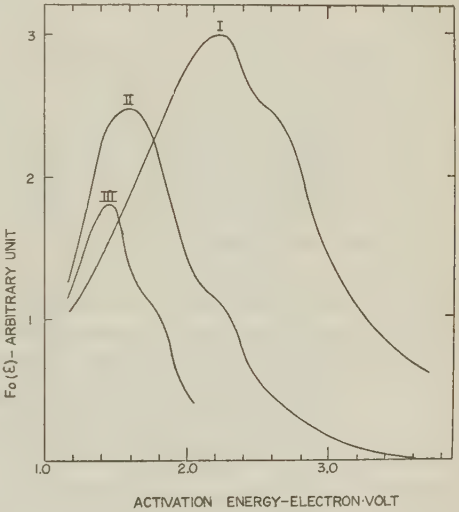

Fig. 9. $F_0(\varepsilon)=\Delta e(\varepsilon)\ N(\varepsilon)$ for three films. Thickness: I, 110 Å; II, 380 Å; III, 2000 Å. Though the ordinate is in arbitrary unit, the curves, drawn as $\int_{\varepsilon_0}^{\infty} F_0(\varepsilon)d\varepsilon \propto \Delta E$, are mutually comparable. If Δe (contribution of one imperfection) is independent of ε, the curves show the distribution of the number of imperfections, except unknown proportional constant.

It is not clear why the resistance increases irreversibly at room temperature after the evaporation. In the research of carbon contact resistance, which is sensitive to the surface gas adsorption, author* has found that in some cases there happened a reversible adsorption effect of oxygen on resistance$^{32)}$. Uebersfeld and Erb^{32} have observed the reversible effect of oxygen on paramagnetic resonance absorption. These may be explained as an interaction between the free radical on the peryphery carbon atom and oxygen. For polycrystalline graphite, it was reported that an irreversible oxidation at elevated temperatures becomes fast, when neutron-irradiated, the effect being caused by displaced atoms$^{34)}$. One can expect that the evaporated carbon, containing many imperfections, is apt to be influenced by gas adsorption, but it is a problem left hereafter to clarify the whole mechanism.

§ 5. Summary

The results are summarized as following.

1) Arc-evaporated carbon films have much higher resistivities than the orther carbon materials, in spite of their large carbon contents.

2) Resistivity depends on film thickness. It is equal to a nearly constant value as thickness exceeds 500Å, but it increases rapidly with decreasing film thickness below 500Å.

3) Themperature coefficient of resistivity is negative and depends on film thickness in a similar way as resistivity.

4) Annealing reduces the resistivity and its temperature dependency. Annealing rate becomes slow as the film thickness decreases.

5) For the films with various thickness from 100 to 2000Å and annealed at different temperatures up to 900°C, there holds an approximately linear correlation between ΔE and logarithm of resistivity. The relation seems to justify the application of a common structure model to all the films.

6) These special characteristics are considered to be attributed to the imperfections existing in the evaporated carbon. Lattice imperfections destroy π-electron network in carbon, and even if the films have the same crystallite size, the contents of imperfections bring about remarkable varietis of electric resistivity or its temperature coefficient.

7) Annealing displaces the imperfections into regular sites, and results in resistance and temperature dependency decrease. From the change of ΔE accompanied by annealing, distribution of imperfections as a function of decay activation energy is calculated. The distributions have maxima about at 1.5 to 2.1 eV, depending on film thickness.

8) As film thickness becomes extremely small, e.g., below 100Å, an effect of irreversible oxidation on resistance is observed.

We wish to thank Mr. H. Hirabayashi for his kindful advices and are grateful to Mr. H. Shibata and Miss T. Ayakawa for their co-operations.

Electrical Properties of Stannous Selenide

By Sizuo ASANABE*

Department of Physics, Faculty of Science,
Kyusyu University

(Received November, 22, 1958)

The electrical resistivity, Hall coefficient and thermoelectric power were investigated over the temperature range from 100°K to 800°K on pure and impurity-doped SnSe crystals. An anomalous hump of the Hall coefficient was found to occur at about 200°C in most of the as-grown crystals and this seems to make the conventional analysis based on a simple semiconductor model impossible. Anisotropies in the resistivity and Hall coefficient were also studied on single crystals and the observed anisotropy in the resistivity seems to be ascribed to an anisotropy in the effective mass of holes. Hole mobility varies as $T^{-2.0}$ at high temperatures and its discrepancy from $T^{-1.5}$ law is explained on the assumption of both optical and acoustical mode scatterings. Further investigation was made of the anomalous Hall coefficient on heating the specimen at various temperatures in vacuum. This anomalous phenomenon was found to depend on the heat-treatment history of the crystal and the experimental results were analysed on such a simple model that acceptors are introduced into SnSe by impurity diffusion above 200°C and caused to disappear on heating at lower temperatures. General features observed seem to be in fair agreement with the proposed model.

§ 1. Introduction

The systematic investigations have recently been made of IV–VI intermetallic compounds in our laboratory with respect to the electrical properties and crystal structures. The crystal structure of SnSe included in the same group has already been reported to be orthorhombic[1] and the preliminary experiments on electrical properties have shown that SnSe behaves as an ordinary *p*-type semiconductor[2]. The original aim of the present investigation was to obtain such physical quantities as the energy gap between the conduction band and valence band, its temperature dependence, the effective mass of electrons or holes, the ionization energy of impurity levels, etc. by performance of the further investigation on electrical properties of very pure SnSe single crystals. In the course of the experiment, we have encountered an anomalous phenomenon which might make the performance of our original aim impossible: the Hall coefficient exhibits an anomalous hump at about 200°C for most of the as-grown crystals as will be described later. According to a simple semiconductor model the Hall coefficient of a *p*-type semiconductor decreases with increasing temperature corresponding to the ionization of acceptors. After full ionization of the acceptors the Hall coefficient takes a constant value and then begins to decrease rapidly with the onset of intrinsic conduction. There should be no temperature range in which the Hall coefficient takes a positive temperature coefficient.

---

* Now at Research Laboratory, Nippon Electric Company Ltd., Kawasaki-shi, Japan.

The positive temperature coefficient of Hall coefficient found in Ge has been explained by impurity band conduction[3] or two hole model[4]. The Hall coefficients of p-type SnTe[5] and p-type GeTe[6] have also been found to take positive temperature coefficients and those of p-type GeSe[7], n-type InAs[8] and n-type GaAs[9] to show an anomalous behaviour. The mechanism is not yet fully understood, but in the case of n-type GaAs it is suggested that at 650°C a number of vacancies exist, possibly occupied by impurities, which trap electrons from the conduction band and give rise to a larger value of the Hall coefficient[10]. Our interests have transfered to the problem of studying some mechanism for the explanation of the observed anomalous behaviour for SnSe.

§ 2. Preparation of Specimens

In the earlier experiment[2] SnSe crystals were prepared in air from a melt containing larger amount of Se than in stoichiometric proportions which was covered with rock salt powder to protect from oxidization. This method is undesirable from such points of view that the obtained crystal might be affected considerably by oxygen, rock salt and excess selenium. All specimens used in the present investigation were prepared in vacuum as follows: the stoichiometric amounts of tin (J. M. 99.998% pure) and selenium (S. K. 99.999% pure) were sealed into an evacuated quartz tube. The inside of some quartz tubes was previously coated with thin carbon film in order to reduce oxygen diffusion, if any, from the wall of the tube into the SnSe melt. When the mixture of tin and selenium contained in the tube is heated to melt and then cooled to solidify, the tube is always forced to be broken and this results in the oxidization of SnSe by air. The unfavourable circumstance, however, may be avoided by a double-sealing technique: in spite of the break-up of the inner tube, the crystal is free from oxidization for the benefit of the outer tube. Putting the tube vertically into a furnace, where there is monotonously longitudinal and no transverse temperature gradient, it was kept at 1000°C for two days to expect the complete reaction. It was then cooled rapidly to 900°C and then with the cooling rate of 10°C per hour to 700°C (the melting point of SnSe=860°C). The melt begins to solidify from the bottom of the tube. In order to reduce such crystal imperfections as dislocations which might be present on solidification, the tube was annealed at 700°C for one day and cooled to 400°C with the speed of about 20°C per hour. The final stage of cooling process to room temperature was done by natural cooling after switching off the heater current. On cutting the obtained SnSe single crystal there must be paid a great care because of easy cleavage along the plane normal to c-axis. Specimens were cut in the shape of a rectangular parallelepiped of about $2\times 3\times 10\,\mathrm{mm}^3$ whose surfaces were polished by emery-paper. Some of the specimens used for anisotropy measurements were cut nearly in the shape of a cube whose edges were parallel to the three crystal axes.

§ 3. Experimental Procedures

An ordinary d.c. method was used on measuring the resistivity and Hall coefficient. Metallic electrodes were applied by means of vacuum evaporation of gold. Four constantan probes, the three on one surface and the rest on the opposite one, were welded by a condenser discharge method on a specimen set on a porcelain sample holder. The sample container was evacuated for low temperature measurements and was filled with nitrogen gas for high temperature measurements. In the course of low temperature measurement the sample container was immersed into a liquid air Dewar vessel between pole pieces of an electromagnet. High temperatures were realized by exchanging the Dewar vessel for a silica tube surrounded by a heating coil. The potential drop between a pair of resistivity probes was found to be linear with applied d.c. current up to 120 mA at both room and liquid air temperatures. Hall voltages at both temperatures were also shown to be a linear function of magnetic field strength up to 5 kilogauss which was measured using a search coil calibrated by a proton resonance technique. The d.c. current of 10 mA and magnetic field of 4 kilogauss were chosen for the most of the measurements. On measuring the potential difference between resistivity probes or Hall probes, we tried to eliminate the effect of the thermo-electromotive force which might be present, by reversing the direction of the current or the magnetic field.

So long as the resistivity and Hall coefficient are independent of magnetic field intensity, the galvano-magnetic effect can be expressed by the following equation[11]:

$$E_i=\rho_{ij}I_j+\varepsilon_{ijk}R_{km}I_jH_m\,, \tag{1}$$

where E_i, I_j and H_m represent, respectively, the rectangular components of the electric field, current density and magnetic field applied to a crystal. ρ_{ij} and R_{km} are the tensor quantities corresponding to the resistivity and Hall coefficient. In the case of SnSe which belongs to the space group D_{2h}, the above tensor components may be written in the form[12]

$$\rho_{ij}=\begin{bmatrix}\rho_{11} & 0 & 0\\ 0 & \rho_{22} & 0\\ 0 & 0 & \rho_{33}\end{bmatrix}, \quad R_{km}=\begin{bmatrix}R_{11} & 0 & 0\\ 0 & R_{22} & 0\\ 0 & 0 & R_{33}\end{bmatrix}. \tag{2}$$

ε_{ijk} in equation (1) is a tensor of the third rank which is equal to zero when $i=j$ or k, or $j=k$, but equal to 1 when $ijk=123$, 231 or 312 and equal to -1 when $ijk=213$, 321 or 132. Taking a, b or c-axis of the crystal as x_1, x_2 or x_3-axis, respectively, and I or H in an adequate direction, we can measure six tensor components in consideration of equations (1) and (2). This situation is shown in Table I.

Table I. Description of directions of both electric current I_j and magnetic field H_m to determine ρ_{ij} and R_{km}.

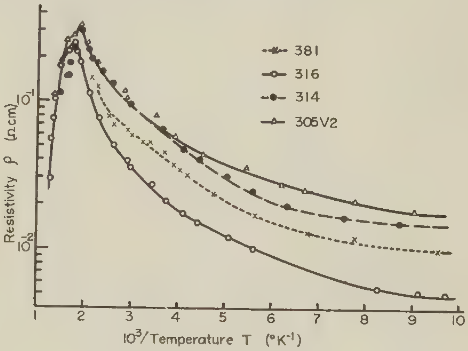
$E_i=\rho_{ij}I_j+\varepsilon_{ijk}R_{km}I_jH_m$					Measurable quantities
I_j	H_m	E_1	E_2	E_3	
I_1	H_2	$\rho_{11}I_1$	0	$R_{22}I_1H_2$	ρ_{11}, R_{22}
I_2	H_3	$R_{33}I_2H_3$	$\rho_{22}I_2$	0	ρ_{22}, R_{33}
I_3	H_1	0	$R_{11}I_3H_1$	$\rho_{33}I_3$	ρ_{33}, R_{11}

On measuring the thermoelectric power a pair of copper-constantan thermo-couples were inserted between brass current electrodes and the specimen. In order to obtain the temperature gradient two copper blocks with heating coils were in good thermal contact to the brass electrodes, but insulated electrically by thin mica films.

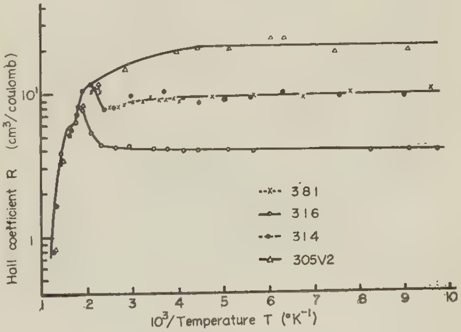
§ 4. Experimental Results

(i) *Resistivity and Hall coefficient*

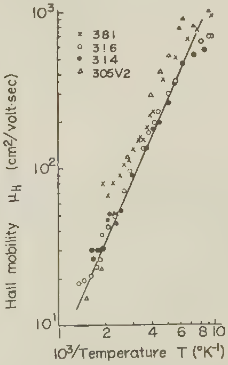
The resistivity ρ and Hall coefficient R have been measured over the temperature range from 100°K to 800°K. The d.c. current and magnetic field were applied parallel and perpendicular, respectively, to the plane perpendicular to c-axis of the single crystal. In Fig. 1 (a), (b) and (c) are, respectively, shown the values of ρ, R and Hall mobility defined as $(8/3\pi)R\sigma$ for pure SnSe crystals. Fig. 2 shows the similar experimental results on impurity-doped and annealed SnSe crystals. The specimens used in these investigations



(a) Resistivity



(b) Hall coefficient



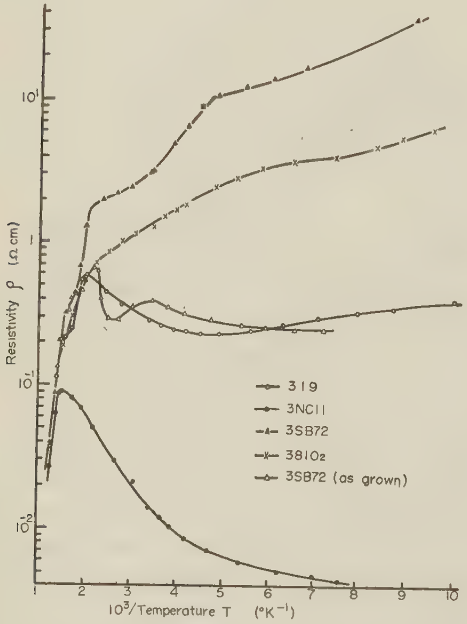
(c) Hall mobility

Fig. 1. Resistivity (a), Hall coefficient (b) and Hall mobility (c) versus inverse absolute temperature for pure SnSe crystals (p-type).

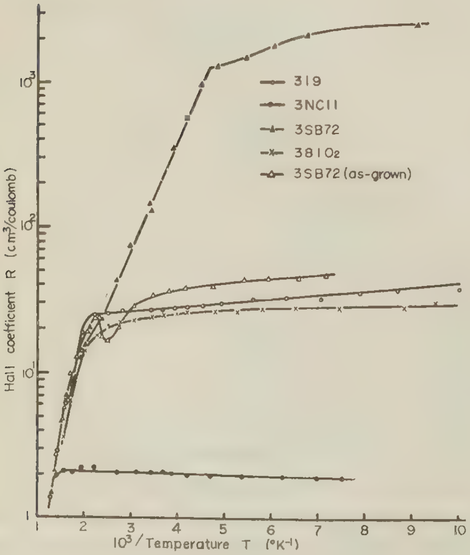
are listed in Table II. Specimens 381O$_2$ and 3NC11 were prepared for the purpose of detecting the effect of oxygen or rock salt on electrical properties by comparing the data with those of the specimen (S5) used in the earlier experiment[2].

(ii) *Anisotropy*

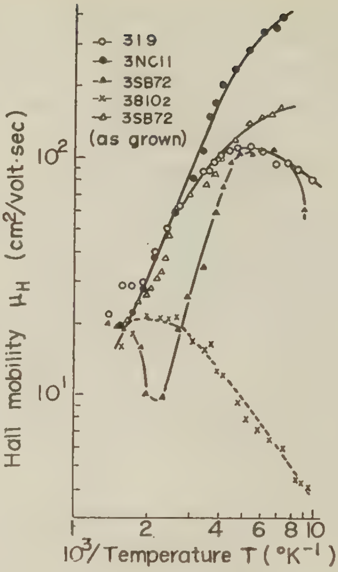
In Fig. 3 (a) and (b) ρ_{ij} and R_{km} defined in § 3 are plotted, respectively, against inverse absolute temperature for single crystal 311 prepared in a carbon-coated quartz tube. Measurements of ρ_{ij} and R_{km} were made first in the low temperature range and then in high temperatures according to the description given in Table I. All curves are on heating and numbers on the high temperature curves represent the order of the measurements. Once the specimen was heated up to high temperatures, then ρ_{ij} and R_{km} took smaller values than the initial ones at room temperature as seen in Fig. 3. Further investigation will be described later with respect to these irreversible phenomena. R_{km} shown in Fig. 3 (b) is the value after a correction due to sample dimension[13]. R_{km} after a correction seems to take a definite value independent of km in the low temperature measurements. Figs. 4 and 5 show ρ_{ij} in temperatures near room temperature for other SnSe crystals 305V1 and 305V3.



(a) Resistivity



(b) Hall coefficient



(c) Hall mobility

Fig. 2. Resistivity (a), Hall coefficient (b) and Hall mobility (c) versus inverse absolute temperature for impurity-doped and annealed SnSe crystals. For comparison, the data for as-grown sample 3SB72 are also included.

(iii) *Thermoelectric power*

The potential difference between both ends of the specimen due to the temperature gradient was measured, the temperature difference being within 10°C. Fig. 6 shows the thermoelectric power determined from the slope of the curve of the thermo-electromotive force plotted against the temperature difference.

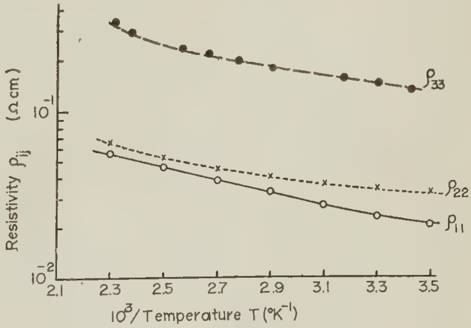

Fig. 5. Resistivity tensor components versus inverse absolute temperature for SnSe single crystal 305V3.

Specimens used in the measurements are also listed in Table II. The thermoelectric force of the single crystal 314 was measured in a direction perpendicular to *c*-axis.

(iv) *Irreversible phenomena*

In connection with the anomalous hump of R shown in Fig. 1 (b) or with the discontinuities of ρ_{ij} and R_{km} in Fig. 3, the detailed investigation is considered to be essential. We, here, attempted to make further experiments in order to clear up whether the anomalous hump of R should be reversible with the temperature, and how the discontinuities of ρ_{ij} and R_{km} should be dependent on the temperature and time of the heat-treatment.

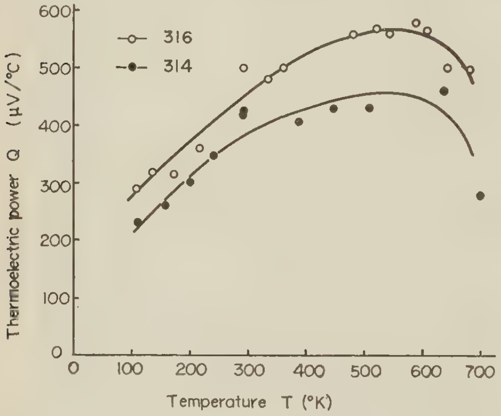

Fig. 6. Thermoelectric power versus absolute temperature for SnSe crystals.

(*a*) *Irreversible change*

When ρ and R of an as-grown crystal were measured with increasing temperature they exhibited maxima at about 200°C as shown by the O-curve in Fig. 7. When the temperature was decreased from the temperature corresponding to these maxima, ρ and R did not vary in accordance with the original curves but took higher values at room temperature: these increased gradually as the specimen was repeatedly subjected to heating cycles between 200°C and room temperature. This aspect is shown in Table III: each column of the table shows, from the left, respectively, the order of a heating cycle, the maximum temperature, the time for which the specimen was maintained at the maximum temperature, the cooling speed to room temperature. The values of ρ and R measured at room temperature after each heat-treatment are also shown in the last two columns. "*Low*" cooling speed means that of about 50°C per hour and "*high*" means such a speed that the time required for the decrease of temperature to a half value of the maximum temperature is of the order of ten minutes. The anomalous hump of R is no longer seen on the B-curve in Fig. 7 (b), which corresponds to the measurement after the 16th heat-treatment in Table III. The anomalous hump was observed to be appreciable again when the specimen

* This series of low resistivity may be ascribed to a systematic error caused by a crack found parallel to the plane perpendicular to *c*-axis.

was gradually heated to 200°C after quenching to room temperature from 519°C after the 17th heat-treatment in Table III. This is shown by the A-curve in Fig. 7 (b). Repeating the similar measurement after quenching to room temperature from 490°C, ρ or R varied as shown by the C-curve which is nearly identical with the A-curve in Fig. 7. Fig. 7 (c) shows the Hall mobility, $R\sigma$, corresponding to the three measurements, O, A and B. The principal results obtained in the present experiment are summarized as follows:

(1) R at room temperature increases after the heat-treatment below 200°C and is independent of cooling speed, but by the heat-treatment above 200°C R at room temperature becomes smaller with higher cooling speed or higher temperature of the heat-treatment.

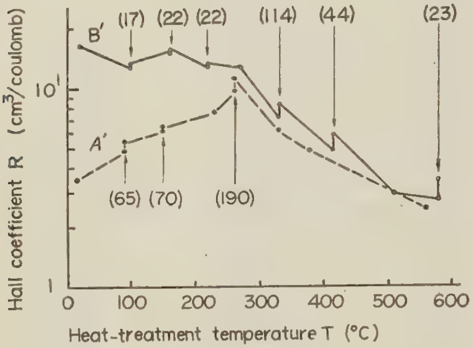
(2) The anomalous hump, being found to be irreversible, appears when R is small at room temperature, but disappears after R becomes larger by the heat-treatment below 200°C.

(3) The irreversible change in ρ or R seems to be ascribed to that in hole concentrations, because the Hall mobility undergoes no change in spite of the remarkable changes observed in ρ and R as seen in Fig. 7.

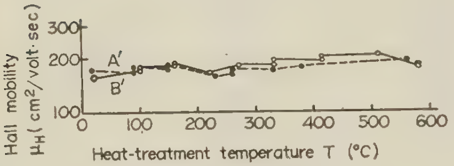
(*b*) *Correlation between R at room temperature and the heat-treatment temperature*

It is easily seen from the above experiment (*a*) that R at room temperature undergoes a remarkable change after the specimen is subjected to a heat-treatment at high temperatures. And from the fact (3) in (*a*) it seems that the heat-treatment at high temperatures should cause some new acceptor level to occur close to the valence band. It is worth while studying how R at room temperature depends on the temperature of the heat-treatment. The specimen sealed into an evacuated Pyrex tube is suddenly put into a furnace whose temperature was kept at 100°C. The specimen was kept at 100°C for 100 minutes and then quenched to room temperature by putting it out of the furnace. Then ρ and R were measured at room temperature. Next, the similar heat-treatment was made at 160°C for 100 minutes again. Repeating the measurement after increasing the temperature of the heat-treatment, R at room temperature varied as the B′-curve in Fig. 8 (a). The A′-curve shows the result obtained by repeating again the similar experiment after that of the B′-curve. Hall mobility does not change through the series of the heat-treatment as shown in

Fig. 8(b). Though the A′- and B′-curves in Fig. 8(a) are, respectively, in close resemblance to the A- and B-curves in Fig. 7(b), it is noted that the abscissa of Fig. 8(a) is not the temperature of the measurement but that of the heat-treatment and measurements of Fig. 8(a) are always made at room temperature.



(a) Hall coefficient



(b) Hall mobility

Fig. 8. Hall coefficient (a) and Hall mobility (b) at room temperature versus temperature of subsequent heat-treatment for SnSe single crystal 382. The heat-treatment period at each temperature is 100 min. Curves B′ and A′ are obtained on the first and second cycles of the heat-treatment, respectively. Numbers in parentheses show the times (in hours), for which the sample is being kept at room temperature not completely in dark, and which correspond to the period between two measurements indicated by the arrows from the numbers.

(c) *Correlation between R at room temperature and the heat-treatment time*

As seen in Fig. 8(a), R with a small value is inclined to become gradually larger, while a specimen is being kept at room temperature not completely in dark. And it is seen from the experiment (*a*) that R takes a larger value by a series of heating cycles below 200°C. In order to understand the anomalous behaviour of R it seems useful to investigate how R at room temperature depends on the time of heat-treatment for a fixed temperature of heat-treatment. The results of annealing effect at various temperatures are shown in Fig. 9. Here the left part of the curves shows a decrease in R which occurs when the temperature of heat-treatment is above 200°C and the right part corresponds to the heat-treatment below 200°C. In both cases the heat-treatment was made in an evacuated Pyrex tube. In Fig. 9 it is evident that for annealing at high temperatures R falls to a constant value in a few minutes, while R increases slowly with time for annealing at low temperatures. The value of R for long annealing time at low temperatures is also shown on each curve in the right part. A similar aspect by heat-treatment is seen in ρ and there is no remarkable change in the Hall

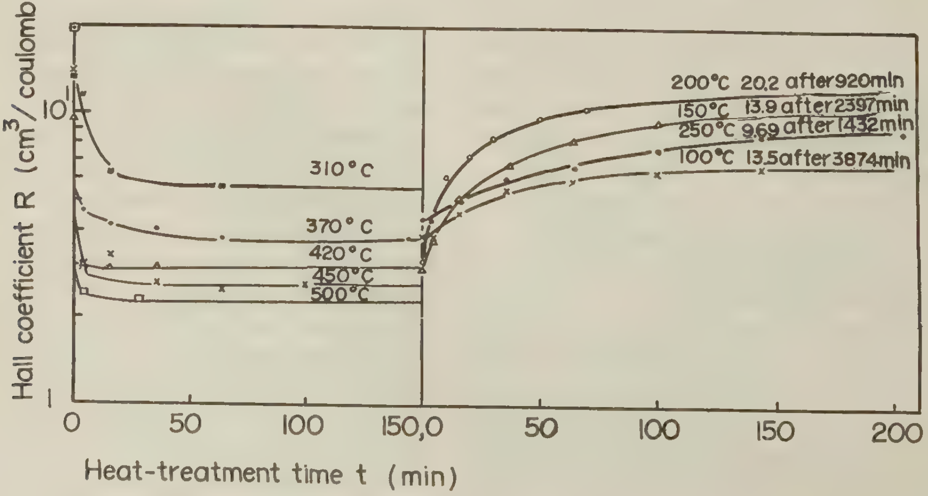


Fig. 9. Hall coefficient at room temperature versus time for various annealing temperatures for SnSe single crystal 382.

mobility. It may be concluded that R approaches in a long time a definite value independent of temperature in the case of heat treatment below 200°C, while R reaches in a few minutes a constant value characteristic to the annealing temperature in the case of heat-treatment above 200°C. In Fig. 10 the above constant saturation value of R is plotted against the annealing temperature above 200°C for a number of specimens listed in Table IV (as for 3SB72 and 3NC11, see Table II).

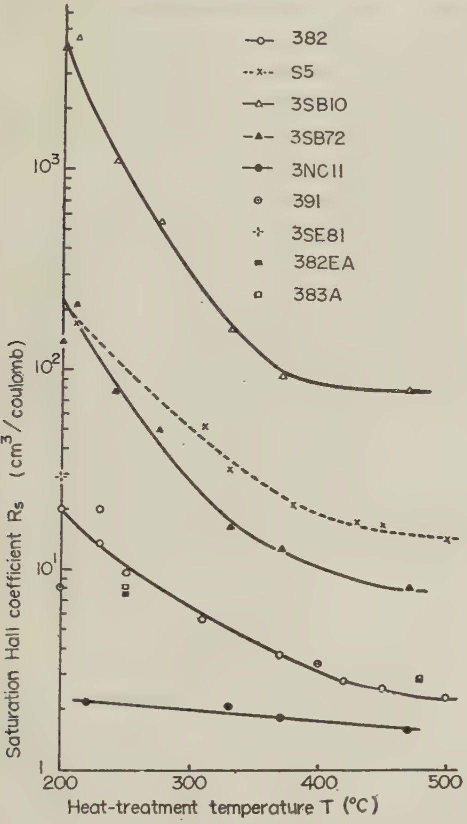

Fig. 10. Saturation Hall coefficient versus temperature of heat-treatment for various pure, impurity-doped and annealed SnSe crystals.

§ 5. Discussion

(i) *Resistivity and Hall coefficient*

It is seen in Fig. 1 that for pure as-grown specimens (314, 316 and 381) which have no heat-treatment history, the resistivity increases monotonously with increasing temperature up to 200°C and then falls via a weak step at about 350°C, and the Hall coefficient, being constant in the temperature range from liquid-air to room temperature, shows an anomalous hump at 200°C and then falls abruptly via a step at about 350°C similar to that in the resistivity. As seen in Fig. 2, among impurity-doped specimens the annealed antimony-doped one 3SB72 especially has large values of the resistivity and Hall coefficient in low temperatures, but the Hall coefficient decreases abruptly from −70°C and approaches a common curve for pure SnSe specimens. This behaviour suggests that antimony atoms in SnSe act as donors at low temperatures and as acceptors at high temperatures. Here, such a model may be proposed that donor levels lie above the valence band by 0.15 eV estimated from the slope of the curve of the Hall coefficient in the low temperature range. If there is any covalent character in SnSe and antimony atoms enter into the lattice by substitution

Table IV. Description of specimens.

Specimens	Origins of component materials Sn	Se	Original composition	Heat-treatment	Crystal type

for tin atoms, it is reasonable for antimony atoms to act as donors in low temperatures. While no remarkable change is observed in the Hall coefficient for iodine-doped (3I9) or heat-treated ($381O_2$) SnSe, the impurity scattering is observed to be predominant in low temperatures as seen in Fig. 2 (c). The reason is not yet understood why the temperature dependence of the Hall mobility of the annealed antimony-doped specimen is remarkably different from that of the as-grown one as shown in the figure. As there is almost no difference between pure and impurity-doped SnSe as to high temperature curves of the resistivity and Hall coefficient, it may be considered that a certain conduction mechanism is dominant at high temperatures which is independent of impurity concentrations. We shall discuss with respect to this point in a later section.

As seen in Fig. 1 (c) the Hall mobility of holes in SnSe varies with temperature as $T^{-2.0}$. If we take into account an optical mode scattering in addition to an acoustical mode scattering and an impurity scattering, the mobility is given approximately as [14]

$$1/\mu=bT^{3/2}+c\{\exp(\Theta/T)-1\}^{-1}+aT^{-3/2}\,. \tag{3}$$

The first term of the equation corresponds to the acoustical scattering and the second the optical one with the Debye temperature Θ and the last the impurity one. In the case of the specimen 381 the experimental points are well represented by the following equation:

$$\begin{aligned}1/\mu=&5.6\times10^{-7}T^{3/2}\\&+3.6\times10^{-2}\{\exp(580/T)-1\}^{-1}\\&+7.0\times10^{-1}T^{-3/2}\,,\end{aligned} \tag{4}$$

as shown in Fig. 7 (c). In the earlier experiment[2] the reversal of the Hall coefficient was observed at high temperatures and the results were analysed to show $b=3.2$ as the ratio of electron to hole mobility and $E_g=0.8$ eV as the energy gap between conduction band and valence band, but we cannot perform the analysis of the present results on a simple semiconductor model. The reason will be presented later. The specimens used in the present experiment have smaller Hall coefficients but larger hole mobility than in the earlier specimen[2]. This means that there took place much compensation between donors and acceptors due to more impurities in the latter. It is of interest that the difference in electrical properties between the earlier specimen and the present ones seems to be attributed to the deviation from stoichiometric compositions in the former, because the effect of oxygen or rock salt which might be considered to exist in the specimen there has been proved to be less important for electrical properties in the high temperature range as shown by 3NC11 in Fig. 2.

(ii) *Anisotropy*

As the shape of specimens used in the study of anisotropy is nearly cubic a uniform current flow is difficult to be realized and Hall voltage must be corrected owing to the geometry of a specimen. From these points of view a cubic specimen seems to be undesirable, but it may be worse to make measurements and discussions on three specimens of different orientations elongated along the direction of the current flow: an anisotropy may be covered with some differences of electrical properties from sample to sample. We, here, adopted a cubic specimen, the relative values being more important than the absolute ones in an anisotropy experiment.

The first of characteristics which are seen in Fig. 3 is that once a specimen is heated up to high temperatures, the Hall coefficient does not go back to its initial value but takes a smaller value. As this will be discussed later in detail, we shall here restrict the discussion to the low temperature range. The fact that there is no anisotropy observed in R after correction seems reasonable in consideration of the proportionality of the Hall coefficient to inverse carrier concentrations. From Figs. 3 (a), 4 and 5, it is found that there holds the relation,

$$\rho_{33}>\rho_{22}\gtrsim\rho_{11} \tag{5}$$

and the ratio, $\rho_{33}:\rho_{22}:\rho_{11}$, seems to be independent of the temperature except for the specimen 305V1. The electrical resistivity ρ is written in the form

$$\rho=(pe\mu_h)^{-1}\,, \tag{6}$$

where p and μ_h are the hole concentration and mobility, respectively. The mobility is expressed by

$$\mu_h=\frac{e}{m_h}\tau_h \tag{7}$$

in terms of effective mass m_h and life time

τ_h of holes. Then we attempt to attribute the anisotropy observed in the resistivity to that of mobility or effective mass of holes, assuming an isotropy of τ_h. From equations (5), (6) and (7) the following relation holds between m_{11}, m_{22} and m_{33}:

$$m_{33} > m_{22} \gtrsim m_{11} \qquad (8)$$

where each suffix corresponds to that of the resistivity. If a constant energy surface is nearly of the shape of the ellipsoid of the revolution which is elongated in the direction of x_3-axis in momentum space, the relation (8) may be understood. This seems to be compatible with the fact that the lattice spacing along x_3-axis is great compared with other spacings. On account of the incompleteness of the experiment, we cannot make further discussion in connection with the electronic structure[15].

(iii) *Thermoelectric power*

The thermoelectric power Q in the impurity range of non-degenerated semiconductors is expressed by Johnson and Lark-Horovitz[16] as follows:

$$\begin{aligned} Q=(k/e)[\ln(|R|T^{3/2})-\ln r-7.16 \\ +q+(3/2)\ln(m_h/m_0)]\,, \qquad (9) \end{aligned}$$

where R is the Hall coefficient, m_0 the free electron mass, r and q are numerical factors which depend upon relative proportions of lattice and impurity scatterings, the lattice scattering being assumed to be due to the acoustical mode only. As seen in Fig. 1 (c) lattice scattering is predominant in low temperatures and we may approximately assume $q=2$ and $r=1.18$, respectively. Then the effective mass of holes may be estimated by substituting R in Fig. 1 (b) and Q in Fig. 6 into equation (9):

$m_{314}=0.5m_0$ for single crystal 314,

and

$m_{316}=1.4m_0$ for polycrystal 316.

As to the difference between the above two estimated values of m we cannot discuss in detail with confidence, but may explain as follows: effective mass which contributes to hole flow to build up the thermo-electromotive force may be probably regarded as the mean of m_{11} and m_{22} for the single crystal sample 314 or of m_{11}, m_{22} and m_{33} for the polycrystalline one 316, respectively. The relations,

$$\left.\begin{aligned} & m_{11} < m_{314} < m_{22} \\ \text{and} \\ (m_{11} \lesssim)\ \ & m_{22} < m_{316} < m_{33}\,, \end{aligned}\right\} \qquad (10)$$

and then

$$m_{314} < m_{316} \qquad (11)$$

will be expected from the relation (8). The relation (11) is in a qualitative agreement with the experimental results.

(iv) *Irreversible phenomena*

The irreversible change observed in the resistivity or Hall coefficient may be ascribed to the change in hole concentrations because the value of hole mobility is independent of the heat-treatment. In order to make the matters in question clear we will summarize the principal results given in § 4 (iv):

(1) Hole concentration at room temperature increases by the heat-treatment above 200°C and approaches a constant value in a few minutes.

(2) The increased hole concentration decreases slowly by the heat-treatment below 200°C.

(3) For the heat-treatment above 200°C hole concentration at room temperature takes a saturation value which is characteristic to the temperature of heat-treatment, and for the heat-treatment below 200°C it approaches in a long time a definite value which is independent of the temperature of heat-treatment.

(4) The saturation values of hole concentrations which are characteristic to the temperature of heat-treatment differ from sample to sample depending upon the impurity concentrations.

(5) The above saturation values seem to approach a definite value with increasing temperature of the heat-treatment.

Recognizing the above five facts we can explain straightforwardly an anomalous hump at 200°C and a step at 350°C on the A-curve in Fig. 7 (b). The increase in the Hall coefficient with increasing temperature may be attributed to a decrease in hole concentration corresponding to the low temperature heat-treatment by (2). With further increasing temperature the Hall coefficient decreases due to increase in hole concentration by (1). The observed step at 350°C seems to show that the intrinsic conduction begins to take place, being superposed on the increase in hole concentration by (1) and (5).

At first we assumed a "*trap model*" to explain the anomalous phenomena. This states that there are electron trap levels below the conduction band and a number of electrons are trapped at high temperatures. On quenching a specimen from high temperatures trapped electrons are not afforded to escape from the trap levels. If the direct recombination of trapped electrons with holes in the valence band is forbidden, trapped electrons must jump in the conduction band to recombine with holes in the valence band by getting sufficient thermal energy. This occurs with increasing temperature and will result in an anomalous hump on the A-curve in Fig. 7(b). But we should abandon the above trap model, because it seems unable to explain a decrease in hole concentrations which occured in the intrinsic range in the specimen S5 showing the reversal of the Hall coefficient at high temperatures.

Then an alternative model—an "*impurity-diffusion model*"—is proposed. When SnSe is heated at above 200°C a certain number of acceptors are generated under thermal equilibrium. On quenching, these acceptors are left generated. This causes to increase hole concentrations even at room temperature because an ionization energy (not a formation energy) of the acceptors is considered to be very small as suggested from the A-curve in Fig. 7(b) in which the Hall coefficient is shown to be constant down to liquid air temperature. We should distinguish these acceptors from the original ones whose density is never changed by the heat-treatment. Acceptors generated on quenching disappear gradually to re-establish a new condition of thermal equilibrium at room temperature as shown in Fig. 8(a). The time required for this recovery is very long on account of the small thermal energy at room temperature. An increase in the Hall coefficient with increasing temperature to 200°C may be then expected reasonable. It is considered probable that acceptors are formed by diffusion of a certain kind of impurity atoms into certain sites in SnSe at high temperatures just as in the case of Cu in Ge[17]. The impurity atoms do not seem to come from the surface but seem to exist originally in the bulk, because the acceptor formation does not depend upon thickness of the specimen or cleanness of the surface (382EA). Another possible mechanism for the acceptor formation is expected to be lattice imperfections which might be present at high temperatures. If the acceptors were originated only from the Frenkel-type imperfections[18], the acceptor density should increase exponentially with increasing temperature of heat-treatment as $\exp(-E/kT)$ and never approach a definite value at high temperatures as seen in all of the specimens. And then the acceptor density generated at high temperatures should be a function of the temperature of heat-treatment only and should not depend upon impurity concentrations as seen in Fig. 10. It is likely that a considerable number of Se vacancies exist in SnSe crystals and impurity atoms diffuse into these vacancies to act as acceptors. Precautions were taken to reduce Se vacancies while preparing the specimen 391 or 3SE81, but it was not clarified whether Se vacancies might not be reduced or the reduction of Se vacancies might be ineffective on acceptor formation. And also in order to reduce the imperfections, e.g. dislocations, which are likely occupied by impurity atoms, care was taken in preparing the specimen 382EA or 383A, but no useful results were obtained. In the present investigation we have nothing to refer to the kind of impurity atoms or the location of acceptor sites.

We shall here discuss the experimental results on a simple model described above, assuming that impurity X-atoms (w_0/cm^3) in certain sites (w_0/cm^3) act as acceptors when they diffuse into certain sites (v_0/cm^3) of vacancies. To distinguish the above impurity atoms from the original impurity atoms which are never affected by the heat-treatment the term X-atom is adopted. If the vacancies are occupied by p(cm^{-3}) of X-atoms at the temperature T, the variation of p with time may be written in the form

$$\frac{dp}{dt}=C_1(v_0-p)(w_0-p)-C_2p^2, \qquad (12)$$

where C_1 and C_2 are functions of T. The first term on the right side of equation (12) represents the acceptor formation and the second term the acceptor disappearance, respectively. Under thermal equilibrium equation (12) is equal to zero and this leads to

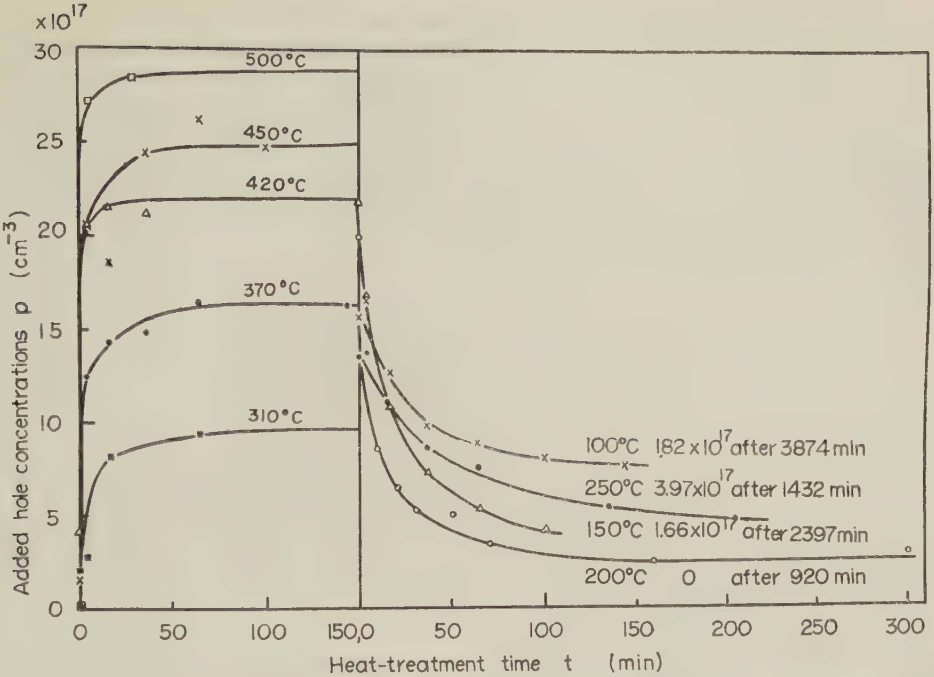

Fig. 11. Variation of added hole concentrations with time for various annealing temperatures for SnSe single crystal 382. The added hole concentrations are derived from the Hall coefficients given in Fig. 9.

$$p=\begin{Bmatrix}\alpha\\ \beta\end{Bmatrix}$$

$$=\{(v_0+w_0)\pm\sqrt{(v_0-w_0)^2+4\gamma v_0w_0}\}/2(1-\gamma) \qquad \text{for} \quad \gamma \neq 1\,, \qquad (13)$$

where

$$\gamma=C_2/C_1\,. \qquad (14)$$

Introducing equation (13) into equation (12) we obtain

$$\frac{dp}{dt}=C_1(1-\gamma)(p-\alpha)(p-\beta)\,. \qquad (15)$$

Thus, under the initial condition of $p=p_0$ at $t=0$ the solution of equation (15) is expressed as follows:

$$p=\frac{\alpha-\beta A\exp\left[C_1(1-\gamma)(\alpha-\beta)t\right]}{1-A\exp\left[C_1(1-\gamma)(\alpha-\beta)t\right]}\,, \qquad (16)$$

where

$$A=\frac{p_0-\alpha}{p_0-\beta}\,. \qquad (17)$$

Under thermal equilibrium p is easily proved to be represented by β (not by α). And it is also seen that the general feature of the curve of p versus t in equation (16) corresponds to the left part for $p_0<\beta$ or to the right part for $p_0>\beta$ of Fig. 11 in which the numbers of added holes calculated from the Hall coefficient in Fig. 9 are plotted against the time of heat-treatment.

First, in the case of the heat-treatment below 200°C the hole disappearance exceeds the hole formation as observed in the experiment. Thus, the first term of equation (12)

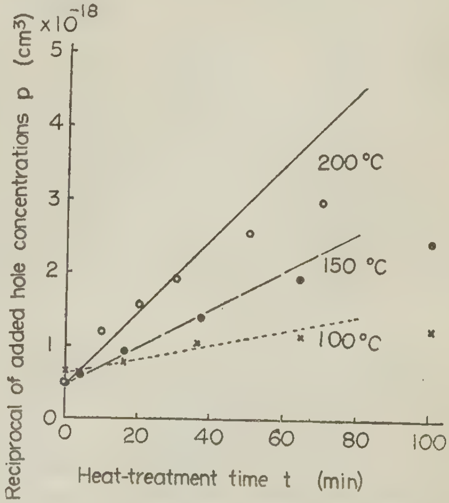

Fig. 12. Reciprocal of added hole concentrations versus time for three annealing temperatures for SnSe single crystal 382.

may be neglected approximately, obtaining

$$\frac{1}{p}=\frac{1}{p_0}+C_2 t\,. \qquad (18)$$

Fig. 12 shows the plots of $1/p$ versus t at three different temperatures. We can obtain C_2 at each temperature by drawing a rough straight line. The linear relationship in the plot of $\log C_2$ versus $1/T$ is shown in Fig. 13, obtaining

$$C_2=1.8\times10^{-16}\exp(-0.25/kT)\,,\quad (kT \text{ in eV})\,. \qquad (19)$$

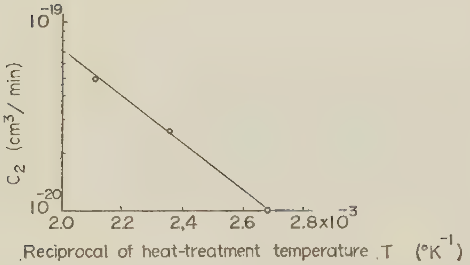

Fig. 13. Plot of C_2 versus reciprocal of heat-treatment temperature for SnSe single crystal 382.

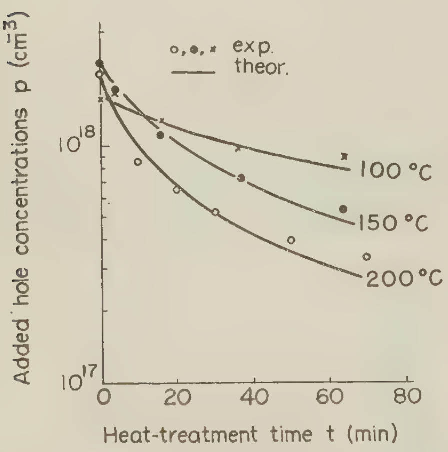

Fig. 14. Comparison between theoretical and experimental values with respect to added hole concentrations versus time for three annealing temperatures for SnSe single crystal 382.

A comparison of the theoretical curve with the experimental points for p is shown in Fig. 14. The experimental values tend to deviate from the theoretical curve with increasing time and increasing temperature. This deviation seems to be ascribed to the above neglect of the first term in equation (12).

Next, we shall discuss with respect to the heat-treatment above 200°C. Under thermal equilibrium condition, p is equal to β as mentioned above, and under the assumption $v_0=w_0$ which means that all of Se vacancies are occupied by the same number of X-atoms when the crystal is grown from the melt, equation (13) is reduced to the simple form,

$$\beta=\frac{v_0}{1+\sqrt{\gamma}}\,. \qquad (20)$$

On the other hand, C_1 and C_2 may be, respectively, written in the forms

$$\left.\begin{aligned} &C_1=C_{10}\exp(-E_1/kT) \\ \text{and}\quad & \\ &C_2=C_{20}\exp(-E_2/kT)\,, \end{aligned}\right\} \qquad (21)$$

where C_{10} (or C_{20}) is independent of T, and E_1 (or E_2) corresponds to the formation (or disappearance) energy of acceptors. We thus obtain

$$\beta=\frac{v_0}{1+\sqrt{C_{20}/C_{10}}\exp\{-(E_2-E_1)/2kT\}} \qquad (22)$$

by substituting equations (14) and (21) into equation (20). Experimental values of β obtained from the curves in Fig. 10 are shown

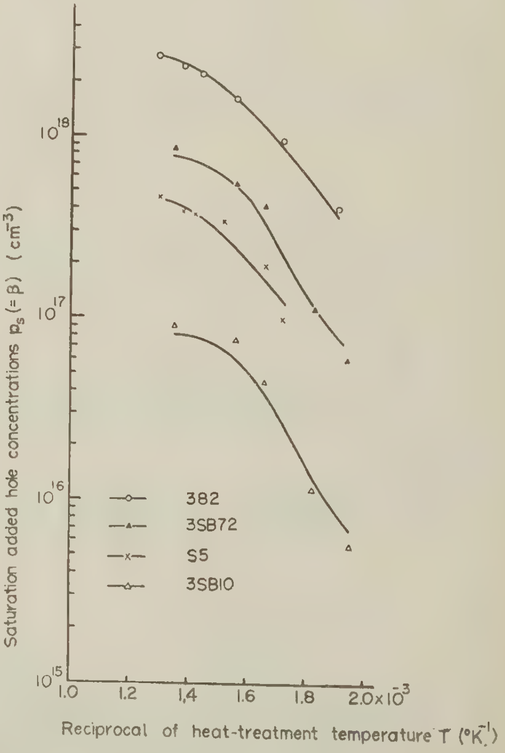

Fig. 15. Comparison between theoretical and experimental values with respect to saturation added hole concentrations versus reciprocal of heat-treatment temperature.

in Fig. 15. It is easily seen that these experimental points may be represented by equation (22), which is expected to show nearly a straight part at the low temperature range. From the average slope of their straight parts for samples 382, S5, 3SB10 and 3SB72, the value $E_2-E_1=1.18$ eV is obtained. Using this value we may estimate the value of v_0 and $\sqrt{C_{20}/C_{10}}$ so that the theoretical curves can fit the experimental points. The theoretical curves with the common value of $\sqrt{C_{20}/C_{10}}=2\times10^{-5}$ and the different values of $v_0\times10^{-17}=34$, 5.3, 1.1 and 9.6, respectively, for samples 382, S5, 3SB10 and 3SB72 are shown in Fig. 15. Thus C_1 may be expressed as follows:

$$C_1=4.5\times10^{-7}\exp(-1.43/kT)\,. \tag{23}$$

Calculated curves of C_1 and C_2 are shown in Fig. 16 and that of γ in Fig. 17.

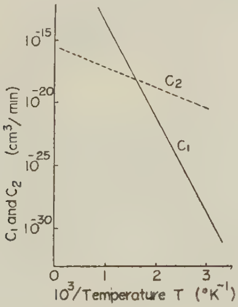

Fig. 16. Plots of C_1 and C_2 versus inverse absolute temperature.

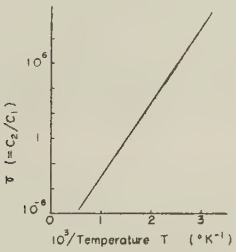

Fig. 17. Plot of $\gamma(=C_2/C_1)$ versus inverse absolute temperature.

At last, we shall show that the steep increase in p as seen in Fig. 11 may be explained on the proposed model. At elevated temperatures, we obtain from equation (16)

$$p\approx v_0-\frac{v_0-p_0}{1+(v_0-p_0)C_1t} \tag{24}$$

because $\gamma\ll1$ from Fig. 17. The time required for attainment of p to a half of (v_0-p_0) is of the order of 10^{-4} min. at 1000°K. When $\gamma=1$ which corresponds to 670°K, p is represented from equation (12) as follows:

$$p\approx\frac{v_0}{2}+\left(p_0-\frac{v_0}{2}\right)\exp(-2C_1v_0t)\,. \tag{25}$$

The value of p reaches approximately the half maximum after $t\approx1/2C_1v_0\approx10^{-1}$ min. The values of these times agree qualitatively with the experimental results shown in Fig. 11.

§ 6. Conclusion

The electrical resistivity, Hall coefficient and thermoelectric power of SnSe crystals were investigated, but we could not analyse fully on a simple semiconductor model. The reason is that a conventional assumption that the hole density in the valence band is equal to the sum of electron density in the conduction band and acceptor density does not hold on account of acceptor formation at high temperatures. Experimental results could be interpreted qualitatively on a simple model of acceptor formation. Impurity band conduction model or two holes model does not seem to be applicable for the present case of SnSe, because either model is expected to imply only the reversible phenomena with temperature, while there take place the irreversible phenomena in SnSe. And also the positive temperature coefficient observed in the Hall coefficient of SnTe or GeTe is reported to be reversible with temperature. In these points of view the anomalous Hall coefficient for SnSe may be concluded to be essentially different from the positive temperature coefficient observed in some materials described above. The irreversible phenomena observed in SnSe seem to resemble the case of GaAs or GeSe. Such a change in carrier concentrations with the heat-treatment as observed in SnSe is also observed in pulled Si[19] crystals though in the case of Si the donors are found to be introduced at about 500°C after a long time of the heat-treatment and caused by the presence of oxygen[20] probably. Appearance of donors at lower temperatures and their disappearance at higher temperatures seem to be equivalent to saying that acceptors disappear at lower temperatures and appear at higher temperatures.

We attempted to ascribe the mechanism of acceptor formation to the impurity diffusion rather than lattice imperfection and resulted in a qualitative agreement with the experimental results. The value of 0.59 eV of $(E_2-E_1)/2$ is of comparable order with 0.55 eV or 0.80 eV as the corresponding formation energy of donors found in PbS or PbSe and PbTe at high temperatures[21], in which the mechanism is not yet known. But some arbitrary assumptions were adopted in the present discussion to simplify the calculations: the numbers of X-atoms are equal to X-atom sites or vacancies in their numbers. In reality, we can say nothing as to the kinds of X-atoms or the mechanism by which the acceptor is formed. It is probable that the number of Se vacancies will vary with temperature and at high temperatures lattice imperfections of other kinds may take place. But the fact that experimental results can be explained on a simple impurity diffusion model seems to suggest that the model described above is a main factor in the mechanism of acceptor formation. A further investigation especially on optical absorption is desired to obtain the energy gap and the trap level, if any.

In conclusion, the author should express his sincere thanks to Prof. A. Okazaki for his kind guidance and encouragement. He is also indebted to Dr. T. Okada, Dr. K. Hirakawa, Messrs. Y. Matsukura and K. Hashimoto for their interests in the present investigation.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 14, No. 3, March, 1959

A Note on the Theories Underlying the Polarimetric Study of Very Thin Dielectric Surface Layers

By Sadao NOMURA and Koreo KINOSITA

Department of Physics and Chemistry,
Gakushuin University, Mejiro, Tokyo

(Received December 6, 1958)

Polarimetric study of very thin dielectric surface layers on dielectric substrates has been most frequently based on Drude's theory, or on Sissingh and Groosmuller's theory obtained by improving the approximation of Drude's calculation. These theories are derived by modifying the boundary conditions for Maxwell's equations. A quite different approach to this problem is possible, however, which is based on discussions concerning the interference of light inside the surface layer.

It has been proved by several workers that Drude's theory is consistent with the interference theory. It is proved in this paper that Sissingh and Groosmuller's theory is also consistent with the interference theory. Some formulae derived in the process of proof are believed to be useful for further discussions in this field.

§ 1. Introduction

The usual method of polarimetric study of a thin dielectric surface layer, be it the so-called *transition layer* or an alien film, on a homogeneous dielectric substrate consists in allowing a parallel beam of linearly polarized light fall on the surface and observing some of the parameters of the elliptical vibration orbit of the reflected light. It is at least in principle possible to express any parameter P of this vibration ellipse like

$$P=P(d, \varepsilon; \varepsilon_1, \varepsilon_2, \varphi_1, \alpha_0, \lambda)\,, \qquad (1)$$

where the symbols in the right-hand side stand for the following quantities respectively (see Fig. 1):

d : thickness of the surface layer.
ε, ε_1 and ε_2: dielectric constants of the surface layer, the ambient medium and the substrate respectively.
φ_1: angle of incidence.
α_0: azimuth of the incident linearly polarized light.
λ : wavelength of light.

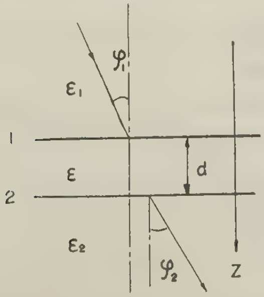

Fig. 1. Illustration for Eq. (1).

The refractive indices of the surface layer, the ambient medium and the substrate are given by $n=\sqrt{\varepsilon}$, $n_1=\sqrt{\varepsilon_1}$ and $n_2=\sqrt{\varepsilon_2}$ respectively.

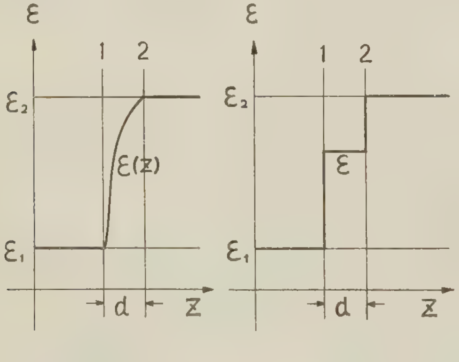
Parameters included in Eq. (1) other than d and ε may be regarded as known quantities. Hence, if we know the functional form of P, and if ε is homogeneous throughout the surface layer or if it denotes the mean dielectric constant of the layer, we can evaluate some simple combination of d and ε, say nd, by the measurement of P. It will be possible to evaluate d and ε separately if two mutually independent P's can be measured. Equations of the type of Eq. (1) shall be called the *equations of polarimetry* in this paper.

The equation of polarimetry which has been most frequently used in this kind of study is that of Alkemade1) and Drude2) (Eq. (8)). Some workers3),4) preferred to Sissingh and Groosmuller's3) two equations (Eqs. (13) and (15)) derived by improving the approximation of Drude's calculation. The above mentioned authors start from a model illustrated in Fig. 2 (a), in which it is assumed that

1° ε is a continuous function of z (z is the coordinate parallel to the inward normal of the surface): $\varepsilon(z)$. $\varepsilon(z)$ is equal to ε_1 at the boundary 1 and is equal to ε_2 at the boundary 2.

2° $d \ll \lambda$.

They derive the boundary conditions for Maxwell's equations valid for the *composite surface* 1–2 by integrating Maxwell's equations under the assumption 2°, and obtain the amplitude reflectives, so to say the modified Fresnel coefficients, valid for this composite surface. In this calculation Drude neglects the second and the higher powers in d/λ and arrives at Eq. (8), whereas Sissingh and Groosmuller take the second powers in d/λ into consideration and arrive at Eqs. (13) and (15). It would be noteworthy that, although these theories assume a continuous variation of ε in the surface layer, what is actually evaluted is nothing but $\bar{\varepsilon}$, a kind of mean value of $\varepsilon(z)$ (see below). For the convenience of later reference, we shall call these theories *the boundary condition theories.*



(a) (b)

Fig. 2. Models adopted in (a) *boundary condition theory* and (b) *interference theory.*

A quite different approach to this problem is possible, in which one starts assuming that the dielectric constant is homogeneous and is equal to ε throughout the surface layer (Fig. 2(b)). In this case, any parameter of the elliptical orbit of the reflected light can be calculated by considering the interference of light in the surface layer, or rather *film.* Theories of this kind shall be cited as the *interference theories.*

Now, a question arises: Do the boundary condition theory and the interference theory yield the same equation(s) of polarimetry if $\bar{\varepsilon}$ in the former theory is equated with ε in the latter theory? As for the first order theories in which only the first powers of d/λ are taken into account, it has been proved by several workers[5] that Drude's result is consistent with that of the interference theory. But no proof has yet been given of the agreement of the results of Sissingh and Groosmuller's theory with those of the interference theory where terms up to the second powers in d/λ are taken into account.

The immediate purpose of this paper is to present an elegant proof of this consistency. Some formulae derived in the process of proof are believed to be useful for further discussions in this field.

§ 2. Preparatory Notes

For the convenience of later reference, a brief description of the equations of polarimetry referred to above will be given in this section. To avoid unnecessary complications, it will be assumed in this and the following sections that

$$\varepsilon_1 = 1 \quad \text{and} \quad \alpha_0 = \pi/4\,. \tag{2}$$

From the second assumption it follows that the ratio in amplitude reflectivity of the p- and the s-components of the electric vector, $\boldsymbol{r}_p/\boldsymbol{r}_s$, is equal to the ratio in (complex) amplitude of the p- and the s-components of the reflected beam, $\boldsymbol{R}_p/\boldsymbol{R}_s$.

a) *Drude's theory (D-theory)*

In this theory in which only the first powers in d/λ are taken into account, it can be shown[2] that

$$\frac{\boldsymbol{R}_p}{\boldsymbol{R}_s} = \frac{\boldsymbol{r}_p}{\boldsymbol{r}_s} = -\frac{\cos(\varphi_1+\varphi_2)}{\cos(\varphi_1-\varphi_2)} \times \left\{1 + i\frac{4\pi}{\lambda}\,\frac{\varepsilon_2}{1-\varepsilon_2}\,\frac{\cos\varphi_1 \sin^2\varphi_1}{\sin^2\varphi_1 - \varepsilon_2\cos^2\varphi_1}\,\eta\right\}. \tag{3}$$

Here φ_2 denotes the angle of refraction of the substrate for the angle of incidence φ_1, and

$$\eta = \int_1^2 \frac{(\varepsilon-1)(\varepsilon-\varepsilon_2)}{\varepsilon}\,dz\,. \tag{4}$$

If φ_1 is equal to φ_B, the *Brewsterian angle* of the substrate, i.e. if

$$\varphi_1 = \varphi_B = \tan^{-1}\sqrt{\varepsilon_2}\,, \qquad \varphi_1+\varphi_2 = \pi/2\,, \tag{5}$$

Eq. (3) is reduced to

$$\left[\frac{\boldsymbol{R}_p}{\boldsymbol{R}_s}\right]_B = i\,\frac{\pi}{\lambda}\,\frac{\sqrt{1+\varepsilon_2}}{1-\varepsilon_2}\,\eta\,. \tag{6}$$

The suffix B indicates that this is the value for $\varphi_1 = \varphi_B$. If we represent the ratio in real amplitude R_p/R_s and the phase difference of the p- and the s-components by ρ and Δ respectively,

$$\frac{\boldsymbol{R}_p}{\boldsymbol{R}_s} = \frac{R_p}{R_s} e^{i\Delta} = \rho e^{i\Delta} . \tag{7}$$

From Eq. (6) and Eq. (7) we get*

$$\rho_{\mathrm{B}} = \pm \frac{\pi}{\lambda} \frac{\sqrt{1+\varepsilon_2}}{1-\varepsilon_2} \eta , \tag{8}$$

$$\Delta_{\mathrm{B}} = \pm \pi/2 . \tag{9}$$

Eq. (9) means that if $\varphi_1 = \varphi_{\mathrm{B}}$ one of the principal axes of the elliptical orbit of the reflected beam lies in the plane of incidence, or that the Brewsterian angle φ_{B} is equal to the *principal angle of incidence* φ_p.

Thus measurement of ρ, the ellipticity of the orbit at the Brewsterian angle incidence, will give η. If we apply the mean value theorem to Eq. (4) and define the *mean dielectric constant* of the surface layer $\bar{\varepsilon}$ by

$$\eta = \frac{(\bar{\varepsilon}-1)(\bar{\varepsilon}-\varepsilon_2)}{\bar{\varepsilon}} d , \tag{10}$$

a combination of d and $\bar{\varepsilon}$ as given by Eq. (10) can be determined experimentally. If we could assign an appropriate value to $\bar{\varepsilon}$ by some other reasoning, we would be able to evaluate d itself.

b) *Sissingh and Groosmuller's theory* (*SG-theory*)

These authors[3)] took the second powers in d/λ into account and arrived at the following equation under the same assumptions as those underlying the derivation of Eq. (6).

$$\left[\frac{\boldsymbol{R}_p}{\boldsymbol{R}_s}\right]_{\mathrm{B}} = i \frac{\pi}{\lambda} \frac{\sqrt{1+\varepsilon_2}}{1-\varepsilon_2} \eta + \frac{4\pi^2}{\lambda^2} \frac{1}{4(1-\varepsilon_2)^2(1+\varepsilon_2)} \eta \Theta . \tag{11}$$

Here η is given by Eq. (4) and

$$\Theta = -(1+\varepsilon_2) \int_1^2 \frac{\varepsilon^2(3+\varepsilon_2) - \varepsilon(1+4\varepsilon_2-\varepsilon_2^2) + \varepsilon_2(1-\varepsilon_2)}{\varepsilon} dz . \tag{12}$$

From Eq. (11) are derived the following equations which correspond to Eqs. (8) and (9).

$$\left\{ \begin{aligned} \rho_{\mathrm{B}} &= \pm \frac{\pi}{\lambda} \frac{\sqrt{1+\varepsilon_2}}{1-\varepsilon_2} \eta , && (13) \\ \cot \Delta_{\mathrm{B}} &= \frac{\pi \Theta}{\lambda(1-\varepsilon_2^2)\sqrt{1+\varepsilon_2}} . && (14) \end{aligned} \right.$$

The difference between D-theory and SG-theory lies in that the latter clears up the inequality between φ_p and φ_{B} ($\Delta_{\mathrm{B}} \neq \pm\pi/2$). The difference is very small, however, and can be shown to be

$$\varphi' = \varphi_p - \varphi_{\mathrm{B}} = -\frac{2\pi^2}{\lambda^2} \frac{\varepsilon_2 \sqrt{\varepsilon_2}}{(1+\varepsilon_2)(1-\varepsilon_2^2)^2} \eta \Theta . \tag{15}$$

Now, if we make measurements of φ' and ρ_{B}, we can make a separate evaluation of the thickness and the dielectric constant of the surface layer from the simultaneous equations of polarimetry, Eqs. (13) and (15). For this, however, again we have to apply the mean value theorem to Eqs. (4) and (12) and equate the mean value of the dielectric constant $\bar{\varepsilon}$ defined by Eq. (10) and that defined by the following equation:

$$\Theta = \frac{-(1+\varepsilon_2)\{\bar{\varepsilon}^2(3+\varepsilon_2) - \bar{\varepsilon}(1+4\varepsilon_2-\varepsilon_2^2) + \varepsilon_2(1-\varepsilon_2)\}}{\bar{\varepsilon}} d . \tag{16}$$

c) *The interference theory*

If we adopt the model illustrated in Fig. 2 (b) and calculate $\boldsymbol{r}_p$ and $\boldsymbol{r}_s$ considering the interference due to multiple reflections inside the surface layer, we can easily obtain

$$\frac{\boldsymbol{R}_p}{\boldsymbol{R}_s} = \frac{\boldsymbol{r}_p}{\boldsymbol{r}_s} = \rho e^{i\Delta} = \frac{r_{1p}+r_{2p}\exp(-iax)}{1+r_{1p}r_{2p}\exp(-iax)} \Bigg/ \frac{r_{1s}+r_{2s}\exp(-iax)}{1+r_{1s}r_{2s}\exp(-iax)} , \tag{17}$$

---

* The sign of the right side of Eq. (8) is to be chosen so as to make d included in η positive.

where r_{1p}, r_{1s} and r_{2p}, r_{2s} represent the Fresnel coefficients of the p- and s-components of the electric vector at the boundaries 1 and 2 respectively, and

$$x = d/\lambda\,, \tag{18}$$

$$a = 4\pi n \cos\varphi\,. \tag{19}$$

φ in Eq. (19) stands for the angle of refraction of the film corresponding to the angle of incidence φ_1 (Fig. 3).

Eq. (17) is too complicated for practical application to the polarimetric study of a film, but approximate equations can be derived by expanding it in powers of x $(=d/\lambda)$. It is expected that the first and the second approximations agree with D-theory and SG-theory respectively. This will be shown to be the case in the following sections.

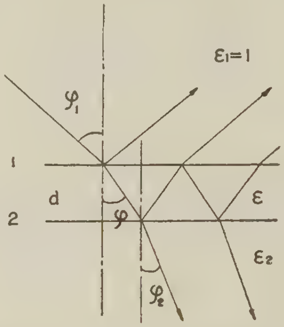


Fig. 3. Interference theory.

§ 3. Expansion of Eq. (17)

a) *Fresnel coefficients for* $\varphi_1 = \varphi_B$

r_{1p} in the right side of Eq. (17) is given by

$$r_{1p} = \frac{\tan(\varphi_1-\varphi)}{\tan(\varphi_1+\varphi)} = \frac{\begin{vmatrix} \tan\varphi_1 & \sin\varphi_1 \\ 1 & \sqrt{n^2-\sin^2\varphi_1} \end{vmatrix}}{\begin{vmatrix} 1 & -\sin\varphi_1 \\ \tan\varphi_1 & \sqrt{n^2-\sin^2\varphi} \end{vmatrix}} \cdot \frac{\begin{vmatrix} 1 & \sin\varphi_1 \\ \tan\varphi_1 & \sqrt{n^2-\sin^2\varphi_1} \end{vmatrix}}{\begin{vmatrix} \tan\varphi_1 & -\sin\varphi_1 \\ 1 & \sqrt{n^2-\sin^2\varphi_1} \end{vmatrix}}\,. \tag{20}$$

When $\varphi_1 = \varphi_B = \tan^{-1}\sqrt{\varepsilon_2}$, i.e. when the angle of incidence is equal to the Brewsterian angle of the substrate, Eq. (20) is reduced to

$$[r_{1p}]_B = \frac{\varepsilon-k}{\varepsilon+k}\,, \tag{21}$$

where

$$k = \sqrt{\varepsilon\varepsilon_2+\varepsilon-\varepsilon_2}\,. \tag{22}$$

It can be shown in the same way that

$$[r_{2p}]_B = -\frac{\varepsilon-k}{\varepsilon+k}\,, \tag{23}$$

$$[r_{1s}]_B = -\frac{k-1}{k+1}\,, \tag{24}$$

$$[r_{2s}]_B = -\frac{\varepsilon_2-k}{\varepsilon_2+k}\,. \tag{25}$$

b) *Expansion of Eq. (17)*

If we put

$$L(x) = r_{1p} + r_{2p}\exp(-iax)\,, \tag{26}$$

$$N(x) = \frac{1+r_{1s}r_{2s}\exp(-iax)}{(1+r_{1p}r_{2p}\exp(-iax))(r_{1s}+r_{2s}\exp(-iax))}\,, \tag{27}$$

Eq. (17) can be written as

$$\boldsymbol{R}_p/\boldsymbol{R}_s = \boldsymbol{L}(x)\boldsymbol{N}(x)\,. \tag{28}$$

Expanding the right side in power series in $x=d/\lambda$, we get

$$\frac{R_p}{R_s}=\rho e^{i\Delta}=L(0)N(0)+\begin{vmatrix} L'(0) & L(0) \\ -N'(0) & N(0) \end{vmatrix}x$$

$$+\frac{1}{2}\left\{\begin{vmatrix} L''(0) & L(0) \\ -N''(0) & N(0) \end{vmatrix}+\begin{vmatrix} L'(0) & N'(0) \\ -L'(0) & N'(0) \end{vmatrix}\right\}x^2+O(x^3)\,. \tag{29}$$

$L(x), L'(x), \cdots$ and $N(x), N'(x), \cdots$ are, in general, complex numbers. But it is obvious from Eqs. (26) and (27) that

$L^{(n)}(0)$ and $N^{(n)}(0)$ are real* for even values (including zero) of n,

and

$L^{(n)}(0)$ and $N^{(n)}(0)$ are imaginary for odd values of n.

Hence, if we put

$$L'(0)=iL_R'(0)\,,\qquad N'(0)=iN_R'(0) \tag{30}$$

and substitute into Eq. (29), an expression for R_p/R_s is obtained *in which all the parameters are real*:

$$\frac{R_p}{R_s}=\rho e^{i\Delta}=L(0)N(0)+i\begin{vmatrix} L_R'(0) & L(0) \\ -N_R'(0) & N(0) \end{vmatrix}x$$

$$+\frac{1}{2}\left\{\begin{vmatrix} L''(0) & L(0) \\ -N''(0) & N(0) \end{vmatrix}-\begin{vmatrix} L_R'(0) & N_R'(0) \\ -L_R'(0) & N_R'(0) \end{vmatrix}\right\}x^2+O(x^3)\,. \tag{31}$$

Now we shall calculate $[R_p/R_s]_\mathrm{B}$ and $[R_p/R_s]_\mathrm{p}$, i.e. the ratio in complex amplitude of the p- and the s-components for $\varphi_1=\varphi_\mathrm{B}$ and $\varphi_1=\varphi_\mathrm{p}$ respectively.

1° $[R_p/R_s]_\mathrm{B}$

From Eqs. (21) and (23) it follows that

$$[L(0)]_\mathrm{B}=0\,. \tag{32}$$

Hence

$$[R_p/R_s]_\mathrm{B}=i[L_R'(0)N(0)]_\mathrm{B}x+\frac{1}{2}[L''(0)N(0)-2L_R'(0)N_R'(0)]_\mathrm{B}x^2+O(x^3)\,. \tag{33}$$

2° $[R_p/R_s]_\mathrm{p}$

This has to be a pure imaginary number because $\Delta=\pi/2$ for $\varphi_1=\varphi_p$. Hence the first and the third terms in the right side of Eq. (31) drop, and we obtain

$$[R_p/R_s]_\mathrm{p}=i[L_R'(0)N(0)+L(0)N_R'(0)]_\mathrm{p}x+O(x^3)\,. \tag{34}$$

§ 4. The First Order Theory

If we neglect the second and the higher power terms in $x=d/\lambda$ in Eq. (33), we get

$$[R_p/R_s]_\mathrm{B}=[\rho\exp i\Delta]_\mathrm{B}=i[L_R'(0)N(0)]_\mathrm{B}\,x\,. \tag{35}$$

As $[L_R'(0)N(0)]_\mathrm{B}$ is real, this means that $\Delta_\mathrm{B}=\pi/2$, or that the Brewsterian angle φ_B agrees with the principal angle of incidence φ_p in this approximation. Accordingly,**

$$\rho_\mathrm{B}=\pm[L_R'(0)N(0)]_\mathrm{B}=\rho_\mathrm{p}\,. \tag{36}$$

$[L_R'(0)]_\mathrm{B}$ and $[N(0)]_\mathrm{B}$ are immediately obtained from Eqs. (26) and (27) respectively:

$$[L_R'(0)]_\mathrm{B}=-[ar_{2p}]_\mathrm{B}\,, \tag{37}$$

$$[N(0)]_\mathrm{B}=\left[\frac{1+r_{1s}r_{2s}}{(1+r_{1p}r_{2p})(r_{1s}+r_{2s})}\right]_\mathrm{B}\,. \tag{38}$$

---

[*] $L^{(n)}(x)$ and $N^{(n)}(x)$ represent the n-th derivatives of $L(x)$ and $N(x)$ respectively.

[**] The right sides of Eqs. (35) and (34) are identical. See Eq. (32).

$[r_{1p}]_{\mathrm{B}}$, $[r_{2p}]_{\mathrm{B}}$, $[r_{1s}]_{\mathrm{B}}$ and $[r_{2s}]_{\mathrm{B}}$ have been given in Eqs. (21)–(25). Substituting these equations into Eq. (36), we get

$$\rho_{\mathrm{B}}=\rho_{\mathrm{p}}=\pm\frac{\pi}{\lambda}\frac{\sqrt{1+\varepsilon_2}}{\sqrt{1-\varepsilon_2}}\eta\,, \tag{39}$$

where

$$\eta=\frac{(\varepsilon-1)(\varepsilon-\varepsilon_2)}{\varepsilon}d\,. \tag{40}$$

In deriving Eq. (39) we need a_{B}, the value of a for $\varphi_1=\varphi_{\mathrm{B}}$. This can be calculated by writing $\cos\varphi$ in Eq. (19) as a function of φ_1, ε_1 and ε and computing its value for $\varphi_1=\varphi_{\mathrm{B}}$.

$$a_{\mathrm{B}}=4\pi k/\sqrt{1+\varepsilon_2}\,. \tag{41}$$

Thus it has been proved that the interference theory in which the second powers in d/λ are neglected agrees with D-theory.

§ 5. The Second Order Theory

Now let us proceed to the approximation in which the terms up to the second powers in $x=d/\lambda$ are taken into account.

As is clear from its derivation, Eq. (34) holds in the second order theory as well. The parameters included in this equation can be expanded about $\varphi_1=\varphi_{\mathrm{B}}$ as follows:

$$\left.\begin{aligned}
[\boldsymbol{L}(0)]_{\mathrm{p}}&=[\boldsymbol{L}(0)]_{\mathrm{B}}+\boldsymbol{C}_1\varphi'+\cdots\,,\\
[\boldsymbol{L}_R'(0)]_{\mathrm{p}}&=[\boldsymbol{L}_R'(0)]_{\mathrm{B}}+\boldsymbol{C}_2\varphi'+\cdots\,,\\
[\boldsymbol{N}(0)]_{\mathrm{p}}&=[\boldsymbol{N}(0)]_{\mathrm{B}}+\boldsymbol{C}_3\varphi'+\cdots\,,\\
[\boldsymbol{N}_R'(0)]_{\mathrm{p}}&=[\boldsymbol{N}_R'(0)]_{\mathrm{B}}+\boldsymbol{C}_4\varphi'+\cdots\,.
\end{aligned}\right\} \tag{42}$$

Here

$$\varphi'=\varphi_{\mathrm{p}}-\varphi_{\mathrm{B}}\,. \tag{43}$$

$\boldsymbol{C}_1$, $\boldsymbol{C}_2$, $\boldsymbol{C}_3$ and $\boldsymbol{C}_4$ are functions of ε_1, ε and ε_2 which can be shown to be of the order of 1～10 for the cases usually met with. The difference between the principal angle of incidence and the Brewsterian angle, φ', must be a small quantity of the second order, because this was equal to zero in the first order theory. Hence

$$\boldsymbol{C}_i\varphi'x=O(x^3)\qquad i=1,2,3,4 \tag{44}$$

and may be neglected in the present approximation. Accordingly,

$$\begin{aligned}
[\boldsymbol{R}_p/\boldsymbol{R}_s]_{\mathrm{p}}&=i[\boldsymbol{L}_R'(0)\boldsymbol{N}(0)+\boldsymbol{L}(0)\boldsymbol{N}_R'(0)]_{\mathrm{p}}\,x\\
&=i[\boldsymbol{L}_R'(0)\boldsymbol{N}(0)+\boldsymbol{L}(0)\boldsymbol{N}_R'(0)]_{\mathrm{B}}\,x\\
&=i[\boldsymbol{L}_R'(0)\boldsymbol{N}(0)]_{\mathrm{B}}\,x\,.
\end{aligned} \tag{45}$$

The last transformation is due to Eq. (32).

Since

$$[\boldsymbol{R}_p/\boldsymbol{R}_s]_{\mathrm{p}}\equiv\pm i\rho_{\mathrm{p}}\,,$$

Eq. (45) means that ρ_{p} is again given by Eq. (36). Thus it has been proved that the interference theory in which the terms up to the second powers in d/λ are taken into account gives the same ρ for $\varphi_1=\varphi_p$ as that calculated by SG-theory if ε in the former theory is assumed to be equal to $\bar{\varepsilon}$ in the latter theory (See Eq. (13)).

$[\boldsymbol{R}_p/\boldsymbol{R}_s]_{\mathrm{B}}$ in the second order theory is given by Eq. (33) in which $O(x^3)$ is neglected. This is not equal to $[\boldsymbol{R}_p/\boldsymbol{R}_s]_{\mathrm{p}}$ given by Eq. (45). But ρ_{B}, which is calculated from Eq. (33) as

$$\rho_{\mathrm{B}}^2=[\boldsymbol{R}_p/\boldsymbol{R}_s]_{\mathrm{B}}^*[\boldsymbol{R}_p/\boldsymbol{R}_s]_{\mathrm{B}}\,,$$

can be shown to be equal to ρ_{p} in so far as $O(x^3)$ is neglected. Hence

$$\rho_{\mathrm{p}}=\rho_{\mathrm{B}} \tag{46}$$

in the second order theory as well as in the first order theory. (This relation is only implicitely suggested in Sissingh and Groosmuller's paper[3)].)

Next we shall show that Eq. (14) is consistent with the second order interference theory. Making use of the relation

$$\boldsymbol{R}_p/\boldsymbol{R}_s\equiv\rho\cos\varDelta+i\rho\sin\varDelta$$

we can compute $\varDelta_{\mathrm{B}}$, the difference in phase between the p- and the s-components at $\varphi_1=\varphi_{\mathrm{B}}$, from Eq. (33):

$$\cot\varDelta_{\mathrm{B}}=\frac{1}{2}\left[\frac{\boldsymbol{L}''(0)}{\boldsymbol{L}_R'(0)}-\frac{2\boldsymbol{N}_R'(0)}{\boldsymbol{N}(0)}\right]_{\mathrm{B}}x\,. \tag{47}$$

In this expression, $[\boldsymbol{L}_R'(0)]_{\mathrm{B}}$ and $[\boldsymbol{N}(0)]_{\mathrm{B}}$ have been calculated in Eqs. (37) and (38), and $[\boldsymbol{L}''(0)]_{\mathrm{B}}$ and $[\boldsymbol{N}_R'(0)]_{\mathrm{B}}$ can be immediately obtained from Eqs. (26) and (27). Substituting these values into Eq. (47), and further substituting Eqs. (21)–(25) for r_{1p}, r_{2p}, r_{1s} and r_{2s}, we obtain

$$\cot\varDelta_{\mathrm{B}}=\frac{a_{\mathrm{B}}}{4k}\frac{\varTheta_1}{1-\varepsilon_2{}^2}x\,, \tag{48}$$

where

$$\varTheta_1=\frac{-(1+\varepsilon_2)\{\varepsilon^2(3+\varepsilon_2)-\varepsilon(1+4\varepsilon_2-\varepsilon_2{}^2)+\varepsilon_2(1-\varepsilon_2)\}}{\varepsilon}\,. \tag{49}$$

Substituting for a_{B} from Eq. (41), and for x from Eq. (18), we finally obtain

$$\cot \Delta_B = \frac{\pi \Theta_1 d}{\lambda(1-\varepsilon_2^2)\sqrt{1+\varepsilon_2}} . \tag{50}$$

Thus it has been proved that $\cot \Delta_B$ calculated by the second order interference theory agrees with that given by SG-theory (Eq. 14) if ε in the former theory is assumed to be equal to $\bar{\varepsilon}$ in the latter theory*.

Now that the expressions for ρ_p and Δ_B in both theories agree with each other, it is almost self-evident that the same holds good of $\varphi' = \varphi_p - \varphi_B$. To make sure, we shall prove this below.

As was pointed out in the derivation of Eq. (34), the sum of the real terms in Eq. (31) must vanish for $\varphi_1 = \varphi_p$:

$$[\boldsymbol{L}(0)\boldsymbol{N}(0)]_p + \frac{1}{2}\left[\begin{vmatrix} \boldsymbol{L}''(0) & \boldsymbol{L}(0) \\ -\boldsymbol{N}''(0) & \boldsymbol{N}(0) \end{vmatrix} - \begin{vmatrix} \boldsymbol{L}_R'(0) & \boldsymbol{N}_R'(0) \\ -\boldsymbol{L}_R'(0) & \boldsymbol{N}_R'(0) \end{vmatrix}\right]_p x^2 = 0 . \tag{51}$$

Substituting from Eq. (42) and neglecting the third order terms in $x = d/\lambda$ (see Eq. (44)), we get

$$\varphi' = -\frac{1}{2\boldsymbol{C}_1[\boldsymbol{N}(0)]_B}\left[\begin{vmatrix} \boldsymbol{L}''(0) & \boldsymbol{N}_R'(0) \\ 2\boldsymbol{L}_R'(0) & \boldsymbol{N}(0) \end{vmatrix}\right]_B x^2 .$$

Here

$$\boldsymbol{C}_1 = \left[\frac{\partial \boldsymbol{L}(0)}{\partial \varphi}\right]_B , \tag{53}$$

as is clear from the derivation of Eq. (42).

All the parameters included in Eq. (51) can be written in terms of $[r_{1p}]_B$, $[r_{2p}]_B$, $[r_{1s}]_B$ and $[r_{2s}]_B$. If we further substitute for these Fresnel coefficients from Eqs. (21)–(25), we obtain

$$\varphi' = \varphi_p - \varphi_B = -\frac{2\pi^2}{\lambda^2}\frac{\varepsilon_2\sqrt{\varepsilon_2}}{(1+\varepsilon_2)(1-\varepsilon_2^2)^2}\eta\Theta \tag{54}$$

in agreement with Sissngh and Groosmuller's theory. (Here η is defined by Eq. (41), and Θ is defined as $\Theta_1 d$ using Θ_1 given by Eq. (48)).

This work was partly supported by the Scientific Research Expenditure of the Ministry of Education.

Electronmicroscopic Observations of Alkali Halide Crystals

By Tetsuhiko TOMIKI*

The Research Institute for Iron, Steel and other Metals,
Tohoku University, Sendai, Japan

(Received November 21, 1958)

A technique making a sheet of replica which casts two surfaces simultaneously is described. This was successfully applied to the alkali halide crystals which were rubbed gently with velvet or which were irradiated either with x-ray or with ultra-violet light. With using such a replica, it was possible to obtain the informations regarding to the effects which were induced by these treatments inside the crystal just beneath the outer surface, and it was also possible to measure with precision the depth in which region these treatments influenced. The results obtained were also described.

§ 1. Introduction

Except for the specimen in a form of thin film, it is usual to use the replica of a specimen as an object of the electron microscope. Though the various methods have been found for making replicas¹⁾, there remains several points to be improved. One of them will be successive electronmicroscopic observations on the same spot of the surface²⁾.

During the course of electronmicroscopic studies of the alkali halide crystals³⁾,⁴⁾ which were coloured additively or with X-ray etc., it was necessary to observe the interior of the crystal. In order to achieve this experiment, the specimen was cleaved along the {100} surface normal to the outer surface, and the fresh cleavage plane obtained was examined electronmicroscopically by means of replica techniques. Although this method offers a greater amount of informations regarding to the effects induced in the inner part of the crystal by the applied treatments, it was inconvenient to measure the distance of the observed spot from the outer surface. Moreover, according to this procedure, it was impossible to observe the interior directly beneath the outer surface.

The present paper describes the technique improved on these points.

§ 2. Method

The description is given to the case of alkali halide crystals whose replica is usually made by obliquely deposited Cr film reinforced subsequently with C film in a high vacuum (see, Fig. 1(a)). The deposited film is removed from the crystal by solving it into the water. This film is used as an object of the electron microscope.

If the proper amounts of chromium and carbon are deposited on the specimen, the deposited film both on the (010) and on the (001) planes can be removed from the surfaces as a sheet of replica, avoiding that it

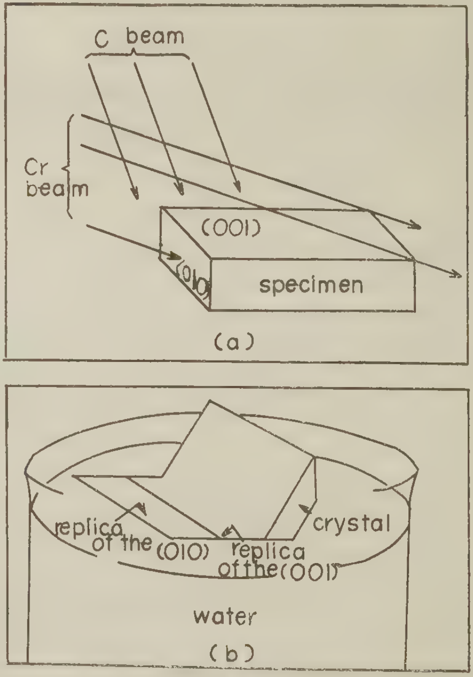

Fig. 1

* The present address: Department of Physics, The Faculty of Science, Tohoku University, Sendai, Japan.

was destroyed along the intersection of these two planes by the force of surface tension of the solvent water (see, Fig. 1 (b)). This procedure was especially favourable to the case of alkali halide crystals, because these crystals have flat cleavage surfaces and hence a linear intersection of the two cleavage planes.

Though this method is a slight modification of the one stage replica technique, this will presumably be applicable to metal which is observed by two stage replica, if the proper precautions are taken.

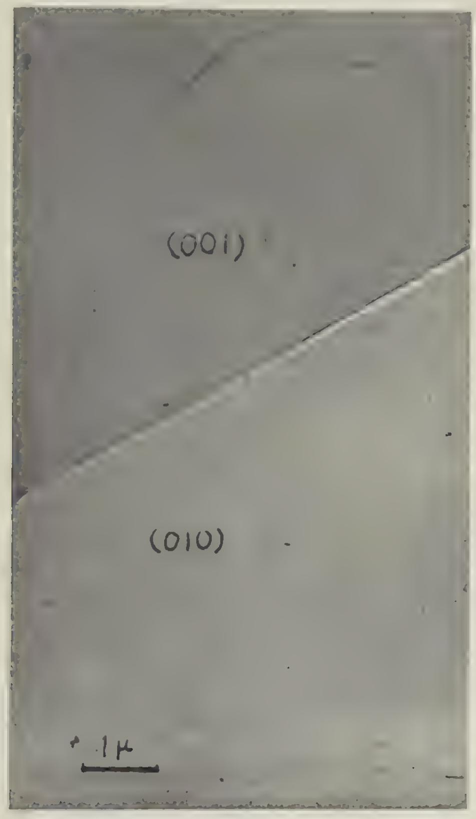

Fig. 2.

§ 3. Experimental Results

(a) After the plate of the KCl single crystal was cleaved from the block crystal, it was cut along the (010) plane normal to the outer (001) surface, and the replica was made both for the fresh (010) cleavage plane and for the outer (001) plane according to the procedure described above. Fig. 2 is the electron micrograph taken with such a replica. It can be observed that a few straight cleavage steps on the (010) plane run quite parallel to the intersection of the two planes.

(b) When the (001) surface of the KCl single crystal was rubbed gently with velvet, this surfaces turns into quite complicated one: Crystallites appear on the one part of the surface as a result of the thermal effects induced by the mechanical friction between the velvet and the surface of the crystal, and shallow grooves are formed on the other part. The latter phenomenon is probably induced both by the adhesion of the contact surfaces and by the mechanical corrosion according to the present status of the experiment of friction⁵⁾. Fig. 3 is the electron image of such a surface and the fresh (010) surface which was obtained by cutting the specimen normal to the (001) surface after the rubbing. The broken line in the figure corresponds to the intersection of the two planes. The parallelopiped crystal, whose edges are parallel to the ⟨110⟩ of the basal plane, appeared aligning along the [101] and $[\bar{1}01]$ directions on the fresh (010) plane down to the depth of 5 microns below the intersection of the two planes.

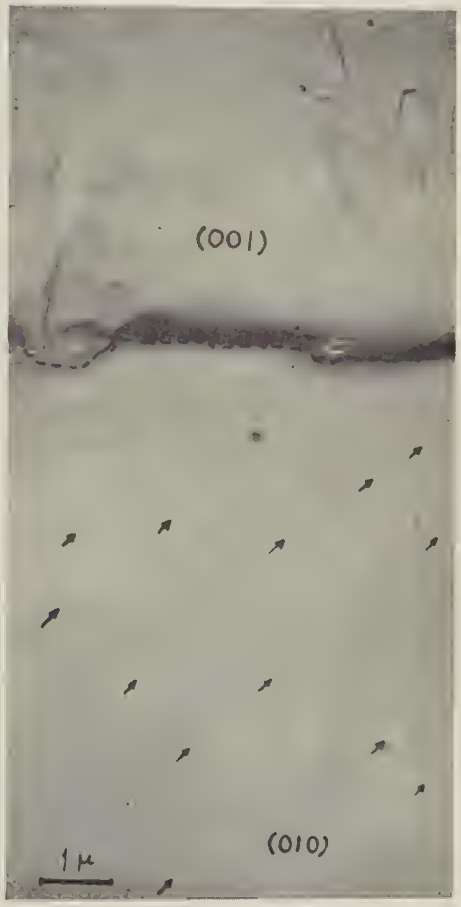

Fig. 3.

(c) Fig. 4 shows both the (001) surface of the KCl crystal which was irradiated with X-ray (Cu target; the applied potential=30 kv) and the fresh (010) plane which was obtained by cutting this crystal after the irradiation. In this case, the distance between the specimen and the X-ray source was 50 *cm*, and the irradiating time was 60 minutes. The cleavage steps on the fresh (010) plane can be seen as white lines nearly parallel to the intersection of the two planes. However, they are not straight as in the case of Fig. 2, but become to be slightly wavy. It must be noted that the crystallites did not grow on the irradiated (001) surface of this crystal (see, Fig. 4) and of the crystal which was irradiated with X-ray for 60 minutes at the distance of 5 *cm* from the target, even though the latter crystal was deeply coloured. (This fact does not contradict to the phenomena reported earlier by Hibi and Yada[2], because the crystallites of the KCl specimen come out on the X-rayed surface with the irradiation time of several hours. In the case of the KI single crystal which was irradiated with X-ray at the distance of 50 *cm* from the target for 60

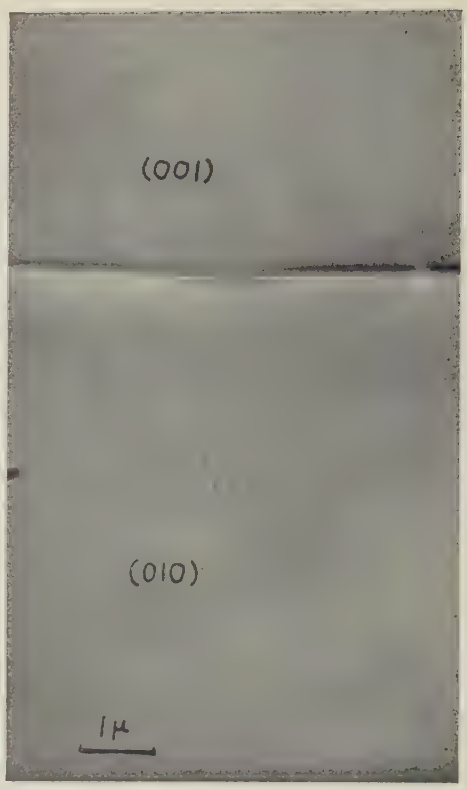

Fig. 4.

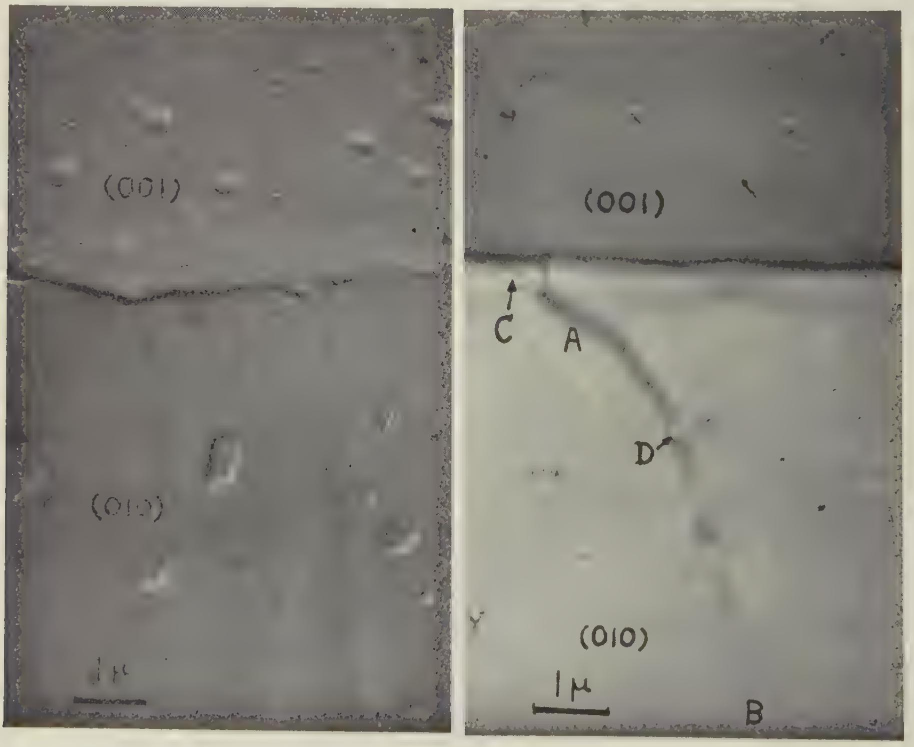

(a) (b)

Fig. 5.

minutes, the crystallites grew on the irradiated surface⁶⁾.)

(d) On the contrary, if the KCl crystal is illuminated with light lying in the tail of the first fundamental absorption band, growth of crystallites occurs both on the irradiated (001) surface and the side planes parallel to the incident beam, although the colour of the crystal was hardly observable. This is illustrated with Fig. 5 (*a*) which is the electron image both of the (001) irradiated surface and of the (010) side surface of the KCl crystal which was illuminated with ultra-violet light for 30 minutes at the distance of 1 *mm* from the light source. Here, the light source was a hydrogen dischage tube with LiF window. We can see that the crystallites grew on these surfaces. The intersection of these two planes is not a straight line, but is a zigzag which will probably represent the crystal imperfections such as the mosaic structure or the grain composed with a low angle boundary in the single crystal.

Fig. 5 (*b*) shows the (001) front surface as well as the fresh (010) cleavage plane which was produced after the illumination with ultra-violet light for 15 minutes at the distance of 1 *mm* from the light source. The wavy steps appeared on the (010) cleavage plane down to the depth of 7 to 5 microns beneath the front surface as the result of the illumination. The step **AB** corresponds to the crystal imperfection such as internal surface or the grain boundary, because this step is perpendicular to the direction of the cleavage steps. Perhaps this is the first time that such a imperfection is observed electonmicroscopically on the single crystal without the process such as etching or decoration.

The wavy steps have been confirmed electronmicroscopically that they always appear whenever the crystal growth occurs³⁾,⁴⁾. The nature of these steps have not yet been clarified, but it is probably that they are produced by the thermal spikes of excitons when they were annihilated at the crystal imperfections. The important results obtained from Fig. 5 (*b*) are as follows:—

(*i*) The crystallites on the (001) front surface grew as a result of the ionic motions inside the crystal and this fact confirms also the experimental results obtained by Hibi and Yada²⁾ (see, for example, the crystallite **C** in Fig. 5 (*b*)).

(*ii*) The step **AB** changed its shape into the zigzag one as the growth of the crystallites proceeded and this fact is also quite in agreement with the suggestions made on the previous experiments³⁾,⁴⁾.

The physical considerations regarding to these phenomena induced by irradiation with ultra-violet light will be described in detail in relation to the action of exciton in another place⁷⁾.

§ 4. Conclusions

A method for making a replica which casts simultaneously both the (001) and the (010) surfaces of alkali halide crystal was described, and some results using with such a replica proved that this method is very effective to observe the inner part of the crystal just beneath the surface on which the various treatments were applied.

Nuclear Magnetic Resonance Studies of Water Sorbed on Fibrous Materials

By Akira Odajima

Research Institute of Applied Electricity,
Hokkaido University, Sapporo

(Received August 6, 1958)

Nuclear magnetic resonance of the water molecules sorbed on the native cellulose, " mulbery paper " was studied.

The measurements of the line width were made under the condition of water content ranging from 10 to 180% at 20°C, by using Varian high resolution type spectrometer.

Within the range of 10 to 20%, the line widths rapidly decreased with increasing water content, and gradually decreased beyond the region. Although this tendency was similar to that of dielectric relaxation, the experimental value of τ_N obtained from Kubo-Tomita equation was much greater in the order of magnitude than that of the dielectric relaxation time τ_D. Accordingly, τ_N and τ_D do not satisfy the BPP's relation of $\tau_N=1/3\cdot\tau_D$. This result suggested to us that the water molecules in the sorbed state do not rotate with spherical symmetry like in the liquid state.

§1. Introduction

Several authors have recently measured the motion of water molecules in the sorbed state, using a nuclear magnetic resonance (NMR) method.[1)-3)]

When the molecular motion becomes rapid and the correlation time small, a high homogeneity of the magnetic field is necessary to measure the line width of absorption line narrowed by the motional-narrowing. Accordingly, no experiment has not yet been made except in the case of low water content, namely except in the case of rather restricted motion.

We tried to extend the measurement in the region of high water content, by using a high resolution magnet of Varian Association Spectromete.r[*)]

According to either BPP theory[4)] or Kubo-Tomita's one[5)], spin-lattice relaxation time T_1 and spin-spin relaxation time T_2 are related with the correlation time τ_N of Brownian motion of nuclear spins. Thus, we can get τ_N through the observation of either T_1 to T_2.

On the other hand, the relaxation time τ_D for the reorientation of the electric dipole of sorbed water molecules has been obtained through the measurements of the dielectric relaxation.[6)-8)] Both τ_N and τ_D are the parameters indicating molecular motion and are expected not to be independent of each other. If we assume the spherical symmetric rotation of a molecule, the theory of Brownian motion gives us the following relation between τ_N and τ_D

$$\tau_N=1/3\cdot\tau_D=4\pi\eta a^3/3k_0T\ , \qquad (1)$$

where η is the viscosity coefficient, and a the radius of molecule. It is well known by experiments that Eq. (1) holds approximately in the case of liquid.[4)] However, our experiments showed that Eq. (1) does not hold for water molecules sorbed on fibrous materials.

At the last section it is discussed that it may be appropriate to consider the unspherical symmetric rotation for the motion of sorbed water insteated of the spherical symmetric ones.

§2. Measurements and Results

Employing a Varian high resolution type NMR spectrometer, we have measured the line widths of water sorbed on the native cellulose, " mulberry paper ", in the range of the water contents from 10 to 180% (weight of sorbed water/weight of dry cellulose) at 20°C. Samples were placed in 6 mm O.D. glass

---

[*)] NMR measurements were carried out at the Chemical Research Institute of Non-Aqueous Solutions, Tohoku University.

tube. The portion of the magnetic field occupied by the samples was found to be uniform within 0.9 milligauss. For samples whose water content was less than 10%, the line widths were too broad to be detectable. This means that the absorption line due to protons in the cellulose is undetectable. The examples of the line width are shown in Fig. 1.

At first it seemed probable to presume that the motion of the OH groups in the cellulose, which are free from hydrogen bonds, becomes more active, as the water content increases. However, in the measurement on the cellulose diacetate-acetone solution within 10% (weight of cellulose/weight of solvent), the absorption line due to the CH_3 group is the only observable and no other absorption lines coming from OH and CH are observable as shown in Fig. (1d). These facts tell us that the freedom of the motion of each radical in the cellulose is hindered considerably even in the case of a liquid solution. Thus, we can reasonably assume that the protons in the water molecules absorbed on the cellulose are the only observable.

Half width *vs.* water content is shown in

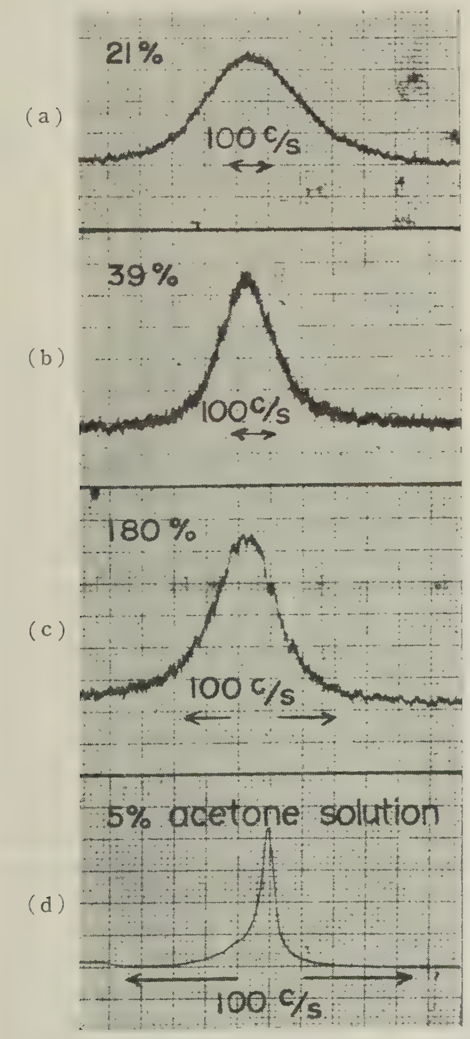

Fig. 1. Absorption lines of sorbed water on the native cellulose (a, b, c) and that of diacetate-acetone solution. (a) 21% (b) 39% (c) 180% (d) 5% acetone solution

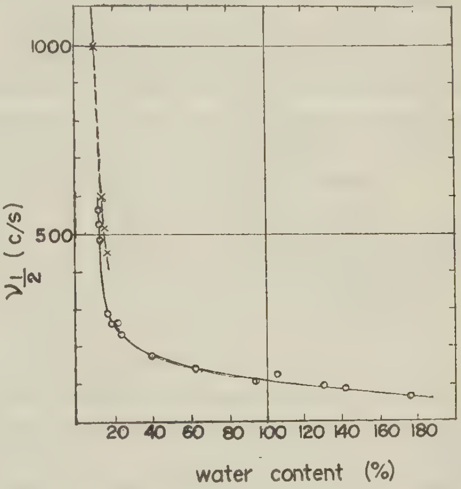

Fig. 2. Variations of half width of absorption lines vs. water content. (—○—○—) Our data, (—×—×—) Shaw's data.

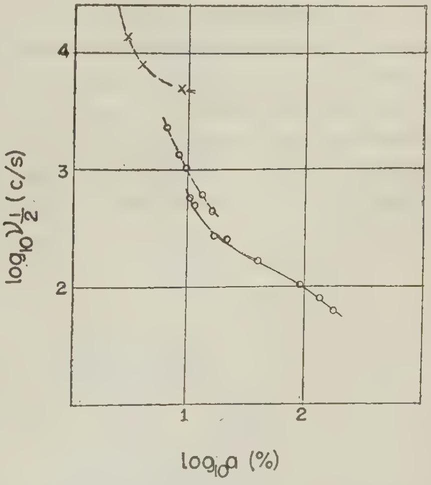

Fig. 3. Variation of half width of lines as a function of water content A (%) in the logarithmic scale. Solid line represents our data. One of the broken line (- - × - - × - -) represents Tanaka's data and the other (- -○- -○- -) Shaw's data.

Fig. 2. In Fig. 3 the data obtained by other researchers,[1)–2)] are shown for comparison with our data. There is a fairly good agreement between the gradients of each curve in the same range of concentration. As is shown in Fig. 2 and Fig. 3, the line widths rapidly decrease with increase with increasing water content within the range of the water content of 10 to 20%, and gradually decrease beyond the region.

§ 3. Apparent Correlation Time of NMR

The theories of Kubo-Tomita[5)] and Solomon[9)] show that the line width may be expressed in terms of the correlation time, τ_N. If the correlation function of the local magnetic dipolar field is given by the following equation, in the condition of $\tau_N < \omega^{-1}$,

$$K(t) = \exp(-|t|/\tau_N) , \tag{2}$$

the spin-spin relaxation time T_1 of two spin system is expressed by

$$T_2^{-1} = \frac{3}{20} \frac{\hbar\gamma^4}{b^6} \left[3\tau_N + \frac{5\tau_N}{1+\omega^2\tau_N^2} + \frac{2\tau_N}{1+4\omega^2\tau_N^2} \right] , \tag{3}$$

where γ is the nuclear gyromagnetic ratio and b is the inter-proton distance in a water molecule.

In the derivation of Eq. (3), the inter-molecular interaction is neglected, but this approximation is supposed to be unreasonable in case of a considerable amount of sorbed water. The contribution from inter-molecular protons to T_2 is estimated to be the same order with that from intra-molecular protons, in the case of free water.[4)] Consequently, it shoud be considered that the spin-spin interaction between protons in another molecules contributes to T_2 of sorbed water in addition to between protons in a water molecule.

If we assume the correlation time as the type of Eq. (2), however, it is shown by Kubo-Tomita[5)] that Eq. (3) consists too in many spin system, substituting for b^{-6} to $\sum_j b_j^{-6}$ where $\sum_j$ means the summation over inter-molecular protons.

T_2 is also given by another form of

$$T_2^{-1} = \frac{\langle \sigma_0^2 \rangle}{3} \left\{ 3\tau_N + \frac{5\tau_N}{1+\omega^2\tau_N^2} + \frac{2\tau_N}{1+4\omega^2\tau_N^2} \right\} , \tag{4}$$

where $\langle \sigma_0^2 \rangle$ is the second moment of rigid case. It is shown that the spin-spin relaxation time $(T_2)_0$ in the rigid case is given by

$$(T_2^{-1})_0 = \sqrt{\langle \sigma_0^2 \rangle} . \tag{5}$$

As the $(T_2)_0$ of sorbed water, we will use the value measured for ice at −40°C,

$$(T_2)_0 = 5 \times 10^{-6} \text{ sec.} \tag{6}$$

In the case that an absorption line is sharpened in the type of the Lorentian curve, a half width is related to T_2 by the following equation

$$\Delta\nu_{1/2} = T_2^{-1}/\pi + \Delta\nu' , \tag{7}$$

where $\Delta\nu'$ is a broadening due to an inhomogeneity of a magnetic field.

Using above equations, from Eq. (4) to Eq. (7), we have a relation between τ_N and the water content, which is shown in Fig. 4. In the same figure, we have plotted a similar relation between dielectric relaxation time τ_D and the water content in case of wood[6)], paper,[7)] and starch.[8)] It is worth noted that τ_N is much larger than τ_D in the same concentration.

§ 4. Comparison with the Dielectric Measurement

According to the dielectric measurements on sorbed water[7)], sorbed water is classified into two classes, that is, localized sorbed water and mobil sorbed water, the latter having two states moreover. Also, through the dielectric measurements the states of sorbed water are grouped by water content into three categories, viz. 0–5%, 5–20% and over 20%.[6)] Comparing the molecular polarizability of each state of sorbed water, Windle and Shaw[10)] concluded that localized water was bound so that it had little freedom of rotation.

In the NMR measurement of sorbed water, the observation of the line width due to localized water is beyond the range of the observation of our apparatus. Therefore, the observed variation of the line widths, which are plotted in Figs. 2 and 3, are reasonably expected to come from mobile water. It is quite apparent that mobile water is not unique but divided into two states having different dependence on water content, that is, the state with a sharp gradient and that with a gradual gradient. The boundary of these states is at the water content of 20%. According to the conventional idea of a mobile state of sorbed water, such a water molecule is expected to be similar to water in the liquid phase[10]. However, these authors[10] found that the molecular polarizability of mobile water was smaller than that of free water, and also explained this fact by assuming that mobile water consists of the truly mobile water molecule, which is quite similar to free water, and intermediate water, which is in a intermediate state between localized and truly mobile ones. This interpretation seems to be qualitatively applicable to the explanation of the existence of the two states of mobile water in the NMR observation.

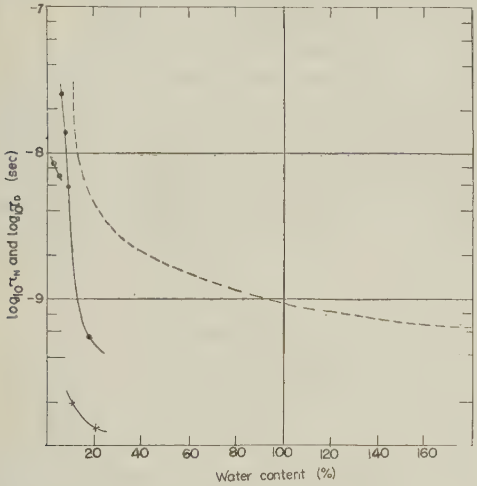

Fig. 4. Comparison of the correlation times τ_N of NMR calculated from Eq. (2) with the dielectric relaxation times τ_D at 20°C, respectively. Broken curve represents τ_N. Solid curves represent τ_D obtained from Takeda's data (--×--×--), Seidman's data (--○--○--) and and Ono's data (—●—●—). Ono's curve is plotted bxtrapolating from the values at −15°C to those at at 20°C.

§ 5. Discussion and Conclusion

Although there is a qualitative similarity between two correlation times τ_N and τ_D, there is a quantitative discrepancy between the experimental result shown in Fig. 4 and the relation expected from Eq. (1), as mentioned in the preceding section.

In the free water molecule, τ_N and τ_D are found to be about 10^{-11} sec. Then, the experimental value of τ_N of sorbed water is seemed to be anomalously greater in the order of magnitude than that of free water.

Concerning the reason why the order of magnitude of τ_N differs from τ_D, we were inclined to presume that the water molecules in the sorbed state do not rotate with spherical symmetry even in mobile water, because τ_N must be in the same order of magnitude with that of τ_D is the spherical symmetric rotation as is shown in Eq. (1). In the liquid phase the water molecules rotate breaking the hydrogen bond among molecules, and the rate of this breaking is expected to proceed isotropically. Thus it is possible to treat such a rotation as a spherical symmetric.

In the sorbed state, however, some of the water molecules are bound so strongly with hydrophilic group of the adsorbent that these molecules are considered to be localized. The remainder of the sorbed water molecules is expected to deposit on the monolayer of such localized water molecules. The farther from the adsorbent the water molecules deposit, the more freely the water molecules can move. Thus, as the water content increases, the fraction of free water molecules increase. On the other hand, the fibre is swollen by the water molecules which are sorbed among the non-crystallized state of the fibre. Hence, the interaction between water and the cellulose molecules which are sorbed at the non-crystallized parts of fibre may be expected to rotate as freely in the plane of adsorbed layer as free water does, but such molecules are also expected to be strongly bound in the vertical direction of the sorbing surface.

It is easily shown that Eq. (3) is not satisfied in the simplest 2-dimensional case in the unspherical symmetric rotation. Namely, the term of finite value caused by the stationary part of the magnetic dipolar field fluctuating randomly still remains in the line width, though the correlation time τ_N becomes very small. The term was given by Gutowsky and Pake[11] as follows:

$$(T_2^{-2})_{rot}=\frac{1}{4}(3\cos^2\alpha-1)(T_2^{-2})_{rig}\,, \qquad (8)$$

where α is the angle between a direction of a nucleus paier and an axis of rotation.

Therefore, if we apply Eq. (3) to the case of the restricted motion of molecules, the correlation time obtained from Eq. (3) will be no more than an apparent one. We should consider a modification of Kubo-Tomita's equation[5] to apply to the general case of unspherical symmetric rotations of molecules.

However, it seems to us that the mechanisms, by which the anomaly in the apparent correlation time is caused in the sorbed state of water, are very complicated. One of them may be supposed to be the fact that the potential barrier hindering the rotation of water molecules is existent in the sorbed state of water. We have already given the theory on the restricted rotation in the field of the potential barrier and the application to T_1 and T_2 of NMR.[12)] But, it may be doubtful that the hindering potential is kept in constant within the correlation time of the Brownian motion of water molecules without being disturbed from thermal fluctuations.

If it is considered that the time variation of the potential barrier occurs rapidly, we had better consider that the rotational motion of water molecules is anisotropic. It is thus considered that values of mobilities are not equal in the vertical and the horizontal direction to the absorbent plane. The anisotropic Brownian motion of molecules has been also reported by us in another paper.[13)]

Both of these mechanisms give the modification of Eq. (3) to T_2 and correct meaning to the correlation time not being the apparent correlation one.

If we take into account effects of the unspherical symmetry rotations, we may come to a conclusion that there is a possibility to give agreement between the NMR results and dielectric result of sorbed water. It is not yet decided, however which mechanisms mentioned above should be correct in the sorbed state of water, because we have to have more accurate information of motions in sorbed water.

In conclusion it may be desirable to measure the spin-lattice relaxation time T_1 in addition to T_2 and especially to obtain the activation energy of motions from data of T_1 and T_2 *vs.* temperature relation. The discussion of these problems will be given in the near future.

Although the effects of multiple phase were treated for T_1 and T_2 of sorbed water,[3),14)] the present paper neglected the non-uniformity of the sorbed state, since the water molecules sorbed on fibrous materials are considered to be distributed uniformly.

However, it seems to us unquestionable that the BPP relation of $\tau_N=1/3\cdot\tau_D$ would not hold for many other cases of the molecular motions, for instance, in case of the molecular motion of polymeric materials in the region of temperature above "glassy transition temperature". Further considerations toward these lines are being undertaken.

Acknowledgement

The author would like to express his hearty thanks to Professor S. Watanabe, Faculty of Engineering, Hokkaido University for his helpful suggestions and co-operations.

Thanks are also due to Professor G. Hazato and his co-workers at Tohoku University for their kind co-operations to carry out measurements, and Assistant Professors A. Miyake, Shizuoka University and J. Sohma, Hokkaido Gakugei University for invaluable discussions and helps.

Phenomenological Theory of Visco-elasticity of Three Dimensional Bodies

Misazo YAMAMOTO
*Department of Chemistry, Faculty of Science,
Kyoto University*

(Received October 29, 1958)

A phenomenological theory of the non-linear visco-elasticity of three dimensional bodies is presented. We start from the two elementary models of the classical linear theory of visco-elasticity, that is, the so-called Maxwell and Voigt models. These models are extended to three dimensional non-linear case by adopting the energy consideration. The three dimensional Maxwell model is defined by "series connection" of a "non-Hookeian spring", i.e. the internal elastic mechanism and a "non-Newtonian dashpot", the energy dissipation mechanism, and the three dimensional Voigt model is represented by the "parallel connection" of these mechanisms. Making use of the Maxwell model, we discuss the tensile viscosity for the stationary simple elongation of elastico-viscous liquids. Our models are shown to be successful in analyzing the so-called normal stress effects, i.e., the Weissenberg effect for elastico-viscous liquids and the Poynting effect for visco-elastic solids. The non-linearity in visco-elastic properties is classified into three cases: elastic, viscous or relaxational, and geometric non-linearities. An essential feature of the three dimensional bodies is the geometric non-linearity. The typical examples of this are the said normal stress effects and the velocity gradient dependence of the tensile viscosity coefficient.

§ 1. Introduction

Elegant phenomenological theories[1] on linear visco-elasticity have been developed since the foremost works of Maxwell,[2] Voigt,[3] Kelvin[4] and others. In these theories two fundamental models and the so-called superposition principle play important roles. One of the two models is the Maxwell model corresponding to viscous liquids having instantaneous rigidity (elastico-viscous liquids), and the other is the Voigt model corresponding to elastic solids possessing retarded elasticity (visco-elastic solids). These are schematically represented by series and parallel connections of a spring and a dashpot, respectively. The mechanical properties of each model can be described in terms of strain and stress by a suitable first order linear differential equation with respect to time. Making use of the superposition principle the theories have been extended to cases of more general visco-elastic properties which are described by suitable higher order differential equations. This generalization corresponds to considering the generalized Maxwell model which is a parallel connection of a number of Maxwell models, or to considering the generalized Voigt model which is a series connection of several Voigt models. Furthermore the relaxation time spectrum and/or the retardation time spectrum have been introduced to characterize these generalized models, in terms of which various mechanical properties of these materials can be consistently described. From the mathematical point of view they have the same structure as in the cases of electric circuits, dielectrics, etc. In fact these theories have been unified in the form of the so-called excitation-response theory.[5]

Recently, several observations have been made on a number of mechanical behaviors including large deformations of the samples, stimulated by the progress made in chemical physics of highpolymeric substances. Examples of these phenomena are the so-called structural viscosity (non-Newtonian flow),[6] the Weissenberg effect,[7] etc. Many of these phenomena cannot be described by the said classical linear theories. The structural viscosity is a typical example which results from the non-linearity in stress-strain relations. As to the Weissenberg effect, we observe not the shearing stress but the normal stress components for simple shearing flow, as has been pointed out in the preceding paper.[8)] These normal components are, moreover, essentially non-linear with respect to the rate of shearing (the velocity gradient). Thus, it is not only the non-linearity in stress-strain relations but also the three dimensional character of bodies that should be considered in the study of such mechanical properties. Here we can see the essential difference from linear cases such as electric circuits, etc.

In the case of purely elastic materials, three dimensional phenomenological theories of elasticity involving non-linear properties have been successfully developed by several authors. Their details are given, for example, in Novozhilov's text, Truesdell's review articles, etc.[9)–12)] The tension vs. elongation curve of vulcanized rubber is upword convex in the range of relatively small elongation. Mooney[13)] showed that this behavior is due to the shrinkage of free sides of the sample which corresponds to the incompressible character of this material. When a cylindrical piece of certain elastic materials such as steel, lead or vulcanized rubber is subjected to a torsional couple, the cylinder shows a change in its length (usually it elongates).[14)] We call this interesting phenomenon the Poynting effect. Mooney[11)] and Rivlin[12)] pointed out that, in order to constrain the simple shearing deformation to these elastic materials, it is necessary to apply an additional tension in the deformation-direction the magnitude of which is proportional to the square of the displacement gradient. They also suggested that the Poynting effect is essentially due to this additional normal tension. Accordingly in the recent terminology, both this effect and the Weissenberg effect which is considered to be the visco-elastic analogue of that effect, are called the normal stress effects.

In the meantime, the theory of elasticity has been established so general that the stress tensor is given its expression for *any* finite deformation of three dimensional bodies, with the help of differential geometry, and that many elastic behaviors are successfully analyzable by this general theory. As regards visco-elasticity, on the other hand, the phenomenological theory mentioned at the beginning of this section just corresponds to the classical *linear* theory of elasticity. And it has been hoped to extend the theory to include the said non-linear three dimensional visco-elastic effects. Indeed several attempts have been made for this purpose up to the present,[15)–18)] but there is no satisfactory theory yet, we believe. Many of these were carried out by applying the simple mechanical models (the Maxwell model and/or the Voigt model) independently to every component of the stress and strain tensors. It is needless to say that these theories cannot describe the cross effect such as the Weissenberg effect.

In this paper, we shall try to formulate phenomenologically a general theory of visco-elasticity in due consideration of the non-linear as well as three dimentional characters. To this end, we start from the Maxwell and the Voigt model which are essentially one dimensional, and extend them to corresponding three dimensional ones. Then it will be shown that the three dimentional Maxwell model has the mechanical properties of elastico-viscous liquids, whereas the three dimensional Voigt model corresponds to visco-elastic solids. Furthermore, non-linearity of the stress-strain relations will be classified into three categories: elastic, viscous (relaxational) and geometric non-linearities. It will be suggested that the structural viscosity is mostly due to the relaxational non-linearity. The Weissenberg effect is essentially the geometric effect, thereby the elastic and relaxational non-linearities being of minor importance.

In Part A of this paper we review the one dimensional models and then give the general consideration for their three dimensional extension. The three dimensional Maxwell model is treated in Part B, and the Voigt model in Part C. Simple elongations (compressions) and simple shearings are also studied in those parts for each of the two models. We treat the so-called tensile viscosity for steady simple elongation of the elastico-viscous liquids and the Poynting effect of the *visco-elastic solids*. In Part D we discuss about the classification of non-linearity and about the generalization of the models.

A. General Consideration

§ 2. Maxwell Model and Voigt Model

In this section, we shall review the classical, one dimensional mechanical models. The so-called Maxwell model and Voigt model are represented by series and parallel connection of a spring and a dashpot, respectively. The spring obeys the Hooke's law

$$\sigma_E=\kappa\alpha_E \tag{1}$$

and the dashpot contains the Newtonian liquid

$$\sigma_\eta=\eta\alpha_\eta\ . \tag{2}$$

σ and α are stress and strain, respectively. The suffixes E and η denote the elastic and the viscous part of them, κ the elastic modulus, and η the viscosity coefficient. Then, these two models are characterized by the conditions

$$\sigma=\sigma_E=\sigma_\eta \qquad \text{(Maxwell)} \tag{3}$$

and

$$a=\alpha_E=\alpha_\eta\ , \qquad \text{(Voigt)} \tag{4}$$

respectively, with apparent stress σ and apparent strain a.

Denote the work done by external force per unit time by dW/dt, the rate of change of the elastic energy in the system by dw/dt, and the rate of energy dissipation by $\delta\mathcal{E}/dt$, in the unit volume of material. Now we have

$$\frac{dW}{dt}=\sigma\dot{a}\ , \tag{5}$$

$$\frac{dw}{dt}=\sigma_E\dot{\alpha}_E \tag{6}$$

and

$$\frac{\delta\mathcal{E}}{dt}=\sigma_\eta\dot{\alpha}_\eta\ . \tag{7}$$

The law of energy-conservation

$$\frac{dW}{dt}=\frac{dw}{dt}+\frac{\delta\mathcal{E}}{dt} \tag{8}$$

can be written as follows:

$$\sigma\dot{a}=\sigma_E\dot{\alpha}_E+\sigma_\eta\dot{\alpha}_\eta\ . \tag{9}$$

Eqs. (1)–(4) and (9) lead the well-known stress-strain relations

$$\dot{a}=\frac{\dot{\sigma}}{\kappa}+\frac{\sigma}{\eta} \qquad \text{(Maxwell)} \tag{10}$$

and

$$\sigma=\kappa a+\eta\dot{a}\ . \qquad \text{(Voigt)} \tag{11}$$

In the extension of those models to three dimensional non-linear case, we may adopt Eqs. (3), (4) and (8) as the fundamental equations of the theory.

§ 3. Deformation and Internal Deformation

Let us consider a deformation of visco-elastic material, owing to which two points A_0 and B_0 initially at a close distance $\overrightarrow{A_0B_0}=\varDelta\boldsymbol{r}_0$ in the material are shifted during a time interval t to A and B at distance $\overrightarrow{AB}=\varDelta\boldsymbol{r}$, respectively. The deformation tensor $\boldsymbol{a}(t)$ may be defined as

$$\varDelta\boldsymbol{r}=\boldsymbol{a}(t)\cdot\varDelta\boldsymbol{r}_0\ , \tag{12}$$

refering to a spatially fixed coordinate system. $\boldsymbol{a}(t)$ is either a symmetric or an asymmetric tensor depending on the nature of deformation.

Consider the change of deformation in the time interval $(t,\ t+\delta t)$. Eq. (12) leads to

$$\varDelta\boldsymbol{r}+\delta(\varDelta\boldsymbol{r})=(\boldsymbol{a}+\delta\boldsymbol{a})\cdot\varDelta\boldsymbol{r}_0=(\boldsymbol{1}+\delta\boldsymbol{a}\cdot\boldsymbol{a}^{-1})\cdot\varDelta\boldsymbol{r}\ , \tag{13}$$

which means that the deformation produced in δt is represented by $(\boldsymbol{1}+\delta\boldsymbol{a}\cdot\boldsymbol{a}^{-1})$. The time rate of change in the relative coordinate of two points $\varDelta\boldsymbol{r}$ is, then, given by

$$\frac{d(\varDelta\boldsymbol{r})}{dt}=\frac{d\boldsymbol{a}}{dt}\cdot\boldsymbol{a}^{-1}\cdot\varDelta\boldsymbol{r}\ . \tag{14}$$

Besides the above deformation tensor, we will soon introduce two "internal" deformation tensors $\boldsymbol{a}_E$ and $\boldsymbol{a}_\eta$ which are responsible for elastic and dissipative mechanisms, respectively. Whereas $\boldsymbol{a}$ is directly observable quantity in the measurement of deformation, $\boldsymbol{a}_E$ and $\boldsymbol{a}_\eta$ are virtual quantities corresponding to change in lengths of spring and dashpot, respectively, in the classical visco-elastic models. The equations analogous to Eqs. (12) and (14) may be supposed to hold for these internal deformation tensors, if suitable definitions are given to displacements in internal mechanisms.

§ 4. Energy Relation

The rate of displacement of points on the surface of a unit cube of material is represented by deformation-rate tensor $(d\boldsymbol{a}/dt)\cdot\boldsymbol{a}^{-1}$. Hence, denoting the stress tensor as $\boldsymbol{\sigma}$, the time-rate of work done by external force per unit volume of the material is written in the form

$$\frac{dW}{dt}=\Sigma_{ij}\sigma_{ij}\left(\frac{d\boldsymbol{a}}{dt}\cdot\boldsymbol{a}^{-1}\right)_{ij}$$

$$=\mathrm{Sp}\left[\boldsymbol{\sigma}\cdot\frac{d\boldsymbol{a}}{dt}\cdot\boldsymbol{a}^{-1}\right], \tag{15}$$

with the well-known stability condition $\boldsymbol{\sigma}=\boldsymbol{\sigma}^{+}$, where $+$ denotes the transposed tensor.

The analogous expressions may be written down for two internal mechanisms. Let us introduce the effective internal stress tensors $\boldsymbol{\sigma}_E$ and $\boldsymbol{\sigma}_\eta$ which correspond to forces acting on the spring and the dashpot, respectively, in the classical sense. The rate of change of the elastic energy per unit volume of material may be read

$$\frac{dw}{dt}=\mathrm{Sp}\left[\boldsymbol{\sigma}_E\cdot\frac{d\boldsymbol{\alpha}_E}{dt}\cdot\boldsymbol{\alpha}_E{}^{-1}\right], \tag{16}$$

and the rate of energy dissipation will be given

$$\frac{\delta\mathcal{E}}{dt}=\mathrm{Sp}\left[\boldsymbol{\sigma}_\eta\cdot\frac{d\boldsymbol{\alpha}_\eta}{dt}\cdot\boldsymbol{\alpha}_\eta{}^{-1}\right]. \tag{17}$$

The law of energy-conservation

$$\frac{dW}{dt}=\frac{dw}{dt}+\frac{\delta\mathcal{E}}{dt} \tag{8}$$

must be satisfied by these rates of energy change. The second law of thermodynamics requires non-negative dissipation of energy, that is,

$$\frac{\delta\mathcal{E}}{dt}\geq 0\,. \tag{18}$$

B. Maxwell Model

§ 5. Internal Deformation in Maxwell Model

The three dimensional Maxwell model may be characterized by the condition

$$\boldsymbol{\sigma}=\boldsymbol{\sigma}_E=\boldsymbol{\sigma}_\eta\,, \tag{19}$$

which is the analogue of Eq. (3). From Eqs. (15)-(17) and (19) we find a particular solution of Eq. (8):

$$\frac{d\boldsymbol{\alpha}}{dt}=\frac{d\boldsymbol{a}}{dt}\cdot\boldsymbol{a}^{-1}\cdot\boldsymbol{\alpha}+\left(\frac{d\boldsymbol{\alpha}}{dt}\right)^{*}, \tag{20}$$

where we have made use of the abbreviations

$$\boldsymbol{\alpha}\equiv\boldsymbol{\alpha}_E \tag{21}$$

and

$$\left(\frac{d\boldsymbol{\alpha}}{dt}\right)^{*}\equiv-\frac{d\boldsymbol{\alpha}_\eta}{dt}\cdot\boldsymbol{\alpha}_\eta{}^{-1}\cdot\boldsymbol{\alpha}_E\,. \tag{22}$$

Eq. (20) may be interpreted as follows: For the case of visco-elastic material, the deformation tensor $\boldsymbol{a}(t)$ which can be observed does not directly give the situation of the internal elastic mechanism or the stress state. For instance, actually the state of internal elastic mechanism may relax even when the observed deformation is fixed.

Define the internal deformation tensor $\boldsymbol{\alpha}$ as the deformation tensor of equivalent elastic material exhibiting the same stress state as in our visco-elastic material. If the dissipative mechanism were absent, the real and internal deformations produced in the time interval δt

$$(\mathbf{1}+\delta\boldsymbol{a}\cdot\boldsymbol{a}^{-1})\text{ and }(\mathbf{1}+\delta\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^{-1}) \tag{23}$$

should be identical. In the actual case, however, there occurs a difference between them due to dissipation mechanism. This is the meaning of Eq. (20).

The dissipative term in Eq. (20), $(d\boldsymbol{\alpha}/dt)^*$ must satisfy the following restrictions:

i) $$(d\boldsymbol{\alpha}/dt)^*\to\mathbf{0}\quad\text{with}\quad\boldsymbol{\alpha}\to\mathbf{1}\,. \tag{24}$$

ii) The energy of dissipation must be non-negative:

$$\frac{\delta\mathcal{E}}{dt}=\mathrm{Sp}\left[\boldsymbol{\sigma}\cdot\left(\frac{d\boldsymbol{\alpha}}{dt}\right)^{*}\cdot\boldsymbol{\alpha}^{-1}\right]\geq 0\,. \tag{25}$$

In what follows, except in § 12, we shall adopt a simplest form of the dissipative term

$$\left(\frac{d\boldsymbol{\alpha}}{dt}\right)^{*}=-\beta(\boldsymbol{\alpha}-\mathbf{1})\,, \tag{26}$$

where β is a positive scalar function depending on the invariants associated with the internal deformation tensor $\boldsymbol{\alpha}$. Eq. (26) satisfies the above restrictions. β represents a measure of the rate of dissipation, and $\tau=1/\beta$ is the so-called relaxation time. When β is constant, we may call Eq. (20) to be linear.

Eq. (20) with Eq. (26) determines the internal deformation tensor $\boldsymbol{\alpha}(t)$ with the knowledge of the apparent deformation $\boldsymbol{a}(t)$ as a function of time.

§ 6. Internal Strain Tensor and Strain Energy

The internal deformation tensor $\boldsymbol{\alpha}(t)$ is in general a real asymmetric tensor. However, there are an orthogonal tensor $\boldsymbol{R}$ and two *real positive* symmetric tensors $\boldsymbol{\alpha}_s$ and $\boldsymbol{\alpha}_s'$ such that

$$\boldsymbol{\alpha}=\boldsymbol{R}\cdot\boldsymbol{\alpha}_s=\boldsymbol{\alpha}_s'\cdot\boldsymbol{R} \tag{27}$$

where

$$\boldsymbol{R}^{+}\cdot\boldsymbol{R}=\boldsymbol{R}\cdot\boldsymbol{R}^{+}=\boldsymbol{1}\,, \tag{28}$$

$$\boldsymbol{\alpha}_s\cdot\boldsymbol{\alpha}_s=\boldsymbol{\alpha}^{+}\cdot\boldsymbol{\alpha}\,,\quad \boldsymbol{\alpha}_s'\cdot\boldsymbol{\alpha}_s'=\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^{+}\,, \tag{29}$$

and $\boldsymbol{\alpha}_s$ and $\boldsymbol{\alpha}_s'$ have the same eigenvalues. Geometrically $\boldsymbol{R}$ corresponds to a rotation, and $\boldsymbol{\alpha}_s$ and $\boldsymbol{\alpha}_s'$ to pure extension or compression along each of three principal directions. Eq. (29) implies that arbitrary deformation $\boldsymbol{\alpha}$ is given by a "pure deformation" $\boldsymbol{\alpha}_s$ preceding to a rotation $\boldsymbol{R}$, or $\boldsymbol{\alpha}_s'$, following to $\boldsymbol{R}$. We shall call $\boldsymbol{\alpha}_s$ and $\boldsymbol{\alpha}_s'$ right and left internal strain tensors, respectively. The left internal strain tensor $\boldsymbol{\alpha}_s'$ defines the internal strain ellipsoid in the deformation state. On the other hand, three principal axes of the right internal strain tensor $\boldsymbol{\alpha}_s$ give the initial directions of the principal axes of internal strain ellipsoid. $\boldsymbol{R}$ represents the mutual rotation of the material during the deformation.

A internal deformation tensor will physically be characterized by a set of three invariants associated with its internal strain tensor, because the internal state of the material may not be affected by pure rotation. While the factors I_1, I_2 and I_3 of λ^2, λ^1 and λ^0, respectively, of the eigenvalue equation,

$$|\boldsymbol{\alpha}_s-\lambda\boldsymbol{1}|=0 \tag{30}$$

give an example of such a set, it will be convenient to take instead the following three expressions:*)

$$I\equiv I_1=\mathrm{Sp}\,\boldsymbol{\alpha}_s=\mathrm{Sp}\,\boldsymbol{\alpha}_s'\,, \tag{31}$$

$$\begin{aligned} J&\equiv I_1^2-2I_2\\ &=\mathrm{Sp}\,\boldsymbol{\alpha}_s\cdot\boldsymbol{\alpha}_s=\mathrm{Sp}\,\boldsymbol{\alpha}_s'\cdot\boldsymbol{\alpha}_s'\\ &=\mathrm{Sp}\,\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^{+}=\mathrm{Sp}\,\boldsymbol{\alpha}^{+}\cdot\boldsymbol{\alpha}\end{aligned} \tag{32}$$

and

$$K\equiv I_3=|\boldsymbol{\alpha}_s|=|\boldsymbol{\alpha}_s'|=|\boldsymbol{\alpha}|\,. \tag{33}$$

Any scalar function of deformation will have to be considered to depend solely on these three invariants. The increment of free energy density in the material due to internal elastic deformation is a typical example of such scalar functions:

$$w=w(I,\ J,\ K)\,. \tag{34}$$

We shall call this quantity the internal strain energy density.

§ 7. Stress Tensor

Consider a unit cube of the material whose edges are parallel to the coordinate axes at time t when the internal deformation is $\boldsymbol{\alpha}(t)$. Let the sample be subjected to an additional virtual small internal deformation $\boldsymbol{1}+\boldsymbol{\varepsilon}$, $(\boldsymbol{\varepsilon}\ll\boldsymbol{1})$. Thereby the internal deformation changes to $(\boldsymbol{1}+\boldsymbol{\varepsilon})\cdot\boldsymbol{\alpha}$. By $w(\boldsymbol{\alpha};\ \boldsymbol{\varepsilon})$ we denote the internal strain energy density of this sample. The virtual displacement of points on the surfaces of our unit cube is given by the components of $\boldsymbol{\varepsilon}$. Then, it is obvious from the consideration on the work done by surroundings to our unit cube that the stress $\boldsymbol{\sigma}$ is obtained by differentiation

$$\sigma_{ij}(\boldsymbol{\alpha})=\left(\frac{\partial w(\boldsymbol{\alpha};\ \boldsymbol{\varepsilon})}{\partial\varepsilon_{ij}}\right)_{\boldsymbol{\varepsilon}\to 0}. \tag{35}$$

As will be seen in the Appendix A, the internal strain tensor, Eq. (29), and, therefore, $w(\boldsymbol{\alpha};\ \boldsymbol{\varepsilon})$ contain symmetrically the nondiagonal elements of the virtual deformation tensor, $\boldsymbol{\varepsilon}$. Hence, the stress tensor, Eq. (35), is symmetrical:

$$\boldsymbol{\sigma}(\boldsymbol{\alpha})=\boldsymbol{\sigma}^{+}(\boldsymbol{\alpha})\,, \tag{36}$$

which is a condition of stability of the deformation.

$w(\boldsymbol{\alpha};\ \boldsymbol{\varepsilon})$ is considered to be a function of the three invariants associated with the internal deformation $(\boldsymbol{1}+\boldsymbol{\varepsilon})\cdot\boldsymbol{\alpha}$. Then, as a result, Eqs. (31)–(35) lead the stress tensor into the expression

$$\boldsymbol{\sigma}=R_M\boldsymbol{\alpha}_s'+2Q_M\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^{+}+P_M\boldsymbol{1} \tag{37}$$

where the scalar coefficients R_M, Q_M and P_M are the functions of I, J and K given by

$$\left.\begin{aligned} &R_M=\partial w/\partial I\,,\\ &Q_M=\partial w/\partial J\\ \text{and}\quad &\\ &P_M=[\partial w/\partial K]K\,.\end{aligned}\right\} \tag{38}$$

Detail of the calculation is given in the Appendix A.

We adopt Eqs. (20) and (37) as the fundamental equations describing the stress-deformation relation of the three dimensional nonlinear Maxwell model.

§ 8. Flow Tensor

Now, we define a new tensor $\boldsymbol{J}$

---

*) Rivlin et al. define the strain tensor by $\boldsymbol{\alpha}^{+}\cdot\boldsymbol{\alpha}=\boldsymbol{\alpha}_s\cdot\boldsymbol{\alpha}_s$ instead of $\boldsymbol{\alpha}_s$ or $\boldsymbol{\alpha}_s'$, in terms of which three invariants are given by

$$J=\mathrm{Sp}\,\boldsymbol{\alpha}^{+}\cdot\boldsymbol{\alpha}\,, \tag{31$'$}$$

$$L=\mathrm{Sp}\,\boldsymbol{\alpha}^{+}\cdot\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^{+}\cdot\boldsymbol{\alpha} \tag{32$'$}$$

and

$$K^2=|\boldsymbol{\alpha}^{+}\cdot\boldsymbol{\alpha}| \tag{33$'$}$$

instead of Eqs. (31), (32) and (33).

$$\boldsymbol{J}=\boldsymbol{a}^{-1}\cdot\boldsymbol{a}\ . \tag{39}$$

$\boldsymbol{J}$ represents the residual deformation of the material just after the internal strain (and, also stress) is suddenly removed, i.e., the deformation impressed upon the dissipative mechanism during the time interval in which the stress is constrained. We may call $\boldsymbol{J}$ the flow tensor. This is the three dimensional analogue of the length of dashpot in the classical Maxwell model.

From Eq. (20) the equation of motion of $\boldsymbol{J}$ is written in the form

$$(d\boldsymbol{J}/dt)\cdot\boldsymbol{J}^{-1}=-\boldsymbol{a}^{-1}\cdot(d\boldsymbol{a}/dt)^{*} \tag{40}$$

or

$$d\boldsymbol{J}^{-1}/dt=\boldsymbol{a}^{-1}\cdot(d\boldsymbol{a}/dt)^{*}\ . \tag{41}$$

The energy dissipation density, Eq. (17), may be read

$$\frac{\delta\mathcal{E}}{dt}=\mathrm{Sp}\left[\boldsymbol{\sigma}\cdot\boldsymbol{a}\cdot\left(\frac{d\boldsymbol{J}}{dt}\cdot\boldsymbol{J}^{-1}\right)\cdot\boldsymbol{a}^{-1}\right]. \tag{42}$$

If $(d\boldsymbol{a}/dt)^{*}$ is a tensor function of $\boldsymbol{a}$ (and $\boldsymbol{a}^{-1}$) only, we can exchange the order of product of the last two factors in the square bracket of Eq. (42), and Eq. (42) reduces to

$$\frac{\delta\mathcal{E}}{dt}=\mathrm{Sp}\left[\boldsymbol{\sigma}\cdot\frac{d\boldsymbol{J}}{dt}\cdot\boldsymbol{J}^{-1}\right]. \tag{43}$$

Eq. (43) suggests that the energy dissipation is, as has been expected, produced by the "flow" of the material.

§ 9. Steady State

Steady states may be characterized by time-independence of internal deformation $\boldsymbol{a}$ because of the direct connection of $\boldsymbol{a}$ with stress $\boldsymbol{\sigma}$ which should be constant in such states. Then, the right-hand side of Eq. (20) must be equal to zero, that is,

$$\frac{d\boldsymbol{a}}{dt}\cdot\boldsymbol{a}^{-1}\cdot\boldsymbol{a}+\left(\frac{d\boldsymbol{a}}{dt}\right)^{*}=\boldsymbol{0}\ . \tag{44}$$

The dissipation term of Eq. (44), $(d\boldsymbol{a}/dt)^{*}$ is considered to be a function of $\boldsymbol{a}$ only, and its time-derivative should vanish in steady states. Hence we have the necessary condition of steady state such that

$$\frac{d}{dt}\left(\frac{d\boldsymbol{a}}{dt}\cdot\boldsymbol{a}^{-1}\right)=\boldsymbol{0}\ . \tag{45}$$

With the deformation satisfying this condition the steady internal deformation tensor $\boldsymbol{a}$ is obtained from Eq. (44).

§ 10. Steady Simple Elongation (Compression)

In this and the next section, we shall treat two typical examples of steady deformations, i.e., the steady simple elongation (or compression) and the steady simple shearing flow.

The deformation tensor for simple elongation in the x-direction is written in the form

$$\boldsymbol{a}(t)=\begin{bmatrix} a(t) & 0 & 0 \\ 0 & a'(t) & 0 \\ 0 & 0 & a'(t) \end{bmatrix}. \tag{46}$$

The so-called Poisson ratio s may be defined by

$$s=-\log a'(t)/\log a(t)\ . \tag{47}$$

This seems to be a reasonable extension of that in the case of small deformation

$$s=-(a'-1)/(a-1),\qquad |a-1|,\ |a'-1|\ll 1\ . \tag{48}$$

The volume of the material in the deformation state is given by

$$v(t)=a(t)^{(1-2s)}v_0\ , \tag{49}$$

where v_0 is the initial volume. $s=1/2$ corresponds to incompressibility of the material.

The condition of steady state, Eq. (45) results in the exponentially varying components of the steady deformation tensor:

$$a(t)=e^{\lambda' t} \tag{50}$$

and

$$a'(t)=e^{-s\lambda' t}\ . \tag{51}$$

In these expressions we have adopted the initial condition, $\boldsymbol{a}(0)=\boldsymbol{1}$. λ' is the parameter characterizing the rate of deformation.

Substituting of Eqs. (46), (50) and (51) into Eq. (44), and making use of Eq. (26) for the dissipation term, we obtain the steady internal deformation tensor

$$\boldsymbol{\alpha}=\begin{bmatrix} \alpha & 0 & 0 \\ 0 & \alpha' & 0 \\ 0 & 0 & \alpha' \end{bmatrix}=\begin{bmatrix} \beta/(\beta-\lambda') & 0 & 0 \\ 0 & \beta/(\beta+s\lambda') & 0 \\ 0 & 0 & \beta/(\beta+s\lambda') \end{bmatrix}. \tag{52}$$

The Poisson ratio s^{*} of the internal deformation may be defined similarly to Eq. (47):

$$s^{*}=-\frac{\log\alpha'}{\log\alpha}=-\frac{\log\left[1+s(\lambda'/\beta)\right]}{\log\left[1-(\lambda'/\beta)\right]}. \tag{53}$$

When the rate of deformation λ' is sufficiently smaller than β, we have simply

$$s^*=s, \quad (\lambda'/\beta)\ll 1\,. \tag{54}$$

In our case $\boldsymbol{\alpha}$ is symmetric, and

$$\boldsymbol{\alpha}_s=\boldsymbol{\alpha}_s'=\boldsymbol{\alpha}, \quad \boldsymbol{R}=\mathbf{1}\,. \tag{55}$$

Substitution of Eq. (53) into Eq. (37) gives the following expression of stress tensor

$$\sigma_{11}=\frac{R_M}{[1-(\lambda'/\beta)]}+\frac{2Q_M}{[1-(\lambda'/\beta)]^2}+\frac{P_M}{[1-(\lambda'/\beta)][1+s(\lambda'/\beta)]^2}\,, \tag{57}$$

$$\sigma_{22}=\sigma_{33}=\frac{R_M}{[1+s(\lambda'/\beta)]}+\frac{2Q_M}{[1+s(\lambda'/\beta)]^2}+\frac{P_M}{[1-(\lambda'/\beta)][1+s(\lambda'/\beta)]^2}\,, \tag{58}$$

$$\sigma_{ij}=0\,, \qquad (i\neq j=1,\ 2,\ 3)\,. \tag{59}$$

The rate of dissipation of energy density, Eq. (25), is written in this case as

$$\frac{\delta\mathcal{E}}{dt}=\beta\,\mathrm{Sp}\,[\boldsymbol{\sigma}\cdot(\mathbf{1}-\boldsymbol{\alpha}^{-1})] \tag{60}$$

$$=\lambda\Big[R_M\Big\{\frac{1}{[1-(\lambda'/\beta)]}-2s\frac{1}{[1+s(\lambda'/\beta)]}\Big\}+2Q_M\Big\{\frac{1}{[1-(\lambda'/\beta)]^2}-2s\frac{1}{[1+s(\lambda'/\beta)]^2}\Big\}$$
$$+P_M(1-2s)\frac{1}{[1-(\lambda'/\beta)][1+s(\lambda'/\beta)]^2}\Big]\,. \tag{61}$$

The so-called tensile viscosity coefficient $\eta^*(\lambda')$ is defined by

$$\eta^*(\lambda')=(1/\lambda'^2)(\delta\mathcal{E}/dt)\,. \tag{62}$$

From Eqs. (61) and (62) we can easily obtain the explicit expression of $\eta^*(\lambda')$. In particular, in the case of incompressible materials, we obtain

$$\eta^*(\lambda')=\frac{3}{2\beta}\Big[\frac{R_M}{[1-(\lambda'/\beta)][1+\frac{1}{2}(\lambda'/\beta)]}+\frac{Q_M[4-(\lambda'/\beta)]}{[1-(\lambda'/\beta)]^2[1+\frac{1}{2}(\lambda'/\beta)]^2}\Big]\,. \tag{63}$$

If λ' is sufficiently smaller than β, $\eta^*(\lambda')$ can be expanded in a power series with respect to λ'/β such that

$$\eta^*(\lambda')=\frac{3}{\beta}\Big[\Big(\frac{R_M}{2}+2Q_M\Big)+\Big(\frac{R_M}{4}+\frac{3}{2}Q_M\Big)\Big(\frac{\lambda'}{\beta}\Big)+\cdots\Big]\,. \tag{64}$$

If the side surfaces of the sample are free from any external forces, we have

$$\sigma_{22}=\sigma_{33}=0\,. \tag{65}$$

In this case, Eq. (58) determines the value of the Poisson ratio s^* when the functional form of the internal strain energy w, i.e., those of the coefficients R_M, Q_M and P_M are known. However, it would be difficult to obtain molecular-theoretically the complete form of w as a function of strain invariants. In many cases the treatment of dilatation-dependence of w is more difficult than that of its shape-dependence, because of the liquid-like molecular distribution in many visco-elastic materials. In such cases we can obtain theoretically the expressions of R_M and Q_M but P_M, and Eq. (58) with Eq. (65) determines the value of hydrostatic pressure P_M with the experimental value of the Poisson ratio. The tensile stress $\sigma=\sigma_{11}$ becomes

$$\sigma=(s+1)\Big(\frac{\lambda'}{\beta}\Big)\Big[R_M\frac{1}{[1-(\lambda'/\beta)][1+s(\lambda'/\beta)]}$$
$$+2Q_M\frac{[2-(1-s)(\lambda'/\beta)]}{[1-(\lambda'/\beta)]^2[1+s(\lambda'/\beta)]^2}\Big]\,. \tag{66}$$

In Fig. 1 are shown the curves of α, α', s^*, σ and η^* versus (λ'/β) for the incompressible material $(s=1/2)$ having the free side surfaces. If R_M, Q_M and β are constant, α,

σ and η^* diverge at $\lambda'=\beta$. Then sample cannot be elongated with larger rate of deformation λ' than the reciprocal of the relaxation time $\beta=1/\tau$, even if any large tensile force acts on both ends of the sample. In actual cases, however, R_M, Q_M and β should not be constants but functions of λ', and any value of deformation-rate may be observed.

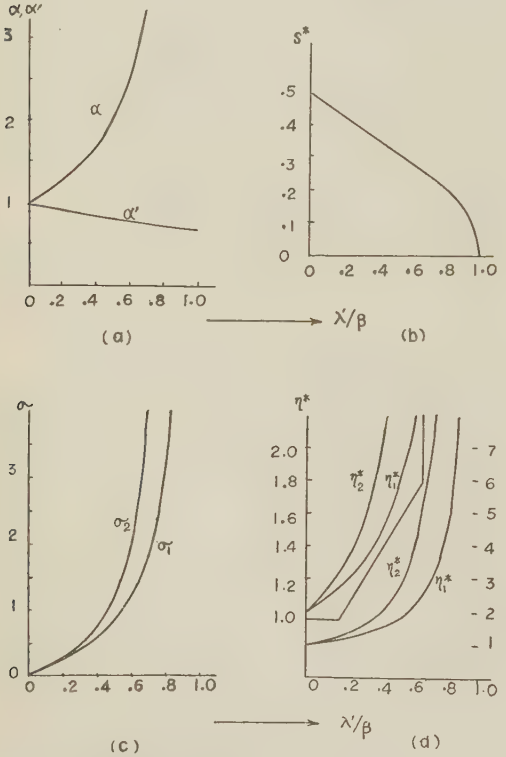

Fig. 1. Internal strain, internal Poisson ratio, tensile stress and tensile viscosity coefficient for the simple elongation of an incompressible Maxwell material.

$$\sigma_{11}=\frac{3}{2}[R_M\sigma_1+4Q_M\sigma_2]\ ,$$

$$\sigma_{22}=\sigma_{33}=0\ ,$$

$$\eta^*=\frac{3}{2\beta}[R_M\eta_1{}^*+4Q_M\eta_2{}^*]\ .$$

The curve of η^* vs. λ' intersects the η^*-axis with a finite, positive slope; the "tensile flow" has essentially the property of so-called non-Newtonian "anti-structural" viscosity. This behavior is experimentally observed by Nitschmann and Schrade for concentrated diphenyl chloride solutions of nitrocellulose.[19]

§ 11. Steady Simple Shearing Flow

Consider the steady simple shearing flow in the x-direction with a constant velocity gradient λ in the y-direction. The deformation tensor

$$\boldsymbol{a}(t)=\begin{bmatrix}1 & \lambda t & 0\\ 0 & 1 & 0\\ 0 & 0 & 1\end{bmatrix} \tag{67}$$

of course satisfies the condition of steady state, Eq. (45). Assuming the dissipation term, Eq. (26), Eq. (44) gives the following steady internal deformation tensor:

$$\boldsymbol{a}=\begin{bmatrix}1 & \lambda/\beta & 0\\ 0 & 1 & 0\\ 0 & 0 & 1\end{bmatrix}. \tag{68}$$

This is a typical asymmetric tensor, and the symmetrization is necessary. $\boldsymbol{a}_s$, $\boldsymbol{a}_s'$ and $\boldsymbol{R}$ in Eq. (27) may be written in the form

$$\boldsymbol{a}_s=\begin{bmatrix}\cos\theta & \sin\theta & 0\\ \sin\theta & \cos\theta+2\dfrac{\sin^2\theta}{\cos\theta} & 0\\ 0 & 0 & 1\end{bmatrix}, \tag{69}$$

$$\boldsymbol{a}_s'=\begin{bmatrix}\cos\theta+2\dfrac{\sin^2\theta}{\cos\theta} & \sin\theta & 0\\ \sin\theta & \cos\theta & 0\\ 0 & 0 & 1\end{bmatrix} \tag{70}$$

and

$$\boldsymbol{R}=\begin{bmatrix}\cos\theta & \sin\theta & 0\\ -\sin\theta & \cos\theta & 0\\ 0 & 0 & 1\end{bmatrix}, \tag{71}$$

where

$$\theta=\mathrm{Tan}^{-1}(\lambda/2\beta) \tag{72}$$

gives the angle of "rotation" of the effective internal elastic mechanism around the z-axis.[*]

Eqs. (37), (68) and (70) cast the stress tensor into such a form that

$$\sigma_{11}=R_M\cos\theta[1+2(\lambda/\beta)^2]+2Q_M[1+(\lambda/\beta)^2]+P_M, \tag{73}$$

$$\sigma_{22}=R_M\cos\theta+2Q_M+P_M, \tag{74}$$

$$\sigma_{33}=R_M+2Q_M+P_M, \tag{75}$$

$$\sigma_{12}=\sigma_{21}=R_M\sin\theta+2Q_M(\lambda/\beta) \tag{76}$$

and

$$\sigma_{13}=\sigma_{31}=\sigma_{32}=\sigma_{23}=0\ . \tag{77}$$

The rate of the dissipation of energy density, Eq. (60), is reduced to

---

[*] θ is related to the extinction angle χ of the flow birefringence in the form

$$(\pi/4)-(\theta/2)=\chi\ . \tag{A}$$

$$\frac{\delta\mathcal{E}}{dt}=\lambda[R_M\sin\theta+2Q_M(\lambda/\beta)]=\lambda\sigma_{12}. \tag{78}$$

The viscosity coefficient $\eta(\lambda)$ is given by

$$\eta(\lambda)=(1/\lambda^2)(\delta\mathcal{E}/dt)=\sigma_{12}/\lambda \tag{79}$$

$$=R_M\sin\theta/\lambda+2Q_M/\beta\,. \tag{80}$$

For sufficiently small values of λ, we have the following expanded form of $\eta(\lambda)$:

$$\eta(\lambda)=\frac{1}{\beta}\left[\left(\frac{R_M}{2}+2Q_M\right)-\frac{R_M}{8}\left(\frac{\lambda}{\beta}\right)^2+\cdots\right]. \tag{81}$$

Comparison of Eq. (81) with Eq. (64) gives the so-called Trouton's relation

$$\eta^*(\lambda'=0)=3\eta(\lambda=0) \tag{82}$$

at the limit of zero rate of the deformations.

For such a special case that

$$R_M=0\,,\quad Q_M=\sigma_0/2=\text{const.} \tag{83}$$

and

$$\beta=\text{const.}\,,$$

the stress tensor is reduced to the simple form

$$\boldsymbol{\sigma}=\sigma_0\begin{bmatrix}1+(\lambda/\beta)^2 & \lambda/\beta & 0\\ \lambda/\beta & 1 & 0\\ 0 & 0 & 1\end{bmatrix}+P_M\mathbf{1}\,. \tag{84}$$

This is identical with that obtained in the previous paper[8] on the Weissenberg effect for the Gaussian network structure. This system shows the typical Newtonian flow. The non-linear additional tension in the flow-direction $\sigma_0(\lambda/\beta)^2$ plays an important rôle in the Weissenberg effect. Since the detailed analysis of this effect has been given in the previous paper, we omit it here. In more general cases, the viscosity coefficient is no longer constant, and the Weissenberg effect also has more complicated velocity gradient-dependence.

§ 12. Visco-elasticity of Gaussian Network

In this section, we shall consider an application of the present theory to visco-elasticity of the weak rubber-like network model constructed by Gaussian chains, which has been treated in detail in the preceding papers.[20),8)] It has been shown that the internal strain energy function w of such system is written in the form

$$w=\frac{3\kappa T}{2a^2}\Sigma_N\frac{1}{N}\iiint\mathrm{Sp}[\boldsymbol{\alpha}^+\cdot(\boldsymbol{\xi}\boldsymbol{\xi})\cdot\boldsymbol{\alpha}]\times F_0(\boldsymbol{\xi},N)d\boldsymbol{\xi}+E(|\boldsymbol{\alpha}|)\,, \tag{85}$$

where $F_0(\boldsymbol{\xi},N)d\boldsymbol{\xi}$ gives the number of chains in the natural state which consist of N-free rotating segments of the fixed length a and which have the end-to-end distance between $\boldsymbol{\xi}$ and $\boldsymbol{\xi}+d\boldsymbol{\xi}$. If the distribution of chains in the natural state is spherically symmetric, Eq. (85) is reduced to

$$w=Q\,\mathrm{Sp}\,(\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha})+E(|\boldsymbol{\alpha}|)\,, \tag{86}$$

where

$$Q=\frac{3kT}{2a^2}\frac{1}{3}\Sigma_N\frac{1}{N}\iiint\xi^2F_0(\boldsymbol{\xi},N)d\boldsymbol{\xi} \tag{87}$$

is a constant scalar coefficient characterizing the network structure. $E(|\boldsymbol{\alpha}|)$ is a part of the inner energy due to the liquid-like segmental distribution and depends only on the dilatation of the material.

From Eqs. (37) and (38) we have the following expression of the stress tensor:

$$\boldsymbol{\sigma}=\boldsymbol{\sigma}_n+P\mathbf{1}\,, \tag{88}$$

$$\boldsymbol{\sigma}_n=2Q\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^+. \tag{89}$$

In order to obtain directly the stress-deformation relation, Eq. (20) is substituted into the time derivative of Eq. (89) with the result

$$\frac{d\boldsymbol{\sigma}_n}{dt}=\frac{d\boldsymbol{\alpha}}{dt}\cdot\boldsymbol{\alpha}^{-1}\cdot\boldsymbol{\sigma}_n+\boldsymbol{\sigma}_n\cdot\boldsymbol{\alpha}^{+-1}\cdot\frac{d\boldsymbol{\alpha}^+}{dt}+\left(\frac{d\boldsymbol{\sigma}_n}{dt}\right)^*, \tag{90}$$

where

$$\left(\frac{d\boldsymbol{\sigma}_n}{dt}\right)^*=2Q\left[\left(\frac{d\boldsymbol{\alpha}}{dt}\right)^*\cdot\boldsymbol{\alpha}^++\boldsymbol{\alpha}\cdot\left(\frac{d\boldsymbol{\alpha}^+}{dt}\right)^*\right] \tag{91}$$

gives the stress production due to the dissipative mechanism. The expression of $(d\boldsymbol{\sigma}_n/dt)^*$ in the network theory is given by

$$\left(\frac{d\boldsymbol{\sigma}_n}{dt}\right)^*=\frac{3kT}{a^2}\Sigma_N\frac{1}{N}\iiint(\boldsymbol{\xi}\boldsymbol{\xi})[G(\boldsymbol{\xi},N,t)-\beta(\boldsymbol{\xi},N)F(\boldsymbol{\xi},N,t)]d\boldsymbol{\xi}\,. \tag{92}$$

In this equation $F(\boldsymbol{\xi},N,t)$ is the distribution function of chains in the deformation state, $\beta(\boldsymbol{\xi},N)$, the probability of the breakage of chains, and $G(\boldsymbol{\xi},N,t)$, the instantaneous distribution function of deformed chains. If $G(\boldsymbol{\xi},N)$ is spherically symmetric and $\beta(\boldsymbol{\xi},N)$ is a constant β_n, Eq. (92) is reduced to

$$\left(\frac{d\boldsymbol{\sigma}_n}{dt}\right)^*=\kappa\mathbf{1}-\beta_n\boldsymbol{\sigma}_n\,. \tag{93}$$

On the other hand, the simple expression of $(d\boldsymbol{\alpha}/dt)^*$ in our phenomenological theory, Eq. (26), leads to the following stress production:

$$\left(\frac{d\boldsymbol{\sigma}_n}{dt}\right)^* = 2\beta Q_M(\boldsymbol{a}+\boldsymbol{a}^+) - 2\beta\boldsymbol{\sigma}_n\,. \tag{94}$$

This expression is essentially different from that of the network theory, Eq. (93). Let us consider instead of Eq. (26) the internal deformation production

$$\left(\frac{d\boldsymbol{a}}{dt}\right)^* = -\beta(\boldsymbol{a}-\boldsymbol{a}^{+-1}) + (\boldsymbol{x}-\boldsymbol{x}^+)\boldsymbol{a}^{-1} \tag{95}$$

with the antisymmetric tensor $(\boldsymbol{x}-\boldsymbol{x}^+)$ satisfying the equation

$$2Q(\boldsymbol{x}-\boldsymbol{x}^+) = \frac{d\boldsymbol{a}}{dt}\cdot\boldsymbol{a}^{-1}\cdot\boldsymbol{a}\cdot\boldsymbol{a}^+ - \boldsymbol{a}\cdot\boldsymbol{a}^+\cdot\boldsymbol{a}^{+-1}\frac{d\boldsymbol{a}^+}{dt}\,. \tag{96}$$

This also satisfies Eqs. (24) and (25). In this case Eq. (91) is reduced to the essentially similar expression to that of the network model, Eq. (93). Then, the Gaussian weak network model is characterized by Eqs. (86), (95) and (96) in our phenomenological theory.

Eqs. (26) and (95) are both qualified for the internal deformation production due to the dissipative mechanism. Eq. (26) leads to the simple equation for internal deformation and the complicated stress equation. On the other hand, Eq. (95) makes the stress simple and the internal deformation equation complex. Which expression would better be used can not be determined from our treatment of this paper, but comparison with experimental results.

For the system in which Eqs. (85) and (95) are satisfied, the essentially similar results as those of the last two sections may be obtained for the steady simple elongation (compression) and for the steady simple shearing flow, although the detailed calculations are ignored here.

C. Voigt Model

§ 13. Stress Tensor in the Three Dimensional Voigt Model

Corresponding to Eq. (4), we can characterize the three dimensional Voigt model with such a condition that

$$\boldsymbol{a} = \boldsymbol{a}_E = \boldsymbol{a}_\eta\,. \tag{97}$$

The law of energy conservation, Eq. (8), is written in this case with Eqs. (15)–(17) that

$$\mathrm{Sp}\left[\{\boldsymbol{\sigma}-\boldsymbol{\sigma}_E-\boldsymbol{\sigma}_\eta\}\cdot\frac{d\boldsymbol{a}}{dt}\cdot\boldsymbol{a}^{-1}\right] = 0\,. \tag{98}$$

Then, we have a tensor relation

$$\boldsymbol{\sigma} = \boldsymbol{\sigma}_E + \boldsymbol{\sigma}_\eta\,. \tag{99}$$

This relation should be considered as the fundamental stress equation for the three dimensional Voigt model.

The stress-strain relation is obtained by expressing $\boldsymbol{\sigma}_E$ and $\boldsymbol{\sigma}_\eta$ in terms of $\boldsymbol{a}$ and $\dot{\boldsymbol{a}}$.

§ 14. Elastic Stress Tensor

The elastic stress-strain relation can be obtained by the similar procedure to the case of the stress tensor for the three dimensional Maxwell model in § 7. Define the symmetric tensors $\boldsymbol{a}_s$ and $\boldsymbol{a}_s'$ by

$$\boldsymbol{a} = \boldsymbol{a}_s'\cdot\boldsymbol{R} = \boldsymbol{R}\cdot\boldsymbol{a}_s \tag{100}$$

with the relations

$$\boldsymbol{a}_s^+ = \boldsymbol{a}_s\,, \quad \boldsymbol{a}_s'^+ = \boldsymbol{a}_s' \tag{101}$$

and

$$\boldsymbol{R}^+\cdot\boldsymbol{R} = \boldsymbol{R}\cdot\boldsymbol{R}^+ = \mathbf{1}\,. \tag{102}$$

We choose the following three invariants associated with $\boldsymbol{a}$

$$I' = \mathrm{Sp}\,\boldsymbol{a}_s = \mathrm{Sp}\,\boldsymbol{a}_s'\,, \tag{103}$$

$$J' = \mathrm{Sp}\,\boldsymbol{a}^+\cdot\boldsymbol{a} = \mathrm{Sp}\,\boldsymbol{a}\cdot\boldsymbol{a}^+ \tag{104}$$

and

$$K' = |\boldsymbol{a}|\,. \tag{105}$$

The elastic strain energy density w may be a function of these three invariants:

$$w = w(I',\ J',\ K')\,. \tag{106}$$

Then, the elastic stress tensor $\boldsymbol{\sigma}_E$ is written in the form

$$\boldsymbol{\sigma}_E = R_V\boldsymbol{a}_s + 2Q_V\boldsymbol{a}\cdot\boldsymbol{a}^+ + P_V\mathbf{1}\,, \tag{107}$$

where the coefficients R_V, Q_V and P_V are given by

$$R_V = \partial w/\partial I'\,,$$

$$Q_V = \partial w/\partial J' \tag{108}$$

and

$$P_V = [\partial w/\partial K']K'$$

analogous to Eqs. (37) and (38).

§ 15. Viscous Stress Tensor

At a glance it might seem that a similar relation to that of $\boldsymbol{\sigma}_E$ hold for $\boldsymbol{\sigma}_\eta$ with replacement of $\boldsymbol{a}$ by $\mathring{\boldsymbol{a}} = (d\boldsymbol{a}/dt)\cdot\boldsymbol{a}^{-1}$. However, it is not the case. For example, let us consider the simple shearing deformation,

$$\boldsymbol{a} = \begin{bmatrix} 1 & \lambda(t) & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}. \tag{109}$$

In this case,

$$\boldsymbol{\mathring{a}}=\begin{bmatrix} 0 & \dot{\lambda} & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \tag{110}$$

and

$$\boldsymbol{\mathring{a}}\cdot\boldsymbol{\mathring{a}}^{+}=\begin{bmatrix} \dot{\lambda}^2 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}. \tag{111}$$

Hence we have

$$\boldsymbol{\mathring{a}}_s=\begin{bmatrix} \dot{\lambda} & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}. \tag{112}$$

Then all non-diagonal elements of the viscous stress tensor corresponding to Eq. (109) should vanish; the relaxation terms do not exist in the shearing stress components $\sigma_{12}=\sigma_{21}$. This results contradicts to our common observations. It is expected that the dissipation mechanism depends not only on the rate of deformation but also on the deformation state. Then we must start from the general tensor relations.

Let us consider a symmetric tensor $\boldsymbol{A}$. Any symmetric tensor, say, $\boldsymbol{B}$, of which principal axes coincide with those of $\boldsymbol{A}$, is represented in such a form that

$$\boldsymbol{B}=s\boldsymbol{1}+t\boldsymbol{A}+u\boldsymbol{A}^2\ , \tag{113}$$

where the scalar coefficients s, t and u are functions of the invariants of $\boldsymbol{A}$ and $\boldsymbol{B}$[10]. On the other hand, for any symmetric tensor, say, $\boldsymbol{C}$, consider three symmetric arbitrary tensors $\boldsymbol{A}_1$, $\boldsymbol{A}_2$ and $\boldsymbol{A}_3$ of which the sets of the principal directions do not coincide with each other. It can be shown that there is a symmetric tensor $\boldsymbol{C}'$ which is a linear combination of these three tensors and of the square of one of these, say, $\boldsymbol{A}_1$, with suitable scalar coefficients a_i:

$$\boldsymbol{C}'=a_1\boldsymbol{A}_1+a_2\boldsymbol{A}_2+a_3\boldsymbol{A}_3+a_4\boldsymbol{A}_1^2, \tag{114}$$

and of which the set of the principal directions is the same as that of the tensor $\boldsymbol{C}$. (Appendix B.)

Eqs. (113) and (114) suggest that any symmetric tensor may be expressed by a suitable linear conbination of three reference symmetric tensors with different sets of principal directions, their squares and the unit tensor.

In our case, $\boldsymbol{\sigma}_\eta$ is a symmetric tensor depending on $\boldsymbol{\mathring{a}}$. If $\boldsymbol{\mathring{a}}$ has any kind of symmetry property, for example, rotational symmetry around a axis or reflection symmetry with a plane, etc., $\boldsymbol{\sigma}_\eta$ should have the same symmetry property. Hence, as the reference tensors we can choose the following three symmetric tensors

$$(1/2)(\boldsymbol{\mathring{a}}+\boldsymbol{\mathring{a}}^{+}),\quad \boldsymbol{\mathring{a}}_s \text{ and } \boldsymbol{\mathring{a}}_s', \tag{115}$$

where

$$\boldsymbol{\mathring{a}}_s^2=\boldsymbol{\mathring{a}}^{+}\cdot\boldsymbol{\mathring{a}} \text{ and } \boldsymbol{\mathring{a}}_s'^2=\boldsymbol{\mathring{a}}\cdot\boldsymbol{\mathring{a}}^{+}. \tag{116}$$

The viscous stress tensor $\boldsymbol{\sigma}_\eta$ may be written in such a form

$$\begin{aligned}\boldsymbol{\sigma}_\eta=&\,p\boldsymbol{1}+q_1(\boldsymbol{\mathring{a}}+\boldsymbol{\mathring{a}}^{+})^2+r_1(\boldsymbol{\mathring{a}}+\boldsymbol{\mathring{a}}^{+})\\ &+q_2\boldsymbol{\mathring{a}}^{+}\cdot\boldsymbol{\mathring{a}}+r_2\boldsymbol{\mathring{a}}_s+q_3\boldsymbol{\mathring{a}}\cdot\boldsymbol{\mathring{a}}^{+}+r_3\boldsymbol{\mathring{a}}_s'.\end{aligned} \tag{117}$$

The scalar coefficients p, q's and r's are functions of invariants of the reference tensors (115) and, in general, of those associated with the deformation tensor. The condition of positiveness of the energy dissipation,

$$\frac{\delta\mathcal{E}}{dt}=\mathrm{Sp}\,[\boldsymbol{\sigma}_\eta\cdot\boldsymbol{\mathring{a}}]\geq 0 \tag{118}$$

makes a restriction to those scalar coefficients.

Among others the most important are Eqs. (99), (107) and (117), and these are the fundamental stress-strain equations for the three dimensional Voigt model.

§ 16. Simple Elongation (Compression)

As an example of deformation, let us consider a simple elongation (compression) along the coordinate axes. The deformation tensor is diagonal:

$$\boldsymbol{a}=\begin{bmatrix} a_1(t) & 0 & 0 \\ 0 & a_2(t) & 0 \\ 0 & 0 & a_3(t) \end{bmatrix} \tag{119}$$

and, hence, is equal to the strain tensors $\boldsymbol{a}_s$ and $\boldsymbol{a}_s'$. Then, Eq. (107) gives the diagonal elastic stress tensor of which the normal components have the form

$$(\boldsymbol{\sigma}_E)_{ii}=R_V a_i+2Q_V a_i^2+P_V\ . \tag{120}$$

Furthermore, $\boldsymbol{\mathring{a}}=(d\boldsymbol{a}/dt)\cdot\boldsymbol{a}^{-1}$ is also diagonal, and the three reference tensors coincide with each other:

$$\begin{aligned}&(1/2)(\boldsymbol{\mathring{a}}+\boldsymbol{\mathring{a}}^{+})=\boldsymbol{\mathring{a}}_s=\boldsymbol{\mathring{a}}_s'\\ &=\begin{bmatrix} \dot{a}_1(t)/a_1(t) & 0 & 0 \\ 0 & \dot{a}_2(t)/a_2(t) & 0 \\ 0 & 0 & \dot{a}_3(t)/a_3(t) \end{bmatrix}.\end{aligned} \tag{121}$$

The viscous stress tensor $\boldsymbol{\sigma}_\eta$ is also diagonal, and from Eq. (117) its normal components are written in the form

$$(\boldsymbol{\sigma}_\eta)_{ii}=r(\dot{a}_i/a_i)+q(\dot{a}_i/a_i)^2+p\ . \tag{122}$$

r, q and p are the functions of invariants associated with $\boldsymbol{a}(t)$ and $\mathring{\boldsymbol{a}}(t)$. They must satisfy the condition (118) which is reduced to

$$r\sum_i (\dot{a}_i/a_i)^2+q\sum_i (\dot{a}_i/a_i)^3+p\sum_i (\dot{a}_i/a_i)\geq 0\,. \tag{123}$$

From Eqs. (120) and (122) we have the total stress tensor of which diagonal elements are

$$\begin{aligned}\sigma_{ii}(t)=P_V'+2Q_Va_i^2(t)+R_Va_i(t)\\ +q(\dot{a}_i/a_i)^2+r(\dot{a}_i/a_i)\,.\end{aligned} \tag{124}$$

Let us consider a special case in which an incompressible material is stretched in the x-direction by a simple tensile force. The diagonal components of deformation and of stress tensor should have the following forms, respectively:

$$\begin{aligned}a_1(t)=a(t)\,,\\ a_2(t)=a_3(t)=1/\sqrt{a(t)}\,,\end{aligned} \tag{125}$$

and

$$\begin{aligned}\sigma_{11}(t)=\sigma(t)\,,\\ \sigma_{22}=\sigma_{33}(t)=0\,.\end{aligned} \tag{126}$$

Eq. (124) and both the second members of Eqs. (125) and (126) determine the hydrostatic pressure P_V', and tensile stress component $\sigma(t)$ is reduced to the form

$$\begin{aligned}\sigma(t)=2Q_V\left(a^2(t)-\frac{1}{a(t)}\right)+R_V\left(a(t)-\frac{1}{\sqrt{a(t)}}\right)\\ +\frac{5}{4}q\left(\frac{\dot{a}(t)}{a(t)}\right)^2+\frac{3}{2}r\frac{\dot{a}(t)}{a(t)}\,.\end{aligned} \tag{127}$$

The restrictive condition Eq. (123) for r, q and p becomes

$$q(\dot{a}(t)/a(t))+2r\geq 0\,. \tag{128}$$

§ 17. Simple Shearing Deformation

Making use of the arguments of § 11, we can easily write down the exression of stress tensor for the simple shearing deformation, Eq. (109), using the similar procedure to that of the last section, such as

$$\sigma_{11}=E\lambda^2+r'\dot{\lambda}+q'\dot{\lambda}^2+P\,, \tag{129}$$

$$\sigma_{22}=r''\dot{\lambda}+q''\dot{\lambda}^2+P\,, \tag{130}$$

$$\sigma_{33}=R_V(1-2/\sqrt{4+\lambda^2})+P\,, \tag{131}$$

$$\sigma_s\equiv\sigma_{12}=\sigma_{21}=E\lambda+\eta\dot{\lambda}\,, \tag{132}$$

$$\sigma_{23}=\sigma_{32}=\sigma_{31}=\sigma_{13}=0\,. \tag{133}$$

In these expressions we have adopted the abbreviations

$$E=(R_V/\sqrt{4+\lambda^2})+2Q_V\,, \tag{134}$$

$$\eta=r_1\,, \tag{135}$$

$$r'=r_3\,,\quad r''=r_2\,, \tag{136}$$

$$q'=q_1+q_3\,,\quad q''=q_1+q_2\,, \tag{137}$$

and

$$P=(2R_V/\sqrt{4+\lambda^2})+2Q_V+P_V+p\,. \tag{138}$$

The condition of positive dissipation of energy, Eq. (118), requires the positiveness of "viscosity coefficient",

$$\eta\geq 0\,. \tag{139}$$

The other coefficients may take arbitrary signs and magnitudes.

Eq. (132) shows that the shearing stress σ_s satisfies formally the classical Voigt equation. However, in our case, the coefficients E and η are in general not constants but functions of λ and $\dot{\lambda}$, that is, Eq. (132) does not exclude non-linearity in the shearing stress-deformation relation.

The term $E\lambda^2$ in σ_{11} is an additional tension analogous to that arises in the three dimensional Maxwell model which gives rise to a normal stress effect (Weissenberg effect). In the present model, a visco-elastic normal stress effect exists as will be discussed in the next section. This is called the Poynting effect. $r'\dot{\lambda}$ and $q'\dot{\lambda}^2$ in σ_{11} and similar terms in σ_{22} can be interpreted as (nonlinear) relaxation cross effects. These are due to the terms associated with $\mathring{\boldsymbol{a}}_s$ and $\mathring{\boldsymbol{a}}'_s$ in Eq. (117).

§ 18. Poynting Effect

Let the circular cyclindrical Voigt material, of which the radius is R and the length is h, be twisted by a torsional couple acted on its ends. Denote the twisting angle $\Delta\Phi(t)$. The simple shearing deformation is produced in the φ-direction with the displacement gradient

$$\lambda(t)=(\Delta\Phi(t)/h)r=sr \tag{140}$$

in the z-direction.

Denote by M the moment of force which is applied on the ends of cylinder. This is obtained by integration of the shearing stress, Eq. (132), over the cross sectional area, that is,

$$M=\kappa s+\mu\dot{s}\,, \tag{141}$$

where

$$\kappa=\int_0^R 2\pi\rho^2E(s\rho)d\rho \tag{142}$$

and

$$\mu=\int_0^R 2\pi\rho^2\eta(s\sigma)d\rho\,. \tag{143}$$

Then, the moment of force and the twisting angle obey the classical Voigt type stress-deformation relation.

Non-isotropic terms in the normal stress components give rise to the additional pressure, as has been seen in the treatment of the Weissenberg effect in the previous paper[8]. Distribution of pressure $\Pi(r)$ is obtained by solving the Euler equation with the stress tensor Eqs. (129)–(133). In the simple case of $R=0$, $\Pi(r)$ becomes

$$\Pi(r)=P_0+\tfrac{1}{2}\overline{E}s^2r^2+(\overline{r'}-r'')\dot{s}r+(\tfrac{1}{2}\overline{q'}-q'')\dot{s}^2r^2\,, \tag{144}$$

where

$$\overline{E}=\left\{2\int_r^R E(s\,\rho)\rho\,d\rho\right\}\Big/r^2\,, \tag{145}$$

$$\overline{r'}=\left\{\int_r^R r'(s\rho)d\rho\right\}\Big/r\,, \tag{146}$$

$$\overline{q'}=\left\{2\int_r^R q'(s\rho)\rho\,d\rho\right\}\Big/r^2\,, \tag{147}$$

and P_0 is the pressure acting on the side surface of the cylinder. In order to keep the length of the cylinder constant, it is necessary to apply the total pressure Π_t on the ends, of which magnitude is given by

$$\Pi_t=SP_0+Ks^2+\psi\dot{s}+\chi\dot{s}^2\,; \tag{148}$$

where $S=\pi R^2$ is the area of the cross section and we have made use of the following notations:

$$K=\pi\int_0^R\overline{E}(\rho)\rho^3d\rho\,, \tag{149}$$

$$\psi=2\pi\int_0^R(\overline{r'}-r'')\rho^2d\rho \tag{150}$$

and

$$\chi=\pi\int_0^R(\overline{q'}-2q'')\rho^3d\rho\,. \tag{151}$$

If the ends of the cylinder are free from the normal stress, its length may elongate or shorten depending on the signs and magnitudes of K, ψ and χ.

Although experimental investigation of this effect has been scarcely made, it should play an important rôle in the analysis of visco-elastic properties of the sample, as that of the Weissenberg effect in the case of the Maxwell model. Especially, responses of the sample to sinusoidal twisting experiment will give valuable informations about its mechanical behaviors. Non-linear visco-elastic properties may be detected by the treatments of overtones in the responded stress and/or strain components. Those in the shearing stress or strain give a measure of the "structural viscosity" of such material, and those of the normal stress and/or strain correspond to the Poynting effect. Analysis of phase and magnitude relations between such excitations and responses will give the estimation of conformity of our three dimensional Voigt model with actual visco-elastic materials.

D. General Discussions

§ 19. Non-linear Behaviors

In the classical theory of visco-elasticity, the considerations are restricted within the framework of linear relations between stress and strain; the elastic modulus and the viscosity coefficient are independent of the stress and the strain state. These systems are characterized by the internal elastic energy density which is proportional to the square of the internal elastic strain or of the elastic stress, and by the constant relaxation or retardation time.

Our three dimensional visco-elastic theory permits us to treat non-linear visco-elastic properties such as non-Newtonian flow, normal stress effect, etc. Non-linearity of visco-elasticity can be classified in three types: elastic, viscous or relaxational, and geometric non-linearities.

Define the elastic linearity by the (internal) strain energy density which is proportional to the sum of squares of three eigenvalues associated with the (internal) deformation tensor, apart from the additional term depending only on the dilatation. Such additional strain energy corresponds to the additional isotropic hydrostatic pressure in the stress tensor. This definition may be a natural extension of that of the classical theory. A typical example of such elastically linear system is the Gaussian network of which strain energy density is given by Eq. (86), and it corresponds to the linear tension-elongation relation of a Gaussian chain. The stress tensor of our elastically linear system is written in such a form as Eqs. (88) and (89) with a constant elastic modulus Q and the hydrostatic pressure P which depends only on the dilatation. We can attribute the dependence of Q on the stress state and the existence of R-term to the elastic non-linearity of our theory of visco-elasticity.

Relaxational linearity for the Maxwell model is defined by the constant "relaxation coefficient" β in Eq. (26). To be more general, β should be replaced by a fourth order "relaxation tensor" $\boldsymbol{\beta}=(\beta_{ij,kl})$, and creation of the internal deformation is written in the form

$$\left(\frac{d\boldsymbol{\alpha}}{dt}\right)^*_{ij}=-\beta_{ij,kl}(\alpha_{kl}-\delta_{kl})\ . \tag{152}$$

When $\boldsymbol{\beta}$ is constant, the system may be called relaxationally linear. In this case, Eq. (20), which determines the internal deformation tensor, is essentially linear with respect to every components of the internal deformation tensor.

Although the resultant stress tensor is essentially the same as that corresponding to Eq. (26) for stational simple shearing flow, the system with different type of creation of the internal deformation, Eq. (95), should be classified in the relaxationally non-linear system. The relaxation tensor is given in this case by

$$\beta_{ij,kl}=[\{\beta(\boldsymbol{\alpha}-\boldsymbol{\alpha}^{+-1})+(\boldsymbol{x}-\boldsymbol{x}^+)\boldsymbol{\alpha}^{-1}\}\cdot \\ \cdot(\boldsymbol{\alpha}-\mathbf{1})^{-1}]_{ik}\delta_{jl}\ . \tag{153}$$

In the case of the Voigt model, the definition of viscous linearity becomes very arbitrary. One of its possible definitions will be given by the following stress tensor

$$\boldsymbol{\sigma}_\eta=\eta(\mathring{\boldsymbol{\alpha}}+\mathring{\boldsymbol{\alpha}}^+) \tag{154}$$

with a constant viscosity coefficient η. This viscous stress tensor gives the shearing stress-deformation relation of simple Voigt type, Eq. (11), for simple shearing deformation, if the system is elastically linear, too. Furthermore, this viscous stress leads to no cross effects in viscous stress-deformation relation, excepting the symmetrization in each pair of complemental non-diagonal elements. The other terms in Eq. (117), apart from the hydrostatic pressure $p\mathbf{1}$, give non-linear stress-strain relations in the usual sence, and/or cross effects at least for asymmetric deformations. Then, the said definition of the viscous linearity, Eq. (154), is reasonable in our system. Deformation-rate dependence of η and/or existence of the other terms in Eq. (117) give causes of viscous non-linearity.

Even if the system is elastically and viscously linear in the above sense, some non-linear behaviors and cross effects may happen to occur between stress and deformation components. One of the typical examples is the normal stress effect. The square terms $\sigma_0(\lambda/\beta)^2$ in Eq. (84) and $E\lambda^2$ in Eq. (129) are such non-linear cross terms, which are essentially due to the three dimensional nature of materials. We shall call these the geometric non-linearities. It is easily shown that the upward convex tension-elongation curve of rubber-like elasticity in the range of relatively small elongation is another example of the geometric non-linearity.

The experimental separation of non-linearity into these three parts can be carried out by independent observations of two or more different stress-strain relations. A typical set of such observations is those of the shearing viscosity and of the Weissenberg effect for elastico-viscous liquids. The details of this analysis have already reported in the previous paper[8].

§ 20. Generalized Model

Visco-elastic properties of the Maxwell and Voigt models in the classical theory are mathematically expressed by the first order linear differential equations of stress, strain and their time derivatives, Eq. (10) and (11). More general linear visco-elastic properties correspond to linear differential equations which contain higher time derivatives of stress and strain. It is well known that suitable parallel and/or series connections of the simple Maxwell and/or Voigt models represent these general linear visco-elastic properties. This generalization has led to the considerations of the so-called relaxation and retardation times, or, in other words, to the considerations of the relaxation and retardation spectra. This is closely connected with the principle of superposition, which has meanings only for the linear systems.

The stress-strain relations of our three dimensional theory are in general non-linear in the usual sense. Then, such generalization procedure may strictly be impossible. However, we can consider formally the parallel and/or series connections of three dimensional Maxwell and Voigt models. Parallel connection is characterized by the condition

$$\boldsymbol{\alpha}=\boldsymbol{\alpha}_1=\boldsymbol{\alpha}_2=\cdots \tag{155}$$

and

$$\boldsymbol{\sigma}=\boldsymbol{\sigma}_1+\boldsymbol{\sigma}_2+\cdots\ , \tag{156}$$

and series connection, by

$$\boldsymbol{\alpha}=\boldsymbol{\alpha}_1+\boldsymbol{\alpha}_2+\cdots \tag{157}$$

and

$$\boldsymbol{\sigma}=\boldsymbol{\sigma}_1=\boldsymbol{\sigma}_2=\cdots . \tag{158}$$

The concept of the relaxation and retardation time spectra may not be kept in these system in which the principle of superposition is no longer estimated. When we restrict our consideration in the special deformation, however, it is possible to define the relaxation and retardation times and their spectra. Let us consider the case of simple shearing. Define the relaxation time for a Maxwell model of which creation of the internal deformation is given by Eq. (26), by

$$\tau(\lambda)=1/\beta(\lambda) . \tag{159}$$

This is in general a function of the velocity gradient. For the generalized Maxwell model, relaxation time spectrum may be given by the quantity

$$F(\tau)=(1/\tau)[R(\lambda\tau)(\sin\theta/\lambda\tau)+Q(\lambda\tau)] \tag{160}$$

with

$$\tan\theta=\lambda\tau/2 . \tag{161}$$

Then, the spectrum depends in general on the velocity gradient λ. On the other hand, the retardation time for a Voigt model may be defined by

$$\tau^*(\lambda,\ \dot{\lambda})=\eta(\dot{\lambda})/E(\lambda) , \tag{162}$$

Retardation time spectrum of the generalized Voigt model takes the form

$$G(\tau^*)=E(\tau^*)/\tau^* \tag{163}$$

as usual. This depends on the magnitudes of the deformation and its time derivative, too. It is easily seen that these definitions of the spectra are natural extensions of those in the classical theory.

§ 21. Summary

A phenomenological theory was presented on the non-linear visco-elastisity of three dimensional bodies. The Maxwell and the Voigt model which were essentially one dimensional were extended to corresponding three dimensional ones. We started from the energy consideration, and defined the "series and parallel connections" of mechanical elements, i.e., the spring and the dashpot. In the case of the three dimensional Maxwell model, we introduced the internal deformation as the deformation of equivalent elastic body which possesses the same stress state as that of our visco-elastic body at each instant. The stress tensor was obtained by application of the three dimensional theory of elasticity to the above internal deformation. In the Voigt case, the stress is divided into two parts; the elastic part and the viscous part. It was assumed that the elastic stress tensor obeys the same stress-strain relation as that of the theory of elasticity, while the viscous stress tensor may have the more complex strain dependence. For examples of applications of our theory, we treated the simple elongation and the simple shearing for both models. Non-linearities in the stress-strain relations were classified into three categories: elastic, viscous (relaxational) and geometric non-linearities. It was shown that deformation-rate dependence of the so-called tensile viscosity and the normal stress effects (the Weissenberg effect and the Poynting effect) are essentially geometric non-linear behaviors due to the three dimensional character of the materials. A typical example of the elastic non-linearity is the upward concave tension-elongation relation of the rubber elasticity for large extension of the sample. The structural viscosity, or, in the other terminology, the non-Newtonian flow is mainly due to the viscous (relaxational) non-linearity.[8)]

If the deformation is not uniform, the treatment of the problem becomes in general complex, and the exact solution may hardly be obtained. In such cases the so-called variation-principle of the stress-strain relation should play an important rôle for the derivation of an approximate solution. This problem is now being considered by the author.

Acknowledgement

The author wishes to express his appreciation to Professor T. Yamamoto for the continuous encouragement and the suggestive discussions, and also for his kind inspection of the manuscript. He is very much indebted to Professor J. Furukawa who has suggested the concept of the internal deformation. His sincere thanks are also due to Professor M. Kurata and the members of our laboratory (Quantum Chemistry Laboratory, Kyoto University) and of Research Group of High Polymer in Kyoto for their fruitful discussions.

The present investigation has been partly supported by the Scientific Research Grant of the Ministry of Education.

Appendix A

Let us consider two closely occupied points A and B of the internal effective elastic mechanism. The distance between them is changed by the internal deformation from $\delta \boldsymbol{r}_0$ to $\delta \boldsymbol{r}$. The square distance is written in the form

$$(\delta s)^2=(\delta \boldsymbol{r})^+\cdot(\delta \boldsymbol{r})=(\delta \boldsymbol{r}_0)\cdot(\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha})\cdot(\delta \boldsymbol{r}_0)$$
$$=\sum_{ij}(\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha})_{ij}\delta r_{0i}\delta r_{0j}\,, \tag{A.1}$$

which must be positive for any δr_0. This implies that the symmetric tensor $\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha}$ is real positive, i.e., its three eigenvalues λ_1^2, λ_2^2 and λ_3^2 are all real positive. We define the new real positive symmetric tensor $\boldsymbol{\alpha}_s$ which has three positive eigenvalues λ_1, λ_2 and λ_3 and the same principal directions as those of $\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha}$. Obviously, we have

$$\boldsymbol{\alpha}_s\cdot\boldsymbol{\alpha}_s=\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha}\,. \tag{A.2}$$

The tensor $\boldsymbol{R}$ defined by

$$\boldsymbol{R}=\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}_s^{-1} \tag{A.3}$$

is orthogonal:

$$\boldsymbol{R}\cdot\boldsymbol{R}^+=\boldsymbol{R}^+\cdot\boldsymbol{R}=\boldsymbol{1}\,. \tag{A.4}$$

Define the real positive symmetric tensor

$$\boldsymbol{\alpha}_s'=\boldsymbol{R}\cdot\boldsymbol{\alpha}_s\cdot\boldsymbol{R}^{-1}\,, \tag{A.5}$$

which has the same eigenvalues as those of $\boldsymbol{\alpha}_s$ but different principal axes. Eqs. (A.3) and (A.5) give the expected separations of internal deformation tensor $\boldsymbol{\alpha}$ such that

$$\boldsymbol{\alpha}=\boldsymbol{R}\cdot\boldsymbol{\alpha}_s=\boldsymbol{\alpha}_s'\cdot\boldsymbol{R}\,. \tag{27}$$

Let us prove that when a small deformations, say, $(\boldsymbol{1}+\boldsymbol{\varepsilon})$, $(\boldsymbol{\varepsilon}\ll\boldsymbol{1})$ is superposed on $\boldsymbol{\alpha}$, $\boldsymbol{\alpha}_s(\boldsymbol{\varepsilon})$ contains the components of $\boldsymbol{\varepsilon}$ symmetrically. Actually, the equation giving $\boldsymbol{\alpha}_s(\boldsymbol{\varepsilon})$,

$$\boldsymbol{\alpha}_s(\boldsymbol{\varepsilon})\cdot\boldsymbol{\alpha}_s(\boldsymbol{\varepsilon})=\boldsymbol{\alpha}^+\cdot(\boldsymbol{1}+\boldsymbol{\varepsilon}^+)\cdot(\boldsymbol{1}+\boldsymbol{\varepsilon})\cdot\boldsymbol{\alpha}$$
$$\simeq\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha}+\boldsymbol{\alpha}^+\cdot(\boldsymbol{\varepsilon}+\boldsymbol{\varepsilon}^+)\cdot\boldsymbol{\alpha} \tag{A.6}$$

is symmetric with respect to the components of $\boldsymbol{\varepsilon}$, and the above statement is proved. Then, any invariant of the tensor $\boldsymbol{\alpha}_s(\boldsymbol{\varepsilon})$ symmetrically contains the components of $\boldsymbol{\varepsilon}$.

The stress tensor $\boldsymbol{\sigma}$ is given by differentiating the internal elastic strain energy density with respect to each component of $\boldsymbol{\varepsilon}$, and by taking the limiting process, $\boldsymbol{\varepsilon}\to\boldsymbol{0}$. The internal elastic strain energy is a function of the invariants of $\boldsymbol{\alpha}_s(\boldsymbol{\varepsilon})$. Symmetrical property of the stress tensor, which is a stability condition of the deformation, is maintained because of the above circumstance. Usually, the following three invariants of $\boldsymbol{\alpha}_s$ are used:

$$I_1=\sum_i\lambda_i=\mathrm{Sp}\,\boldsymbol{\alpha}_s\,, \tag{A.7}$$
$$I_2=\sum_{i<j}\lambda_i\lambda_j\,, \tag{A.8}$$
$$I_3=\lambda_1\lambda_2\lambda_3=|\boldsymbol{\alpha}_s|\,. \tag{A.9}$$

However, in what follows, we shall choose the different sets of invariants (I, J, K) or (J, L, K),

$$I\equiv I_1=\sum_i\lambda_i=\mathrm{Sp}\,\boldsymbol{\alpha}_s\,, \tag{A.10}$$
$$J\equiv I_1^2-2I_2=\sum_i\lambda_i^2=\mathrm{Sp}\,\boldsymbol{\alpha}_s\cdot\boldsymbol{\alpha}_s=\mathrm{Sp}\,\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha}\,, \tag{A.11}$$
$$K\equiv I_3=\lambda_1\lambda_2\lambda_3=|\boldsymbol{\alpha}_s|=|\boldsymbol{\alpha}| \tag{A.12}$$

and

$$L\equiv I_1^4+2I_2^2+2I_1I_3-4I_1^2I_2$$
$$=\sum_i\lambda_i^4=\mathrm{Sp}\,(\boldsymbol{\alpha}_s)^4=\mathrm{Sp}\,\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha}\,. \tag{A.13}$$

In the text, we have used the set (I, J, K). Making use of another set (J, L, K) we obtain another expression of the stress tensor, although this difference may be only apparent. Rivlin et. al.[14] have adopted the different set of invariants,

$$I_1'\equiv J=\mathrm{Sp}\,\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha}\,, \tag{A.14}$$
$$I_2'\equiv\tfrac{1}{2}(J^2-L)=\sum_{i<j}\lambda_i^2\lambda_j^2\,, \tag{A.15}$$
$$I_{3'}\equiv K^2=|\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha}|\,, \tag{A.16}$$

which corresponds to their definition of strain tensor, $\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha}$.

In obtaining the expressions of stress tensor necessary are the differentials of the invariants associating with the internal deformation $(\boldsymbol{1}+\boldsymbol{\varepsilon})\cdot\boldsymbol{\alpha}$ with respect to each components of $\boldsymbol{\varepsilon}$ for the limiting case of $\boldsymbol{\varepsilon}\to\boldsymbol{0}$. That is,

i) $I(\boldsymbol{\varepsilon})$

In Eq. (A.6), put $\boldsymbol{\alpha}_s(\boldsymbol{\varepsilon})=\boldsymbol{\alpha}_s+\Delta\boldsymbol{\alpha}_s$. We have at once

$$\boldsymbol{\alpha}_s\cdot\Delta\boldsymbol{\alpha}_s+\Delta\boldsymbol{\alpha}_s\cdot\boldsymbol{\alpha}_s=\boldsymbol{\alpha}^+\cdot(\boldsymbol{\varepsilon}+\boldsymbol{\varepsilon}^+)\cdot\boldsymbol{\alpha}\,. \tag{A.17}$$

Then, Eqs. (27) and (A.5) result in

$$\Delta\boldsymbol{\alpha}_s+\boldsymbol{\alpha}_s^{-1}\cdot\Delta\boldsymbol{\alpha}_s\cdot\boldsymbol{\alpha}_s=\boldsymbol{\alpha}_s^{-1}\cdot\boldsymbol{\alpha}^+\cdot(\boldsymbol{\varepsilon}+\boldsymbol{\varepsilon}^+)\cdot\boldsymbol{\alpha}$$
$$=(\boldsymbol{R}^+\cdot\boldsymbol{\alpha}_s'^{-1}\cdot\boldsymbol{R})\cdot(\boldsymbol{R}^+\cdot\boldsymbol{\alpha}_s')\cdot(\boldsymbol{\varepsilon}+\boldsymbol{\varepsilon}^+)\cdot\boldsymbol{\alpha}_s'\cdot\boldsymbol{R}$$
$$=\boldsymbol{R}^+\cdot(\boldsymbol{\varepsilon}+\boldsymbol{\varepsilon}^+)\cdot\boldsymbol{\alpha}_s'\cdot\boldsymbol{R}\,. \tag{A.18}$$

Therefore we get

$$2\,\mathrm{Sp}\,\Delta\boldsymbol{\alpha}_s=\mathrm{Sp}\,(\boldsymbol{\varepsilon}+\boldsymbol{\varepsilon}^+)\cdot\boldsymbol{\alpha}_s' \tag{A.19}$$

or,

$$I(\varepsilon)=\mathrm{Sp}\,\boldsymbol{\alpha}_s+\tfrac{1}{2}\textstyle\sum_{ik}(\varepsilon_{ik}+\varepsilon_{ki})(\boldsymbol{\alpha}_s')_{ki}\,. \qquad (A.20)$$

Making use of the symmetrical property of $\boldsymbol{\alpha}_s$ we obtain

$$\left(\frac{\partial I(\varepsilon)}{\partial \mathcal{E}_{ik}}\right)_{\varepsilon\to 0}=(\boldsymbol{\alpha}_s')_{ik}\,. \qquad (A.21)$$

ii) $J(\varepsilon)$

From Eq. (A.6), we have

$$\begin{aligned}J(\mathcal{E})&=\mathrm{Sp}\,\boldsymbol{\alpha}_s(\varepsilon)\cdot\boldsymbol{\alpha}_s(\varepsilon)\\&=\mathrm{Sp}\,\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha}+\mathrm{Sp}\,\boldsymbol{\alpha}^+\cdot(\varepsilon+\varepsilon^+)\cdot\boldsymbol{\alpha}\\&=\mathrm{Sp}\,\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha}+\textstyle\sum_{ik}(\mathcal{E}_{ik}+\mathcal{E}_{ki})\cdot(\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^+)_{ki}. \qquad (A.22)\end{aligned}$$

Then,

$$\left(\frac{\partial J(\varepsilon)}{\partial \mathcal{E}_{ik}}\right)_{\varepsilon\to 0}=2(\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^+)_{ik}\,. \qquad (A.23)$$

iii) $K(\varepsilon)$

In this case,

$$K(\varepsilon)=|(\mathbf{1}+\varepsilon)||\alpha|\simeq(1+\textstyle\sum_i\mathcal{E}_{ii})|\boldsymbol{\alpha}|\,, \qquad (A.24)$$

and we have

$$\left(\frac{\partial K(\varepsilon)}{\partial \mathcal{E}_{ik}}\right)_{\varepsilon\to 0}=|\boldsymbol{\alpha}|\delta_{ik}\,. \qquad (A.25)$$

iv) $L(\varepsilon)$

The expressions

$$\begin{aligned}L(\mathcal{E})&=\mathrm{Sp}\,[(\boldsymbol{\alpha}_s)^4]\\&=\mathrm{Sp}\,[\boldsymbol{\alpha}^+\cdot(\mathbf{1}+\varepsilon^+)\cdot(\mathbf{1}+\varepsilon)\cdot\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^+\cdot(\mathbf{1}+\varepsilon^+)\\&\quad\cdot(\mathbf{1}+\varepsilon)\cdot\boldsymbol{\alpha}]\\&=\mathrm{Sp}\,\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha}+2\,\mathrm{Sp}\,[(\varepsilon+\varepsilon^+)\cdot\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^+]\\&=\mathrm{Sp}\,\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha}+2\textstyle\sum_{ik}(\mathcal{E}_{ik}+\mathcal{E}_{ki})(\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^+)_{ki}\end{aligned} \qquad (A.26)$$

give the differentials

$$\left(\frac{\partial L(\varepsilon)}{\partial \mathcal{E}_{ik}}\right)_{\varepsilon\to 0}=(\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^+)_{ik}\,. \qquad (A.27)$$

Eqs. (A.21), (A.23), (A.25) and (A.27) give the expressions of stress tensor for the two sets of invariants (I, J, K) and (J, L, K) such that

i) For the set (I, J, K):

$$\boldsymbol{\sigma}=R\boldsymbol{\alpha}_s'+2Q(\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^+)+P\mathbf{1}\,, \qquad (A.28)$$

where

$$R=\partial w(I,\ J,\ K)/\partial I\,, \qquad (A.29)$$

$$Q=\partial w(I,\ J,\ K)/\partial J \qquad (A.30)$$

and

$$P=[\partial w(I,\ J,\ K)/\partial K]K\,. \qquad (A.31)$$

ii) For the set (J, L, K):

$$\boldsymbol{\sigma}=2Q'(\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^+)+4S'(\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^+\cdot\boldsymbol{\alpha}\cdot\boldsymbol{\alpha}^+)+P'\mathbf{1}\,, \qquad (A.32)$$

where

$$Q'=\partial w(J,\ L,\ K)/\partial J\,, \qquad (A.33)$$

$$S'=\partial w(J,\ L,\ K)/\partial L \qquad (A.34)$$

and

$$P'=[\partial w(J,\ L,\ K)/\partial K]K\,. \qquad (A.35)$$

Appendix B

Take the three linearly independent symmetric tensor $\boldsymbol{A}_1$, $\boldsymbol{A}_2$ and $\boldsymbol{A}_3$ which have different sets of principal axes from each other. Let us prove that for any symmetric tensor $\boldsymbol{A}$, we can find a suitable linear combination of above three tensors and the square of any-one of them, say $\boldsymbol{A}_1$, such that the linear combination has the same set of principal axes as that of $\boldsymbol{A}$. Through the transformation of coordinate which diagonalizes $\boldsymbol{A}$, above three reference tensors and, thus, their squares cannot be brought into diagonal forms simultaneously. If one of our reference tensors happens to become diagonal, our statement is trivial. Then, we assume that our reference tensors are all non-diagonal in the new coordinate system. We can define the three dimensional "vectors" of which elements are the non-diagonal elements of reference tensors and of their squares, that is,

$$\boldsymbol{l}_i=(\boldsymbol{A}_{i,23},\ \boldsymbol{A}_{i,31},\ \boldsymbol{A}_{i,12})\,,$$

$$\boldsymbol{l}_{i+3}=((\boldsymbol{A}_i^2)_{23},\ (\boldsymbol{A}_i^2)_{31},\ (\boldsymbol{A}_i^2)_{12})\,. \qquad (B.1)$$

Because of linear independence of the vectors, we have the relation

$$a_1\boldsymbol{l}_1+a_2\boldsymbol{l}_2+a_3\boldsymbol{l}_3+a_4\boldsymbol{l}_4=\mathbf{0} \qquad (B.2)$$

with suitable coefficients a_i. Hence, with these coefficients, our linear combination of tensors may be brought into a diagonal form together with tensor $\boldsymbol{A}$.

Quantum Theoretical Study on Single, Double and Triple Bonds between Carbon Atoms

By Sigeru NAGAHARA

Department of Physics, Faculty of Literature and Science,
Toyama University

(Received October 30, 1958)

We study the characteristic features of single, double and triple bonds between carbon atoms by idealizing the problem to the electronic structure of fictitious diatomic molecules $\equiv C-C\equiv$, $=C=C=$ and $-C\equiv C-$, where the "open" bonds of carbon atoms are represented by a suitably hybridized orbitals, associated with free spins. Thus, adiabatic potentials are non-empirically and numerically computed and bond energies and equilibrium internuclear distances are evaluated. We obtain 3.1 e.v., 1.25 e.v. and 0.20 Å, 0.10 Å for the values of relative bond energy differences and bond distance differences of single and triple, double and triple bonding. The corresponding experimental values are 2.9 e.v., 1.0 e.v., and 0.34 Å, 0.12 Å respectively.

§ 1. Introduction

The nature of the single bond was quantum-mechanically disclosed by many authors by working out quantitative theories of the *ss*- and *sp*-bonds. However the quantum-mechanical nature of the double and triple bonds has not yet been fully known. The double bond was first discussed by Hückel[1] on the basis of quantum mechanics. The theory was later improved to some extent by Pauling[2], Penney[3] and Mulliken[4]. It was known that the double or triple bond was due to two or three *p*-electrons partly associated with *s*-electrons.

Although the relation between bond order and bond length is of great importance in the theory of carbon compounds, the quantum theoretical study for these has not yet been fully carried out. Systematical and quantum theoretical investigation of the true nature of single, double and triple bonds is of great importance, especially from a chemical point of view. Among the bonds between simpler atoms (for example, oxygen, nitrogen and carbon atoms), those formed between two carbon atoms are of special interest in organic chemistry. The typical cases of these bonds occur in C_2H_6, C_2H_4 and C_2H_2, so that the problem is a study of the electronic structure of polyatomic molecules. In this paper, we intend to study the characteristics of single, double and triple bonding between carbon atoms.

It has been suggested that each bond in a polyatomic molecule possesses an energy which is independent of the other bonds in the molecule and that the dissociation energy of the molecule will be equal to the sum of the energies of various bonds occurring in the molecule (semi-empirical "rule of bond additivity")[5]. For example, the energy of formation of methane is equal to fourtimes of the energy of a C—H bond; that of ethane to the sum of the bond energies of one C—C bond and six C—H bonds, etc.

In general, for the molecule C_nH_{2n+2}, we may write

$$E=(n-1)E_{C-C}+(2n+1)E_{C-H} \tag{1}$$

where E_{C-C} and E_{C-H} represent respectively the bond energies of the C—C and C—H bonds. We may therefore use the data for the molecules from C_5H_{12} to $C_{12}H_{26}$ for the calculation of the energies of the C—C and C—H bonds and using the method of least squares, obtain[6],

$$E_{C-C}=62.77\text{ kcals}\ ,\quad E_{C-H}=85.56\text{ kcals}\ . \tag{2}$$

In a similar manner, the double bond energy $E_{C=C}$, the triple bond energy $E_{C\equiv C}$ are deter mined from the dissociation energies of ethylene molecular system, and of acetylene molecular system, and we obtain

$$E_{C=C}=101.16\text{ kcals}\ , \tag{3}$$

$$E_{C\equiv C}=128,15\text{ kcals}\ . \tag{4}$$

§ 2. Quantum Theoretical Treatment of Single, Double and Triple Bonds between Carbon Atoms

According to chemical experiences mentioned above, each "bond" seems to retain its individuality fairly well irrespective of the condition of neighbouring bonds, and the bond distances of single, double and triple bonds between carbon atoms are

$R_{C-C}=1.54$ Å, $R_{C=C}=1.32$ Å, $R_{C\equiv C}=1.20$ Å

respectively (see Fig. 1 and Table I).

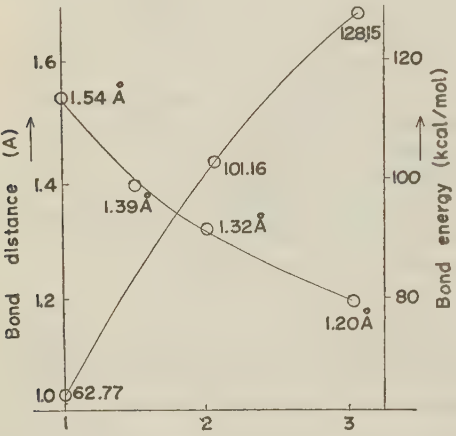

Fig. 1. Bond energies and bond distances between carbon atoms.

Table I. Dissociation energy D of C_nH_{2n+2}.

C_nH_{2n+2}	D Expt.	D Calc. (kcal/mol)
CH_4	348.6	342.2
C_2H_6	579	576.1
C_3H_8	811.6	810.0
C_4H_{10}	1044.8	1043.2
C_5H_{12}	1277.8	1277.8
C_6H_{14}	1511.9	1511.7
C_7H_{16}	1745.8	1745.6
C_8H_{18}	1979.5	1979.5
C_9H_{20}	2213.5	2213.4
$C_{10}H_{22}$	2447.1	2447.2
$C_{11}H_{24}$	2681.3	2681.1
$C_{12}H_{26}$	2914.2	2915.0

We may therefore hope to be able to study the characteristic features of these carbon-carbon bonds by idealizing the problem to fictitious diatomic molecules $\equiv C-C\equiv$, $=C=C=$ and $-C\equiv C-$, where the "open" bonds of the carbon atoms are represented by suitably hybridized orbitals, associated with free spins, which mean all possible structures having α or β spin in each "open" bond.

In other wards, we do not explicitly take account of the presence of hydrogen atoms (or other atoms forming bonds with the carbon atoms) but only consider their effects by keeping the carbon atoms in their appropriate valence states, and 1*s* electrons are not treated quantum-mechanically but we take account of the effect of the shielding of the nuclear field by them.

Thus we have merely to deal with only an eight electron system, with the Hamiltonian

$$\mathscr{H}=\sum(H_i+\varDelta H_i)+\sum G_{ij}+\frac{16}{R} \qquad (5)$$

where

$$H_i=-\frac{1}{2}\varDelta_i-\frac{4}{r_{ci}}-\frac{4}{r_{c'i}} \qquad (6)$$

H_i is the hamiltonian operator for the *i*th electron in the field of the nuclei alone, and

$$\varDelta H_i=2\left\{\int\frac{1}{r_{cj}}c^2(j)\,d\tau_j+\int\frac{1}{r_{c'j}}c'^2(j)\,d\tau_j\right\}-\frac{2}{r_{ci}}-\frac{2}{r_{c'i}} \qquad (7)$$

$$G_{ij}=1/r_{ij} \qquad (8)$$

R is the carbon-carbon internuclear distance.

$\varDelta H_i$ is a correction term which takes account of the finite extention of 1*s* electron orbitals in the carbon atoms. $c(j)$ and $c'(j)$ are the wave functions of 1*s* electrons in the carbon atoms C and C' respectively.

All quantities are measured in atomic units: lengths in units of the Bohr radius $a_H=0.529$ Å; energies in units of 27.204 e.v. (This is twice the ionization energy of the hydrogen atom.) In these units, the kinetic energy operator for an electron is $-\frac{1}{2}\varDelta$, the potential energy of an electron at a distance r from a nucleus of charge Z is $-Z/r$, and the repulsion energy of two electrons i and j at a distance r_{ij} apart is $1/r_{ij}$.

A. H-L-S-P *Method*

There are two fairly distinct and fundamental methods of investigating the electronic structure of polyatomic molecules. One is associated principally with the names Hund7), Mulliken8), Lennard-Jones9) and others10), (namely the molecular orbital method), while the other owes its development chiefly to Heitler, London11), Slater12) and Pauling13) (namely the valence bond method). The H-L-S-P method on based on the idea of electron pairs. The spin of an electron on one nucleus is coupled with that of another electron on another nucleus to give a resultant spin zero, and the pair then forms a saturated bond. Pairing occurs between the spins in such a way as to give a maximum bonding energy, and the number of free spins capable of being paired with electrons on other atoms constitutes the valency of the atom.

It is a well-known fact[14] that the valence bond method including ionized states and the molecular orbital method including interaction between configurations eventually give identical results. The H–L–S–P method is the one most closely associated with the chemical treatment of molecular structure. In this paper, we consider the localized fictitious molecular system and therefore calculate by the H–L–S–P method.

B. *Models*

We take the following models for these diatomic molecular system. (see Fig. 2–6). Model I and Model II represent the tetrahedrally hybridized bonding[15] in ethane and acetylene molecule. Model III shows the trigonally hybridized bonding in an ethylene molecule as superposition of a σ bond formed by overlaps of two trigonal hybrids and a π-bond formed by overlaps of two unhybridized p-type orbitals (trigonal sp^2 hybridization model). Model IV[16] shows the tetrahedrally hybridized bonding in ethylene and Model V is the π-model in an acetylene molecule which is composed of one σ and two π bonds and here also the π-bonds are formed between electrons in non-hybridized p status. The σ electrons, two to each carbon atom, are located in sp hybrid orbitals, formed by the linear combination of one s and one p wave function and the molecule is therefore linear.

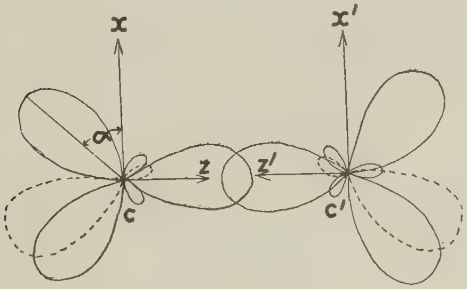

Fig. 2. Model I. The tetrahedrally hybridized bonding in ethane molecule.

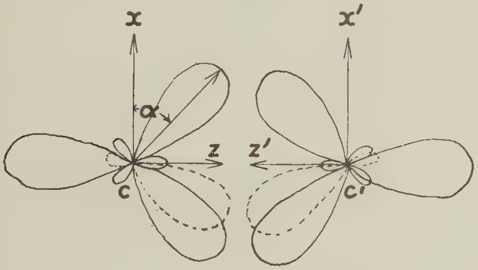

Fig. 3. Model II. The tetrahedrally hybridized bonding in acetylene molecule.

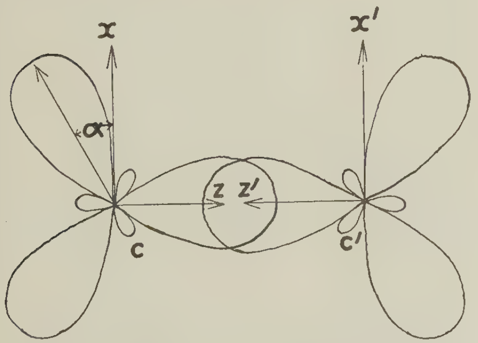

The π orbitals on C and C' are not shown to avoid confusion. They are directed perpendicularly to the plane of the paper.

Fig. 4. Model III. The trigonally hybridized bonding in ethylene molecule (trigonal sp^2 hybridization model).

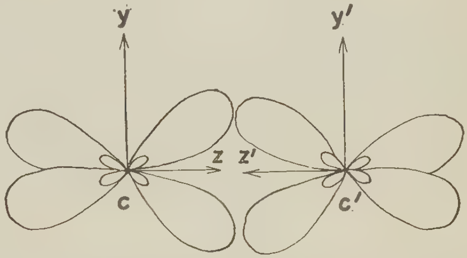

Fig. 5. Model IV. The tetrahedrally hybridized bonding in ethylene molecule.

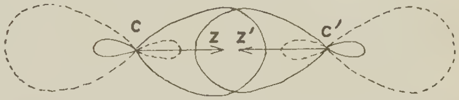

The four π-orbitals of the two atoms C and C' are not shown. They are in perpendicular pairs at right angles to the line CC'.

Fig. 6. Model V. The π-model in acetylene molecule.

C. *Atomic orbitals*

Of the free atom AO's, the self-consistent field AO's of Hartree and Fock are the most accurate for atomic calculations, but it is not guaranteed that they are the best for molecular calculations as well. For the latter, the simple atomic orbitals of Zener[17] and Slater[18] are most often used.

The following set of Slater atomic orbitals is therefore adopted:

$$\left.\begin{aligned}
(1s)&=(\delta'^3/\pi)^{1/2}\exp(-\delta' r)\\
(2s)&=(\delta^5/3\pi)^{1/2}r\exp(-\delta r)\\
(2p_x)&=(\delta^5/\pi)^{1/2}r\sin\theta\sin\phi\exp(-\delta r)\\
(2p_y)&=(\delta^5/\pi)^{1/2}r\sin\theta\cos\phi\exp(-\delta r)\\
(2p_z)&=(\delta^5/\pi)^{1/2}r\cos\theta\exp(-\delta r)
\end{aligned}\right\}\qquad (9)$$

where

$$\delta'=5.70\,,\qquad \delta=1.625 \qquad (10)$$

The atomic orbitals on one atom are normalized and mutually orthogonal, except that the nodeless Slater $2s$ is not orthogonal to the $1s$. Orthogonal $2s$ functions are formed from the original $2s$ and $1s$ in the following way[19]:

$$\begin{aligned}
s&=\frac{(2s)-0.2205(1s)}{0.9754}\\
&=(2s)+a(2s)-b(1s)
\end{aligned}\qquad (11)$$

where

$$a=0.024\,,\qquad b=0.2205\,. \qquad (12)$$

The normalized orbitals are then orthogonal to all the other orbitals of the same atom. The notations c, s, x, y, z will be adopted for the carbon $1s$, $2s$, $2p_x$, $2p_y$ and $2p_z$ orbitals respectively, with c', s', x', y', z' for the corresponding orbitals of the second carbon atom. The $2p_z$ orbitals are directed along the inter-

Table II. Interatomically orthogonal $2s$, $2p$-hybrid orbitals.

$$\varphi_i^N=a_{i1}^N s+a_{i2}^N x+a_{i3}^N y+a_{i4}^N z$$

Model I and Model II.

$$a_{ij}^I,\ a_{ij}^{II}\quad\begin{bmatrix}
v\,, & \sqrt{\frac{2}{3}}\,, & 0\,, & \mp\sqrt{\frac{2}{3}}\tan\alpha\\
v\,, & -\frac{1}{\sqrt{6}}\,, & -\frac{1}{\sqrt{2}}\,, & \mp\sqrt{\frac{2}{3}}\tan\alpha\\
v\,, & -\frac{1}{\sqrt{6}}\,, & +\frac{1}{\sqrt{2}}\,, & \mp\sqrt{\frac{2}{3}}\tan\alpha\\
\sqrt{2}\tan\alpha, & 0\,, & 0\,, & \pm\sqrt{3}\,v
\end{bmatrix}$$

Model III.

$$a_{ij}^{III}\quad\begin{bmatrix}
\frac{1}{\sqrt{2}}w\,, & \frac{1}{\sqrt{2}}\,, & 0\,, & -\frac{1}{\sqrt{2}}\tan\alpha\\
\frac{1}{\sqrt{2}}w\,, & -\frac{1}{\sqrt{2}}\,, & 0\,, & -\frac{1}{\sqrt{2}}\tan\alpha\\
0\,, & 0\,, & 1\,, & 0\\
\tan\alpha\,, & 0\,, & 0\,, & w
\end{bmatrix}$$

Model IV.

$$a_{ij}^{IV}\quad\begin{bmatrix}
\frac{1}{\sqrt{2}}w\,, & \frac{1}{\sqrt{2}}\,, & 0\,, & -\frac{1}{\sqrt{2}}\tan\alpha\\
\frac{1}{\sqrt{2}}w\,, & -\frac{1}{\sqrt{2}}\,, & 0\,, & -\frac{1}{\sqrt{2}}\tan\alpha\\
\frac{1}{\sqrt{2}}w'\,, & 0, & \frac{1}{\sqrt{2}}\,, & \frac{1}{\sqrt{2}}\tan\beta\\
\frac{1}{\sqrt{2}}w'\,, & 0, & -\frac{1}{\sqrt{2}}\,, & \frac{1}{\sqrt{2}}\tan\beta
\end{bmatrix}$$

Model V.

$$a_{ij}^{V}\quad\begin{bmatrix}
0\,, & 1\,, & 0\,, & 0\\
0\,, & 0\,, & 1\,, & 0\\
\sin\alpha'\,, & 0\,, & 0\,, & -\cos\alpha'\\
\cos\alpha'\,, & 0\,, & 0\,, & \sin\alpha'
\end{bmatrix}$$

where

$$v=\left(\cos^2\alpha-\frac{2}{3}\right)^{1/2}\Big/\cos\alpha\,,\qquad w=(\cos 2\alpha)^{1/2}/\cos\alpha\,,$$

$$w'=(\cos 2\beta)^{1/2}/\cos\beta\,,\qquad (\tan^2\alpha+\tan^2\beta=1).$$

nuclear axis, and the positive direction of both $2p_z$ orbitals is taken in the positive z direction.

D. *Interatomically orthogonal* 2*s*, 2*p*-*hybrid in homopolar bonds*

In general, we construct the interatomically orthogonal $2s$, $2p$ hybrid AO's in homopolar bonds corresponding to each model. The results are shown in Table II.

These include the most frequently used orthogonal sets[20] as follows:

$$\left.\begin{array}{l} \text{For } 90^\circ \text{ bond angle: } s,\ \sigma,\ \sigma',\ \sigma'' . \\ \text{For tetrahedral bond angle:} \\ \qquad\qquad te,\ te',\ te'',\ te''' . \\ \text{For } 120^\circ \text{ (trigonal) bond angles:} \\ \qquad\qquad tr,\ tr',\ tr'',\ \sigma . \\ \text{For } 180^\circ \text{ (diagonal) bond angles:} \\ \quad s,\ \sigma,\ \pi,\ \pi', \text{ or } di,\ di',\ \pi,\ \pi' . \end{array}\right\} \qquad (13)$$

Symbols differing by the use of one or more primes in (13) denote mutually orthogonal and geometrically equivalent but differently oriented AO's.

E. *Structures associated with free spins*

We discuss the case of Model I. We consider the possible structures associated with free spins in the "open" bonds of carbon atoms. Since the bonding orbinals φ_4 and $\varphi_{4'}$, which are supposed to point to z and z' directions respectively, are occupied by electrons with anti-parallel spin, the possible spin orientations are (α, β) and (β, α). For each of these two, there are $2^6=64$ possible structures corresponding to the spin orientation of the remaining six electrons housed in φ_1, φ_2, φ_3, $\varphi_{1'}$, $\varphi_{2'}$ and $\varphi_{3'}$. We shall divide these orbitals into two groups $(\varphi_1, \varphi_2, \varphi_3)$ and $(\varphi_{3'}, \varphi_{2'}, \varphi_{1'})$, and, according to their spin orientation $(\alpha\alpha\alpha)$, $(\alpha\alpha\beta)$, $(\beta\alpha\alpha)$, $(\alpha\beta\alpha)$, $(\alpha\beta\beta)$, $(\beta\alpha\beta)$, $(\beta\beta\alpha)$ and $(\beta\beta\beta)$, denote the structures of these two groups by A, B, C, $\cdots$ and H and a, b, c, $\cdots$ and h respectively. Then the structures of the total eight electron system can be specified by the combination as Pq, where P and q stand for any one of A, B, $\cdots$, H and of a, b, $\cdots$, h respectively, and by the spin orientation of the bonding electrons. For the structures with (α, β) spin of $(\varphi_4, \varphi_{4'})$ we shall use the symbol Pq, and for those with (β, α) spin of $(\varphi_4, \varphi_{4'})$ the symbol $\overline{Pq}$ will be employed.

Then, the unnormalized wave function for any one of the structures Pq, say Aa, is given by

$$\phi_{Aa}=(|\varphi_1\varphi_2\varphi_3\varphi_4\bar{\varphi}_{4'}\varphi_{3'}\varphi_{2'}\varphi_{1'}|)\ , \qquad (14)$$

and the function for $\overline{Aa}$ is

$$\phi_{\overline{Aa}}=(|\varphi_1\varphi_2\varphi_3\bar{\varphi}_4\varphi_{4'}\varphi_{3'}\varphi_{2'}\varphi_{1'}|)\ . \qquad (15)$$

The notation $(|\cdots|)$ represents the usual Slater determinant (multiplied by $1\sqrt{8!}$), the orbitals without bar including α-spin and with bar β-spin functions of electrons in them.

The wave function of the structure corresponding to the electron pair bond between φ_4 orbital and $\varphi_{4'}$ orbital is

$$\Phi_{Pq}=\frac{1}{\sqrt{2}}(\phi_{Pq}-\phi_{\overline{Pq}})\ . \qquad (16)$$

F. *General formulas for electronic energy*

We have to derive the general formulas for the adiabatic potential which characterizes the nature of binding of the molecular system. We shall illustrate it in the case of Model I.

According to the chemical experiences as mentioned in § 1, we may hope that the bond energy can be calculated by the wave function of the electrons which are housed in carbon-carbon atoms, and therefore if we remove the surrounding atoms in the real saturated compound to infinite distance, the energy of this system is the sum of the energy E of the fictitious molecular system defined in § 2 and the proper energy of the surrounding atoms. Thus when we consider the nature of bond between carbon atoms in this case, we may calculate the energy E of the fictitious molecular system.

Based on this idea, the total energy E of the fictitious molecular system with open bonds $\equiv$C$-$C$\equiv$ is found to be given by

$$E=\frac{\Sigma\int\Phi_{Pq}{}^*\mathscr{H}\Phi_{Pq}\,d\tau}{\Sigma\int\Phi_{Pq}{}^*\Phi_{Pq}\,d\tau}=\frac{\left\langle\int\Phi_{Pq}{}^*\mathscr{H}\Phi_{Pq}\,d\tau\right\rangle}{\left\langle\int\Phi_{Pq}{}^*\Phi_{Pq}\,d\tau\right\rangle} \qquad (17)$$

where $\langle Q\rangle$ means the average value of the quantity Q taken over all 2^6 possible structures Pq mentioned in § E. For the proof of this formula, the reader is refered to Appendix I.

In our calculation, as the overlap integrals $S_{ij'}$ between the non-bonding orbitals are small, we expand E in powers of $S_{ij'}$ and we neglect all terms of third and higher powers in $S_{ij'}$. Thus in our approximation, we take into calculation terms up to the second power in non-orthogonality between non-bonded orbital·.

When we substitute (16) in (17), we obtain

$$\begin{aligned}E=&\left\langle\left[\frac{1}{2}\int(\phi_{Pq}-\phi_{\overline{Pq}})^*\mathscr{H}(\phi_{Pq}-\phi_{\overline{Pq}})\,d\tau\right]\right\rangle\\ &\div\left\langle\left[\frac{1}{2}\int(\phi_{Pq}-\phi_{\overline{Pq}})^*(\phi_{Pq}-\phi_{\overline{Pq}})\,d\tau\right]\right\rangle\\ =&\left\langle\left[\frac{1}{2}\left(\int\phi_{Pq}{}^*\mathscr{H}\phi_{Pq}\,d\tau\right)+\frac{1}{2}\left(\int\phi_{Pq}{}^*\mathscr{H}\phi_{\overline{Pq}}\,d\tau\right)-\left(\int\phi_{\overline{Pq}}{}^*\mathscr{H}\phi_{Pq}\,d\tau\right)\right]\right\rangle\\ &\div\left\langle\left[\frac{1}{2}\left(\int\phi_{Pq}{}^*\phi_{Pq}\,d\tau\right)+\frac{1}{2}\left(\int\phi_{\overline{Pq}}{}^*\phi_{\overline{Pq}}\,d\tau\right)-\left(\int\phi_{\overline{Pq}}{}^*\phi_{Pq}\,d\tau\right)\right]\right\rangle.\end{aligned}\tag{18}$$

If we calculate the integration $\int\phi_{Aa}{}^*\mathscr{H}\phi_{Aa}\,d\tau$ substituting (14) in ϕ_{Aa}, we obtain

$$\begin{aligned}\int\phi_{Aa}{}^*\mathscr{H}\phi_{Aa}\,d\tau=&(\phi_{Aa}|\mathscr{H}|\phi_{Aa})\\ =&\sum(-1)^P\int\varphi_1{}^*(1)\alpha(1)\varphi_2{}^*(2)\alpha(2)\varphi_3{}^*(3)\alpha(3)\varphi_4(4)\alpha(4)\\ &\times\varphi_{4'}{}^*(5)\beta(5)\varphi_{3'}{}^*(6)\alpha(6)\varphi_{2'}{}^*(7)\alpha(7)\varphi_{1'}{}^*(8)\alpha(8)\\ &\times\mathscr{H}P\varphi_1(1)\alpha(1)\varphi_2(2)\alpha(2)\varphi_3(3)\alpha(3)\varphi_4(4)\alpha(4)\\ &\times\varphi_{4'}(5)\beta(5)\varphi_{3'}(6)\alpha(6)\varphi_{2'}(7)\alpha(7)\varphi_{1'}(8)\alpha(8)\\ &\times d\tau_1\,d\tau_2\,d\tau_3\,d\tau_4\,d\tau_5\,d\tau_6\,d\tau_7\,d\tau_8\\ =&\int\phi_{Aa}^{(0)*}\mathscr{H}\phi_{Aa}^{(0)}\,d\tau-\int\phi_{Aa}^{(0)*}\mathscr{H}\phi_{Aa}^{(1)}\,d\tau+\cdots\\ =&E_0-C_0-\sum_{Aa}^{(1)}\{(ij':ij')+S_{ij'}(H_{ij'}+H_{j'i})\\ &+S_{ij'}^2(\sum_{k\neq i,j'}H_{kk})+2S_{ij'}\sum_{k\neq i,j'}(ij':kk)+S_{ij'}^2\sum_{k,l\neq j,j'}(kk:ll)\}+\cdots\\ =&E_0-C_0-\sum_{Aa}^{(1)}\{(ij':ij')-S_{ij'}^2(ii:j'j')+S_{ij'}^2(ii:j'j')\\ &+2_{ij'}H_{ij'}-S_{ij'}^2(H_{ii}+H_{j'j'})+S_{ij'}^2(\sum H_{kk})\\ &+2S_{ij'}\sum_{k\neq i,j'}(ij':kk)-S_{ij'}^2\sum_{k\neq i,j'}\{(ii:kk)+(j'j':kk)\}\\ &+S_{ij'}^2\sum_{k\neq i,j'}\{(ii:kk)+(j'j':kk)\}+\cdots\\ =&E_0-C_0-\sum_{Aa}^{(1)}S_{ij'}^2\{\sum H_{kk}+\sum_{i>j}(ii:jj)\}\\ &-\sum_{Aa}^{(1)}\{(ii':ij')-S_{ij'}^2(ii:j'j')+2S_{ij'}H_{ij'}\\ &-S_{ij'}^2(H_{ii}+H_{j'j'})+2_{ij'}\sum_{k\neq i,j'}(ij':kk)\\ &-S_{ij'}^2\sum((ii:kk)+(j'j':kk))\}+\cdots\\ =&E_i-C_0-E_0(\sum_{Aa}^{(1)}S_{ij'}^2)-C_{Aa}^{(1)}+\cdots\end{aligned}\tag{19}$$

where

$$E_0=\int\phi_{Aa}^{(0)*}\mathscr{H}\phi_{Aa}^{(0)}\,d\tau=\sum H_{ji}+\sum_{(i>j)}(ii:jj)\tag{20}$$

(Coulomb integral term)

$$C_{Aa}^{(1)}=\sum_{Aa}^{(1)}G_{ij}\,,\tag{21}$$

(Interatomic exchange integral)

$$C_0=\sum\nolimits_{Aa}^{(1)} G_{ij} \,. \tag{22}$$

(Interatomic exchange integral)

$$\begin{aligned}G_{ij'}&=(ij':ij')-S_{ij'}^2(ii:j'j')+2S_{ij'}H_{ij'}-(H_{ii}+H_{j'j'})S_{ij'}^2\\&\quad+2S_{ij'}\sum_{k\neq i,j'}(ij':kk)-S_{ij'}^2\sum_{k\neq i,j'}\{(cii:kk)+(j'j':kk)\}\end{aligned} \tag{23}$$

$$H_{ij'}=\int\varphi_i{}^*(1)H(1)\varphi_{j'}(1)\,d\tau_1 \tag{24}$$

(One-electron potential and kinetic energy integral)

$$(ij':ij')=\int\varphi_i{}^*(2)\varphi_{j'}{}^*(2)\frac{1}{r_{12}}\varphi_i(1)\varphi_j{}'(1)\,d\tau_1\,d\tau_2 \tag{25}$$

(Exchange integral)

$$\begin{aligned}\phi_{Aa}^{(1)}&=\sum\nolimits_{Aa}^{(1)}(-1)^P P\varphi_1(1)\alpha(1)\varphi_2(2)\alpha(2)\varphi_3(3)\alpha(3)\varphi_4(4)\alpha(4)\\&\quad\times\varphi_{4'}(5)\beta(5)\varphi_{3'}(6)\alpha(6)\varphi_{2'}(7)\alpha(7)\varphi_{1'}(8)\alpha(8)\,.\end{aligned} \tag{26}$$

The notation $\sum_{Aa}^{(1)}$ means the summation over all possible single exchanges in the structure *Aa*.

In a similar manner, we obtain

$$\begin{aligned}\int\phi_{\overline{Aa}}{}^*\mathscr{H}\,\phi_{\overline{Aa}}\,d\tau&=(\phi_{\overline{Aa}}|\mathscr{H}\,|\phi_{\overline{Aa}})\\&=E_0-C_0-E_0\sum\nolimits_{\overline{Aa}}^{(1)}S_{ij'}^2-C_{\overline{Aa}}^{(1)}+\cdots\end{aligned} \tag{27}$$

$$\begin{aligned}-\int\phi_{\overline{Aa}}{}^*\mathscr{H}\,\phi_{Aa}\,d\tau&=-(\phi_{A\bar{a}}|\mathscr{H}\,|\phi_{Aa})\\&=E_0S_{44'}^2-C_0S_{44'}^2-E_0(\sum\nolimits_{Aa}^{(1)}S_{ij'}^2)S_{44'}^2+C_{44'}^{(1)}+\cdots\end{aligned} \tag{28}$$

where

$$C_{44'}^{(1)}=G_{44'}\,. \tag{29}$$

Thus, substituting (19)–(29) in (18), we obtain:

$$\begin{aligned}E&=\{E_0(1+k-ks^2)-C_0(1+k-ks^2)-C_s{}^{(1)}(1+k)+C_b{}^{(1)}\}\div(1+k-ks^2)\\&\fallingdotseq E_0-C_0+\frac{C_b{}^{(1)}}{1+k}-C_s{}^{(1)}+\frac{ks^2}{1+k}(C_b{}^{(1)}-C_s{}^{(1)})\end{aligned} \tag{30}$$

where

$$E_0=\sum H_{ii}+\sum{}'(ii:jj) \tag{31}$$

$$C_0=3(12:12)+3(14:14) \tag{32}$$

$$C_s{}^{(1)}=\frac{3}{2}G_{11'}+3G_{12'}+3G_{14'} \tag{33}$$

$$C_b{}^{(1)}=G_{44'} \tag{34}$$

$C_s{}^{(1)}$ and $C_b{}^{(1)}$ are defined in such a way that the former contains only $G_{ij'}$, associated with non-bonding electron orbitals φ_i and $\varphi_{j'}$, while the latter contains only $G_{ij'}$, associated with bonding electron orbitals.

$$k=S_{44'}^2 \tag{35}$$

$$s^2=\langle\sum\sum\nolimits_{Pq}^{(1)}S_{ij'}^2\rangle \tag{36}$$

In a similar manner, the general formulas for electronic energy in the cases of Model II, Model III, Model IV and Model V are obtained. The results are given in Table III.

G. *Numerical calculation*

The adiabatic potential between two atoms in the molecule is the eigenvalue of electronic energy as a function of the distance between the nuclei. In order to know explicitly this dependence on the distance we have to evaluate the eigenvalue for various distances. For this purpose we have to carry out the numerical calculations of molecular integrals $S_{ij'}$, $H_{ij'}$, $(pq:rs)$ etc., which may be rather tedious and laborious, but they can be carried out in

Table III. The general formulas for electronic energy in each model.

Model I and Model II:

$$\begin{aligned}E_0=&2H_{ss}+4H_{xx}+2H_{zz}+\left(\frac{16}{3}\tan^4\alpha-\frac{4}{3}\tan^2\alpha+\frac{16}{3}\right)(ss:ss)-\frac{8}{3}(1-2\tan^2\alpha)(1+\tan^2\alpha)(sz:sz)\\&+\left(-\frac{16}{3}\tan^4\alpha+4\tan^2\alpha+\frac{2}{3}\right)(zz:zz)+\frac{4}{3}(3-2\tan^2\alpha)(xx:zz)-\frac{16}{3}\tan^2\alpha(xz:xz)\\&+2(xx:yy)+(ss:s's')+2(ss:z'z')+(zz:z'z')+4(xx:s's')\\&+4(xx:z'z')+2(xx:x'x')+2(xx:y'y)+\frac{16}{R}\end{aligned}$$

Model III:

$$\begin{aligned}E_0=&2H_{ss}+4H_{xx}+2H_{zz}+\left(\frac{11}{2}+\frac{3}{2}\tan^4\alpha-\tan^2\alpha\right)(zz:ss)-2(1+3\tan^2\alpha)(1-\tan^2\alpha)(sz:sz)\\&+\left(-\frac{3}{2}\tan^4\alpha+2\tan^2\alpha\right)(zz:zz)+(6-\tan^2\alpha)(xx:zz)-2\tan^2\alpha(xz:xz)+\frac{1}{2}(xx:xx)+(ss:s's')\\&+2(ss:z'z')+(zz:z'z')+4(xx:s's')+4(xx:z'z')+2(xx:x'x')+2(xx:y'y')+\frac{16}{R}\end{aligned}$$

Model IV:

$$\begin{aligned}E_0=&2H_{ss}+4H_{xx}+2H_{zz}+\left(\frac{1}{2}+\tan^2\alpha\tan^2\beta\right)\{(ss:ss)+2(ss:zz)+(zz:zz)\}\\&-4\tan^2\alpha\tan^2\beta\,(sz:sz)+3(ss:xx)+3(xx:zz)+(xx:xx)+2(xx:yy)-2(sx:sx)-2(zx:zx)+(ss:s's')\\&+2(ss:z'z')+(zz:z'z')+4(xx:s's')+4(xx:z'z')+2(xx:x'x')+2(xx:y'y')+\frac{16}{R}\end{aligned}$$

Model V:

$$\begin{aligned}E_0=&2H_{ss}+4H_{xx}+2H_{zz}+2\sin^2\alpha'\cos^2\alpha'\{(ss:ss)-2(ss:zz)+(zz:zz)-4(sz:sz)\}\\&+2(ss:zz)+2(xx:yy)+4(xx:ss)+4(xx:zz)+(ss:s's')+2(ss:z'z')+(zz:z'z')+4(xx:s's')\\&+4(xx:z'z')+2(xx:x'x')+2(xx:y'y')+2(1-\sin^2 2\alpha')(ss:z'z')+\frac{16}{R}\end{aligned}$$

Model I and Model II:

$$\begin{aligned}C_0=&3(12:12)+3(14:14)=\left(\frac{8}{3}\tan^4\alpha-\frac{2}{3}\tan^2\alpha-\frac{1}{3}\right)(ss:ss)+\left(\frac{1}{3}+2\tan^2\alpha-\frac{8}{3}\tan^4\alpha\right)(xx:xx)\\&+\left(\frac{5}{3}-\frac{8}{3}\tan^2\alpha+\frac{32}{3}\tan^4\alpha\right)(sz:sz)+\left(2-\frac{8}{3}\tan^2\alpha\right)(zx:zx)-\frac{4}{3}\tan^2\alpha(xx:zz)+(xy:xy)\end{aligned}$$

Model III:

$$\begin{aligned}C_0=&(12:12)+2(13:13)+2(14:14)+(34:34)=\left(-\frac{1}{4}-\frac{1}{2}\tan^2\alpha+\frac{3}{4}\tan^4\alpha\right)(ss:ss)\\&+\left(\frac{1}{4}+\tan^2\alpha-\frac{3}{4}\tan^4\alpha\right)(zz:zz)+(2-2\tan^2\alpha+3\tan^4\alpha)(sz:sz)+3(zx:zx)\\&-\frac{1}{2}\tan^2\alpha(xx:zz)-\tan^2\alpha(zx:zx)\end{aligned}$$

where

$$a=\tan\alpha'$$

a straight forward way by making use of table of Kotani et al.[21], and other tables[22].

In order to make use of the tables for our calculation we have to prepare some supplementary formulas and tables for the integrals, (see Appendix II). Actually we have used only ordinary desk machine of the type "Tiger".

§ 3. Result and Discussion

The numerical calculations of the adiabatic potential are carried out in cases as follws:

For Model I and Model II

$\alpha=\tan^{-1}(1/\sqrt{8})$

For Model III $\alpha=30°$

For Model IV $\alpha=\beta=\tan^{-1}(1/\sqrt{2})$

For Model V $\alpha'=45°$

The results of evaluating the adiabatic potential according to the general formulas given in Table III are shown in Table IV. The potential curve $E(R)-E(\infty)$ are plotted in Fig. 7. The binding energies of the molecular system and corresponding equilibrium distances between two nuclei are evaluated from these curves. It should, however, be noted that, when the molecular system dissociates into each atom, it may give rise to valence atoms, not normal atoms. Relative values of $E(\infty)$ in each model are shown in Table V.

Table IV. Relative bond distances and bond energies.

	Bond distance	Bond energy
Relative value of C−C and C≡C	Calc. 0.20Å	Calc. 3.1 ev.

(C: $s^2p^2\,{}^3p$)

Thus we obtain 3.1 e.v., 1.25 e.v., and 0.20 Å, 0.10 Å for the values of relative bond energy differences and bond distance differences of single and triple, double and triple bonding. The experimental values of these quantities are 2.9 e.v., 1.0 e.v., and 0.34 Å, 0.12 Å, respectively.

These results of our numerical computation are in good agreement with the experimental values, in spite of all possible sources of error in molecular calculation by H–L–S–P method, in addition to the approximations adopted here.

There are several possible sources of error in the numerical values carried out by our calculation as follows:

Best energies should really be determined by a method which includes inner shell electrons explicitly. Of this question, we shall discuss later in detail.

The forms of the AO's which are used in constructing the atomic bond orbital should themselves be determined by a variational procedure. Even in atoms, Slater functions cannot be made to fit the true self-consistent field²³⁾. The use of Slater functions reduces the electronic interaction between non-neighbors too much, since Slater functions die down more rapidly than Hartree-Fock SCF orbitals at large distances²⁴⁾. The Slater $2p$ AO's with $2\delta=3.25$ which we have used might thus need to be strongly modified. This question of the form of the atomic orbitals to be used in molecular calculations appears to be one of the most serious and difficult problems²⁵⁾.

There are other sources of error caused by neglecting the ionized states and higher permutation terms in H–L–S–P method. But among higher permutation terms, some of double permutation terms, for example, in the case of Model III, ((44′)(33′)), ((43′)(4′3)), ((14′)(12)), ((44′)(12)) etc., are taken in our calculation.

Approximation of expansion in powers of

overlap integrals $S_{ij'}$, between non-bonding orbitals is made for obtaining the general formulas of adiabatic energy potential in each model and further approximations are made for the evaluation of hybrid Coulomb-exchange molecular integrals (for the latter, see Appendix II).

Table VI.

Bond distance	Calc.		Expt.
	a case	b case	
R_{C-C} Model I	1.06 Å	1.50 Å	1.54 Å
$R_{C=C}$ Model III	0.98 Å	1.30 Å	1.32 Å
Model IV	0.98 Å	1.30 Å	
$R_{C\equiv C}$ Model II	0.85 Å	*	1.20 Å
Model V	0.90 Å	1.09 Å	

* For Model II, the adiabatic energy potential does not show minimum.

Absolute values of the equilibrium distances between two nuclei in each model are shown in Table VI, compared with the experimental values. These values shift uniformly toward smaller values than the corresponding experimental values. We can account for this discrepancy by taking account of the effect of inner shells. If we estimate the contribution to the energy by taking account of 1s electrons, we obtain the following expression.

$$\varDelta E=\varDelta_1-\mathcal{E} \tag{37}$$

where

$$\varDelta_1=\frac{20}{R}-24(C:c'c')+4(cc:c'c') \tag{38}$$

(Coulomb interaction energy between 1*s* electrons and 1*s* electrons in each carbon atom)

$$\mathcal{E}=\varDelta_2+\varDelta_3+\varDelta_4 \tag{39}$$

(Exchange interaction energy term between 1*s* electrons and *s*, *x*, *y*, *z* electrons)

$$\varDelta_2=2(cs':cs')+2(cz':cz')+4(cx':cx') \tag{40}$$

$$\left.\begin{array}{ll} \varDelta_3=6A_{c1'}+2A_{c4'} & \text{for Model I and Model II} \\ \varDelta_3=4A_{c1'}+2A_{c4'} & \text{for Model III} \\ \varDelta_3=4A_{c1'}+4A_{c3'} & \text{for Model IV} \\ \varDelta_3=2A_{c3'}+2A_{c4'} & \text{for Model V} \end{array}\right\} \tag{41}$$

$$\left.\begin{array}{ll} \varDelta_4=6B_{c1'}+2B_{c4'} & \text{for Model I and Model II} \\ \varDelta_4=4B_{c1'}+2B_{c4'} & \text{for Model III} \\ \varDelta_4=4B_{c1'}+4B_{c3'} & \text{for Model IV} \\ \varDelta_4=2B_{c3'}+2B_{c4'} & \text{for Model V} \end{array}\right\} \tag{42}$$

$$A_{ci'}=2S_{ci'}H_{ci'}-S_{ci'}^2(H_{cc}+H_{i'i'}) \tag{43}$$

$$B_{ci'}=2S_{ci'}\sum_{j=c,i'}(ic':jj)-S_{ci'}^2\sum_{j\neq c,i'}((i'i':jj)+(cc:jj)) \tag{44}$$

$$S_{ci'}=\int c(1)\varphi_{i'}(1)\,d\tau_1\,. \tag{45}$$

Carrying out the numerical evaluation of $\varDelta E$, we obtain the total energy which takes into account of the 1*s* electrons and these results are shown in Fig. 8.

Evaluating from these potential curves, we obtain the equilibrium distances between two nuclei in each model and the results are shown in Table VII. These results are in very good agreement with experimental values. It has been pointed out by James[26] that the inner shells of the atoms may have an important effect on the value of molecular binding and may either increase or decrease it and since their effect is associated with electron exchange, it appears that they cannot be replaced by an equivalent potential field without serious error. The effect of the inner shells (chiefly Δ_3 effect) seems to give rise to a repulsive potential in our calculation, varying much more rapidly with distance than the other terms in the adiabatic potential. For sufficiently large separations of the atoms, this effect would presumably sink to negligible value, but for internuclear distances of the order of the equilibrium distance, it is by no means unimportant.

We consider the absolute values of bond energy, (for example, in the case of Model I). When the molecule dissociates into each atom, it may give rise to atoms in valence states. We have to study the valence state of carbon atom. Van Vleck[27] pointed out that the valence state which is characteristic of tetravalent carbon compounds involving four electron pair bonds, is shown to involve an increase of about 7.1 e.v. in the internal energy of the carbon atom over that in the ground state. Thus, we assume that each bond in the tetravalent carbon valence atom has one-fourth of 7.1 e.v. The absolute value of bond energy between carbon-carbon atoms is calculated by the following formula.

$$E_{C-C}=|E(R_e)-E(\infty)|-2\times\tfrac{1}{4}\times 7.1\text{ e.v.}$$
$$=|E(R_e)-E(\infty)|-3.55\text{ e.v.} \qquad (46)$$

where $E(R_e)$ represents the adiabatic potential

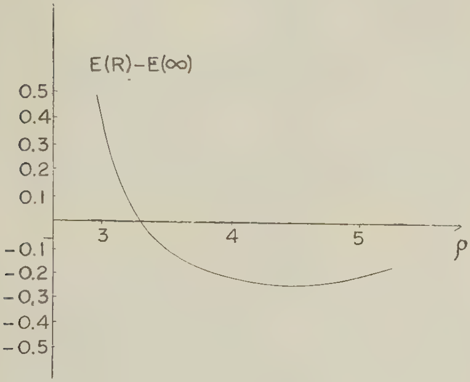

Fig. 8. Adiabatic energy potential $E(R)-E(\infty)$ in the case of Model I taking into account the inner shells, (in the atomic units; the units of energy and length being 27.204 e.v. and 0.529 Å respectively).

energy in equilibrium internuclear distance.

We obtain 3.04 e.v. in the case of taking account of the inner shells and 1.50 e.v. in the case of neglecting these inner shells for bond energy E_{C-C}. Compared with the experimental value $E_{C-C}=2.9$ e.v., the satisfactory agreement is obtained in the case of taking account of the inner shells and the latter shows good agreement also in equilibrium internuclear distances.

But in the calculation of the heats of dissociation of Li_2 molecule, James shows, for instance, that the nice agreement which Bartlett and Furry[28)] found between their calculated value 1.09 e.v. of the heat of dissociation of Li_2 by the Heitler-London method and the observed value 1.14 e.v. is completely destroyed when one includes the effect of the 1*s* electrons, the calculated value is then 0.3 e.v. Consequently better wave functions are needed than those in the Heitler-London method. James finds that by using a variational method he can increase the calculated value to 0.7 e.v. (see Table VIII). Omission of the inner shells in the calculation of Li_2 molecule tends to correct for a serious underestimate of the binding energy associated with the external electrons and also shifts the computed equilibrium nuclear distance strongly toward smaller values.

The general formula (30) corresponds to the equation (2) or (4) in the paper of Serber[29)] who calculated the energies of a number of hydrocarbon molecules by the H–L–S–P method. Our general formulas involve no semi-empirical parameters but are calculated non-empirically. Results obtained here show that the non-empirical calculation can give useful quantitative knowledge in the problems. Therefore, these formulas have more advanced contents for the evaluation of bond energies and bond distances between carbon atoms. Our results seem to encourage further work along similar lines about various chemical bonds between atoms other than carbon.

Acknowledgement

The author wishes to express his sincere thanks to Prof. M. Kotani, who suggested the problem for his much helpful advice and continuous encouragement throughout this work. This work has been supported in part by the scientific Research Expenditure of the Ministry of Education.

Appendix I

Proof of

$$E=\left(\Sigma\int\Phi_{Pq}^{*}\mathscr{H}\Phi_{Pq}\,d\tau\Big/\Sigma\int\Phi_{Pq}^{*}\Phi_{Pq}d\tau\right)=\left(\left\langle\int\Phi_{Pq}^{*}\mathscr{H}\Phi_{Pq}\,d\tau\right\rangle\Big/\left\langle\int\Phi_{Pq}^{*}\Phi_{Pq}d\tau\right\rangle\right)$$

As an example, we discuss the case of model I. The wave function of the complete ethane molecule is

$$\Psi=\Sigma^{\dagger}\{(|\varphi_1\varphi_2\varphi_3\varphi_4\bar{\varphi}_{4'}\varphi_{3'}\varphi_{2'}\varphi_{1'}\hbar_1\hbar_2\hbar_3\hbar_{3'}\hbar_{2'}\hbar_{1'}|)-(|\varphi_1\varphi_2\varphi_3\bar{\varphi}_4\varphi_{4'}\varphi_{3'}\varphi_{2'}\varphi_{1'}\hbar_1\hbar_2\hbar_3\hbar_{3'}\hbar_{2'}\hbar_{1'}|)\} \qquad (A.1)$$

where h_i etc. are the wave functions of the bonding electrons in the surrounding atoms.

According to the determinant theory, the determinant

$$(|\varphi_1\varphi_2\varphi_3\varphi_4\bar{\varphi}_{4'}\varphi_{3'}\varphi_{2'}\varphi_{1'}\hbar_1\hbar_2\hbar_3\hbar_{3'}\hbar_{2'}\hbar_{1'}|)$$

is expanded in the sum of the products of the minor eight-by-eight determinants having only the wave functions φ_i and the minor six-by-six determinants having only the wave functions h_i as follows:

$$(|\varphi_1\varphi_2\varphi_3\varphi_4\bar{\varphi}_{4'}\varphi_{3'}\varphi_{2'}\varphi_{1'}\hbar_1\hbar_2\hbar_3\hbar_{3'}\hbar_{2'}\hbar_{1'}|)=\Sigma^{\dagger\dagger}M_{A\alpha}(\varphi:\ i_1,i_2,\cdots,i_8)N_{A\alpha}(h:\ j_1,j_2,\cdots j_6) \qquad (A.2)$$

---

† Where Σ means the summation over all possible spin configurations corresponding to the 8×8 structures P_q.

†† Where Σ means the summations over all possible combination $(i_1, i_2, \cdots, i_8)$ and $(j_1, j_2, \cdots, j_6)$ of the coordinates of the electrons which are put in the $M_{A\alpha}(\varphi: i_1, i_2, \cdots, i_8)$ and $N_{A\alpha}(h: j_1, j_2, \cdots, j_6)$.

where

$$M_{Aa}(\varphi:\ i_1,\ i_2,\cdots,\ i_8)=(|\varphi_1\varphi_2\varphi_3\varphi_4\bar{\varphi}_{4'}\varphi_{3'}\varphi_{2'}\varphi_{1'}|) \tag{A.3}$$

$$N_{Aa}(h:\ j_1,\ j_2,\cdots,\ j_6)=(|\hbar_1\hbar_2\hbar_3\hbar_{3'}\hbar_{2'}\hbar_{1'}|) \tag{A.4}$$

In a similiar way, we obtain

$$(|\varphi_1\varphi_2\varphi_3\bar{\varphi}_4\varphi_{4'}\varphi_{3'}\varphi_{2'}\varphi_{1'}\hbar_1\hbar_2\hbar_3\hbar_{3'}\hbar_{2'}\hbar_{1'}|)=\Sigma M_{\overline{Aa}}(\varphi:\ i_1,\ i_2,\cdots,\ i_8)N_{\overline{Aa}}(h:\ j_1,\ j_2,\cdots,\ j_6) \tag{A.5}$$

where

$$\left.\begin{aligned}M_{\overline{Aa}}(\varphi:\ i_2,\ i_2,\cdots,\ i_8)&=(|\varphi_1\varphi_2\varphi_3\bar{\varphi}_4\varphi_{4'}\varphi_{3'}\varphi_{2'}\varphi_{1'}|)\\ N_{\overline{Aa}}(h:\ j_1,\ j_2,\cdots,\ j_6)&=N_{Aa}(h:\ j_1,\ j_2,\cdots,\ j_6)\end{aligned}\right. \tag{A.6}$$

If we integrate the $\int\Psi^*\mathscr{H}\Psi d\tau$, substituting (A.2) and (A.5) in Ψ, we obtain:

$$\begin{aligned}\int\Psi^*\mathscr{H}\Psi d\tau=\Sigma\Sigma\Sigma\int&(M_{Rs}{}^*(\varphi:\ i_1',\ i_2',\cdots,\ i_8')-M_{\overline{Rs}}{}^*(\varphi:\ i_1',\ i_2',\cdots,\ i_8')\\ &\times N_{Rs}(h:\ j_1',\ j_2',\cdots,\ j_6')\mathscr{H}(M_{Pq}-M_{\overline{Pq}})(\varphi:\ i_1,\ i_2,\cdots,\ i_8)\\ &\times N_{Pq}(h:\ j_1,\ j_2,\cdots,\ j_6)d\tau_1,\ d\tau_2,\cdots,\ d\tau_{14}\ .\end{aligned} \tag{A.7}$$

When there is at least one pair of the different co-ordinates (for example, we assume this pair as j_1 and j_1') in the combinations $(j_1,\ j_2,\ \cdots,\ j_6)$ and $(j_1',\ j_2',\cdots,\ j_6')$ of the coordinates of the electrons which are horsed in the minor determinants $N_{Pq}(h:\ j_1,\cdots,\ j_6)$ and $N_{Rs}(h:\ j_1',\cdots,\ j_6')$, we integrate the $\int(M_{Rs}-M_{\overline{Rs}})^*N_{Rs}\mathscr{H}(M_{Pq}-M_{\overline{Pq}})N_{Pq}d\tau_{j_1}d\tau_{j_1'}$ for these coordinates j_1 and j_1' and we remove the surrounding atoms to infinite distance and then the integral $\int(M_{Rs}-M_{\overline{Rs}})^*N_{Rs}{}^*\mathscr{H}(M_{Pq}-M_{\overline{Pq}})N_{Pq}d\tau_{j_1}d\tau_{j_1'}$ vanishes. Therefore, we may consider only the case of the same combinations $(j_1,\cdots,\ j_6)$ and $(j_1,\cdots,\ j_6)$ of the coordinates of the electrons which are put in the $N_{Pq}(h:\ j_1,\ j_2,\cdots,\ j_6)$ and $N_{Rs}(h:\ j_1,\ j_2,\cdots,\ j_6)$.

As the hamiltonian $\mathscr{H}$ is invariant for all permutations over 1, 2, ⋯, 14, the following equality is obtained:

$$\begin{aligned}\int\Psi^*\mathscr{H}\Psi d\tau=\Sigma\int&(M_{Rs}{}^*(\varphi:\ 1,\ 2,\cdots,\ 8)-M_{\overline{Rs}}{}^*(\varphi:\ 1,\ 2,\cdots,\ 8))N_{Rs}{}^*(h:\ 9,\ 10,\cdots,\ 14)\\ &\times\mathscr{H}(M_{Pq}-M_{\overline{Pq}})(\varphi:\ 1,\ 2,\cdots,\ 8)N_{Pq}(h:\ 9,\ 10,\cdots,\ 14)d\tau\end{aligned} \tag{A.8}$$

The spin configurations of the electrons which are put in the wave functions φ_i, correspond to the spin configurations of the electrons which are put in the wave functions h_i respectively and so if we integrate for the spin coordinates of the electrons which are put in the wave functions h_i, the interaction energy between the structure Pq and Rs does not vanish only in the case that the structures Pq and Rs have the same configuration of spin.

Thus, we obtain

$$\begin{aligned}\int\Psi^*\mathscr{H}\Psi d\tau=\Sigma\int&(M_{Pq}{}^*(\varphi:\ 1,\ 2,\ \cdots,\ 8)-M_{\overline{Pq}}{}^*(\varphi:\ 1,\ 2,\cdots,\ 8))\\ &\times\mathscr{H}(M_{Pq}(\varphi:\ 1,\ 2,\cdots,\ 8)-M_{\overline{Pq}}(\varphi:\ 1,\ 2,\cdots,\ 8))d\tau_1,\ d\tau_2,\cdots,\ d\tau_8\end{aligned} \tag{A.9}$$

In a similar way, we obtain

$$\begin{aligned}\int\Psi^*\Psi d\tau=\Sigma\int&(M_{Pq}{}^*(\varphi:\ 1,\ 2,\cdots,\ 8)-M_{\overline{Pq}}{}^*(\varphi:\ 1,\ 2,\cdots,\ 8))\\ &\times(M_{Pq}(\varphi:\ 1,\ 2,\cdots,\ 8)-M_{\overline{Pq}}(\varphi:\ 1,\ 2,\cdots,\ 8))d\tau_1,\ d\tau_2,\cdots,\ d\tau_8\end{aligned} \tag{A.10}$$

Taking account of the equality of $(M_{Pq}-M_{\overline{Pq}})\propto(\phi_{Pq}-\phi_{\overline{Pq}})\propto\Phi_{Pq}$, we obtain

$$E'=\int\Psi^*\mathscr{H}\Psi d\tau_1\cdots d\tau_{14}\Big/\int\Psi^*\Psi d\tau_1\cdots d\tau_{14}$$

$$=\left(\Sigma\int\Phi_{Pq}{}^*\mathscr{H}\Phi_{Pq}d\tau_1\cdots d\tau_8\right)\Big/\left(\Sigma\int\Phi_{Pq}{}^*\Phi_{Pq}d\tau_1\cdots d\tau_8\right)+\mathcal{E}_0=E+\mathcal{E}_0 \qquad \text{(A.11)}$$

where $\mathcal{E}_0$ is the proper energy of the surrounding atoms.

Appendix II. Evaluation of Molecular Integrals

In this appendix II, the evaluation of the molecular integrals occuring in our calculation is explained.

A. The overlap integral S_{ij}', one-electron potential and kinetic energy integrals, exchange integrals for interatomically orthogonal $2s$, $2p$- hybrid orbitals are expressed in convienent form and are easily evaluated using the Table of Kotani, et. al..

B. In computing the hybrid Coulomb-exchange integrals, we use the following approximation.[30]

$$ij':kk)=S_{ij}'(\bar{i}\,\bar{j}':kk) \qquad \text{(A.12)}$$

Where $\bar{i}$ and $\bar{j}'$ are the atomic orbitals associated with the center of gravity, which has to be chosen in a suitable way.

These exchange integral term associated hybrid Coulomb-exchange integrals are not negligible.

C. The molecular integrals involving $1s$ orbitals are calculated as follow:

One-electron potential and kinetic energy integrals and Coulomb integrals are calculated by using Roothaan's formulas.[31]

Exchange integrals and hybrid Coulomb-exchange integrals are calculated by the following approximation formulas[32]

$$(cj':cj')=S_{cj'}{}^2(\bar{c}\,\bar{j}':\bar{c}\,\bar{j}') \qquad \text{(A.17)}$$

$$(cj':kk)=S_{cj'}(\bar{c}\,\bar{j}':kk) \qquad \text{(A.18)}$$

On the Non-Orthogonality Difficulty in Ferromagnetism

By Fumihiko TAKANO

Department of Physics, Tokyo University of Education

(Received October 31, 1958)

In a many-electron system, one is faced to some difficulties when one-electron wave functions are not orthogonal to each other. For example, the inner product (Φ, Φ) (Φ is a Slater determinant made from these non-orthogonal wave functions) loses its meaning as the number of electrons becomes large. We avoid this difficulty by using the expansion coefficients instead of the inner products, in order to define the matrix elements of operators. Applying this method to a magnetic problem, in which there are some doubts about the validity of the Heisenberg model $\mathscr{H}=-2\sum_{i>j} J_{i,j}\boldsymbol{S}_i\cdot\boldsymbol{S}_j$, we can derive the energy of the ground state and the energy spectrum of spin waves. The results are written as

$$W_0=\sum_{i=1}^{N} f_{i,j}+\tfrac{1}{2}\sum_i\sum_j(g_{ij,ij}-g_{ij,ji}) ,$$

and

$$\varepsilon(K)=\sum_{j=1}^{N}\alpha_K(j)\beta_K(j) .$$

Some mathematical difficulties which occur in the case of the state in which more than two spins are reversed are discussed.

§ 1. Introduction

The Heisenberg model, usually used in magnetic problems, has a difficulty arising from non-orthogonality of atomic functions. This is the following: Let us consider an electronic configuration in which each atomic orbital φ_i (i denotes the number specifying an atom) is occupied by one electron, and solve the spin degeneracy in this configuration. If the orbitals are orthogonal to each other, the Hamiltonian for a spin system can be rigorously written in a usual form[1]

$$\mathscr{H}=-2\sum_{i>j} J_{i,j}\boldsymbol{S}_i\cdot\boldsymbol{S}_j , \tag{1.1}$$

where $J_{i,j}$ is the exchange energy between the orbitals φ_i and φ_j, and $\boldsymbol{S}_i$ is the spin operator of the orbital i. In this case, however, $J_{i,j}$ has always a positive value, and all materials should be ferromagnetic. This is contrary to the original idea of the Heisenberg model in which we can distinguish ferro- and antiferro-magnetism according to the sign of $J_{i,j}$.

To keep the advantage of the original Heisenberg model we must use the non-orthogonal atomic orbitals. In this case, however, the Hamiltonian cannot be written in such a simple form as Eq. (1.1). Therefore, an attempt to investigate the situation in detail will be important and desirable. We suppose that the form of Eq. (1.1) is probably valid as a first approximation, but it is difficult to show this mathematically because of the following situation. As Slater[2] has pointed out, the inner product (Φ, Φ) of the Slater determinant made from the non-orthogonal orbitals tends to infinity as the number N of electrons becomes large. This is physically meaningless. Of course, this divergence should cancel out in the expression $(\Phi, A\Phi)/(\Phi, \Phi)$. However, it is very difficult to prove this for general cases.

In this paper we shall avoid this difficulty using the expansion coefficients instead of the inner products to define the matrix elements of operators. This method is very useful in the problems in which non-orthogonal functions appear. Previously, the author applied this method to liquid He⁴, and succeeded to obtain the smooth connection between the Bose condensation theory and the phonon-roton model[3].

We consider the idealized case only, in which each atom has only one electron. Moreover, the orbital configuration of electrons is limited to non-ionized one. Thus, there is just the same number of orbitals as electrons, and there is neither empty nor doubly occupied orbital. The extension to more realistic case in which each atom has more than two electrons can be done easily. Moreover, we shall treat the ferromagnetic case only, although the antiferro-magnetic one can be treated similarly.

For the ground state of a ferromagnet, in which all electrons have parallel spins, there is no spin degeneracy, and the energy eigenvalue can be easily calculated by calculating the value of $(\Phi, H\Phi)/(\Phi, \Phi)$[4]. For an excited state, in which a certain number of spins are reversed, the situation is not so simple as for the ground state, and it is difficult to get the energy eigenvalue by calculating the value of $(\Phi, H\Phi)/(\Phi, \Phi)$. In this paper, we use the above-mentioned method and obtained the rigorous expression for the energy spectrum of spin waves. The solution, in which more than two spins are reversed, would be obtained in a similar way, but we could not do it due to some mathematical difficulties.

In § 2, we shall show the outline of the method used. In § 3, this method will be applied to the case of hydrogen molecule in order to illustrate the features of this method. In § 4 and § 5, we shall treat the N-electron system and derive the energy spectrum of spin waves. Some difficulties in the problem of the scattering between spin waves will be discussed in § 6.

§ 2. Outline of the Method

As mentioned above, the difficulty of the non-orthogonality arises when one wants to calculate a matrix element in a form $(\Phi_i, A\Phi_j)$, where Φ_i, Φ_j are many-electron wave functions. Here, we do not use such an inner product at all, but use the following procedure. Let us consider a set of functions $|i)$, which is complete in the Hilbert space considered, but not orthonormal. We represent an operator A in terms of the following $a_{j,i}$,

$$A|i)=\sum |j)a_{j,i} . \qquad (2.1)$$

Using this matrix representation, the eigenvalues α of A is determined from

$$|a_{j,i}-\alpha\delta_{j,i}|=0 . \qquad (2.2)$$

Compare this equation with that appears in the usual method, i.e., with

$$|A_{j,i}-\alpha(j|i)|=0 , \qquad (2.2')$$

where $A_{j,i}=(j|A|i)$ is the inner product of $A|i)$ with $(j|$. The relation between $a_{j,i}$ and $A_{j,i}$ is

$$A_{j,i}=\sum_k (j|k)a_{k,i} . \qquad (2.3)$$

The basic concept of the present paper is to use Eq. (2.2) instead of Eq. (2.2′).

In the present problem, there are two different ways of choosing $|i)$. We shall illustrate these two methods in the following.

(I) The direct application of the above method leads to the following results. As was done by Dirac[1], we write $\psi_0=\varphi_1(1)\varphi_2(2)\cdots\varphi_N(N)$ where φ_j's are atomic orbitals, and limit the space considered to that which is made from $N!$ functions $P\psi_0$, where P denotes the permutation operator of electron coordinates. According to Eq. (2.2), we can define the matrix elements $h_{P',P}$ of the Hamiltonian H by

$$HP\psi_0=\sum_{P'} P'\psi_0 h_{P',P} . \qquad (2.4)$$

Then, the effective Hamiltonian $\mathscr{H}$ for spin variables can be written as

$$\mathscr{H}=\sum_{P_\sigma}(-1)^{P_\sigma}h_{1,P}P_\sigma , \qquad (2.5)$$

where P_σ is the permutation operator of electron spins, and the relation $h_{P',P}=h_{1,P'^{-1}P}$ is used. The derivation of Eq. (2.5) is completely similar to that due to Dirac[1].

This method appears to be quite simple, but the difficulty arises when we want to calculate the value of $h_{1,P}$. As is seen from Eq. (2.3), it is necessary to calculate the inverse of the overlap matrix $(P'\psi_0|P\psi_0)$. The dimension of this overlap matrix, however, is $N!$ and it is as difficult as to use the inner product to calculate the inverse matrix when atomic orbitals are not orthogonal. Moreover, in order to derive the form such as Eq. (1.1) from Eq. (2.5), it is necessary to write P_σ in the form of the product of the interchange $P_{(i,j)}$, and to express $P_{(i,j)}$ in terms of $(S_i\cdot S_j)$, $P_{i,j}=\frac{1}{2}(1+4(S_i\cdot S_j))$. And then we must pick up the terms proportional to $(S_i\cdot S_j)$. Since the number of such terms is very large, we have the same difficulty and in the usual method.

(II) Next, we use the one electron wave functions φ_i (atomic orbitals) as $|i)$ in Eq. (2.1). Hamiltonian of our system consists from the sum of one-electron functions and of two-electron functions,

$$H=\sum_{i=1}^{N} f(r_i)+\sum_{i>j}\sum g(r_{ij}) . \qquad (2.6)$$

we define the matrix elements of f and g in accordance with Eq. (2.1),

$$\left.\begin{aligned} f(1)\varphi_i(1)&=\sum_{j=1}^{N}\varphi_j(1)f_{j,i}\,,\\ g(1,2)\varphi_i(1)\varphi_j(2)&=\sum_{k=1}^{N}\sum_{l=1}^{N}\varphi_k(1)\varphi_l(2)g_{kl,ij}\,. \end{aligned}\right\} \tag{2.7}$$

Using these $f_{j,i}$ and $g_{kl,ij}$, we can define the matrix elements of H. The relations between these $f_{j,i}$ and $g_{kl,ij}$ and the usual matrix elements $F_{j,i}\equiv(j|f|i)$, $G_{kl,ij}\equiv(kl|g|ij)$ can be written as

$$\left.\begin{aligned} f_{j,i}&=\sum_{k}t_{j,k}F_{k,i}\,,\\ g_{kl,ij}&=\sum_{m}\sum_{n}t_{k,m}t_{l,n}G_{mn,ij}\,, \end{aligned}\right\} \tag{2.8}$$

where t is the inverse of the overlap matrix S ($S_{i,j}=(\varphi_i|\varphi_j)$). In this case, the dimension of the overlap matrix S is only N, compared with $N!$ of $(P'\psi_0|P\psi_0)$ used in method (I). Thus, the inverse matrix t can be calculated very easily. For example, let us assume that the overlap integral $(\varphi_i|\varphi_j)$ has a value 1 when $i=j$ and a value α when i and j are nearest neighbours to each other and vanishes otherwise. The formal expansion of the inverse matrix of $(P'\psi_0|P\psi_0)$ by power series of α converges only when $N\alpha^2<1$, which means that α must vanish in practice. When one uses t instead, however, the expansion parameter is $z\alpha^2$ (z=the number of nearest neighbours) and the expansion converges if $z\alpha^2<1$.

If $z\alpha^2>1$, we must use another method to calculate the matrix t, and this is in fact possible. However, when α is too large, the approximation of Heitler-London, in which atomic functions are used, becomes inferior to the band approximation, in which the functions of Bloch type are used. Slater[4] discussed about this point by using Wannier functions and Bloch functions in each case. We can do so quite similarly by using atomic functions φ_j instead of Wannier functions and the tightly bound approximation $(1/\sqrt{N})\times\sum_j e^{ikR_j}\varphi_j(r)$ of Bloch functions. Since the essential point does not differ from that of Slater, we shall discuss no more about this point, and employ the viewpoint of Heitler-London, only.

It is to be noted here that the method (II) is not equivalent to (I), while the latter is equivalent to the usual method. In the method (I) we consider $N!$ functions $P\psi_0$, where each function $P_i\psi_0$ has the same energy as ψ_0. In the method (II), however, we must consider functions involving ionic states, although some of these are inhibited by Pauli principle. It is not permissible in the method (II) to neglect the ionic states from the begining, because then it is not equivalent to the method (I) or the usual method. In other words, when and only when the spaces to be considered are the same, the method using the expansion coefficients is equivalent to the usual method using the inner products. In the method (II), $H\psi_0=H\varphi_1(1)\varphi_2(2)\cdots\varphi_N(N)$ does not involve $P\psi_0$ except $P=1$ and $P=P_{(ij)}$ (interchange), but necessarily involve many ionized states such as $\varphi_1(1)\varphi_1(2)\cdots\varphi_N(N)$. Thus, the space to be considered is not same to that of the usual method in which we neglect the ionized states. In the method (I), however, we restrict the space to $N!$ states $P\psi_0$ from the begining, that is same as the usual method. In this case, $H\psi_0$ involves all $P\psi_0$ generally, so that the calculation becomes very complicate. Here, we employ the method (II). In this case we must find an approximation equivalent to the usual method in which we neglect the ionized states. Before going into the general discussion, we shall treat the hydrogen molecule by three methods, the usual method, method (I) and (II), in order to illustrate the features of each method and to find the approximation in the method (II) equivalent to that in the usual method in which the ionized states are neglected.

§ 3. A Simple Example; Hydrogen Molecule

In order to show the equivalence or the difference among three methods mentioned in § 2, and to find the above-mentioned approximation for the method (II), first we treat a simple example, that is, a hydrogen molecule.

(a) *Usual method*

Let two protons of the hydrogen molecule be a and b, ane the s-functions of each atom be $a(r)$, $b(r)$, respectively. In the approximation neglecting the ionized states, we may consider only two orbital configurations, $|1)=a(1)b(2)$ and $|2)=b(1)a(2)$. Thus the secular equation can be written as

$$\begin{vmatrix} H_{11}-W & H_{12}-W(1|2) \\ H_{21}-W(2|1) & H_{22}-W \end{vmatrix}=0\,, \tag{3.1}$$

where $H_{i,j}=(i|H|j)$. If we set $\int a(r)b(r)d^3r=\alpha$

then $(1|2)=(2|1)=\alpha^2$. From the symmetry consideration, we can set $H_{11}=H_{22}\equiv A$, $H_{12}=H_{21}\equiv B$. Using these notations, the solution of Eq. (3.1) can be written as

$$W_t=\frac{A-B}{1-\alpha^2}\,,\quad W_s=\frac{A+B}{1+\alpha^2}\,. \tag{3.2}$$

Corresponding orbital wave functions are

$$\Psi_t=\frac{1}{\sqrt{2}}(|1)-|2))\,,\quad \Psi_s=\frac{1}{\sqrt{2}}(|1)+|2))\,. \tag{3.3}$$

These are well-known results.

(b) *Method* (I)

In this method, we define the matrix elements of H as follows,

$$H|1)=|1)h_{11}+|2)h_{21}\,,$$
$$H|2)=|1)h_{12}+|2)h_{22}\,.$$

From the symmetry considerations, we can set $h_{11}=h_{22}\equiv a$, $h_{12}=h_{22}\equiv b$. The secular equation can be written as

$$\begin{vmatrix} a-W & b \\ b & a-W \end{vmatrix}=0\,.$$

The roots of this equation are

$$W_s=a-b\,,\quad W_t=a+b\,. \tag{3.2$'$}$$

The corresponding wave functions are same as Eq. (3.3). The overlap matrix $(i|j)$ has a form as

$$\begin{pmatrix} 1 & \alpha^2 \\ \alpha^2 & 1 \end{pmatrix},$$

so that the inverse of this matrix becomes

$$\frac{1}{1-\alpha^4}\begin{pmatrix} 1 & -\alpha^2 \\ -\alpha^2 & 1 \end{pmatrix}.$$

Thus, a and b can be written in terms of A and B, using Eq. (2.3)

$$a=\frac{1}{1-\alpha^4}(A-\alpha^2B)\,,\quad b=\frac{1}{1-\alpha^4}(-\alpha^2A+B)\,. \tag{3.3}$$

Substituting Eq. (3.4) into Eq. (3.2′), it is easily seen that Eq. (3.2′) coincides with Eq. (3.2).

(c) *Method* (II)

The Hamiltonian of this system can be written as

$$H=f(1)+f(2)+g(12)\,.$$

We can define the matrix elements of f and g in accordance with Eq. (2.7),

$$f(1)a(1)=a(1)f_0+b(1)f_1\,,\qquad f(1)b(1)=a(1)f_1+b(1)f_0\,,$$
$$g(12)a(1)b(2)=a(1)b(2)k_0+b(1)a(2)j_0+(a(1)a(2)+b(1)b(2))l\,,$$
$$g(12)b(1)a(2)=a(1)b(2)j_0+b(1)a(2)k_0+(a(1)a(2)+b(1)b(2))l\,,$$
$$g(12)a(1)a(2)=(a(1)b(2)+b(1)a(2))l'+a(1)a(2)k_1+b(1)b(2)j_1\,,$$
$$g(12)b(1)b(2)=(a(1)b(2)+b(1)a(2))l'+a(1)a(2)j_1+b(1)b(2)k_1\,.$$

As was previously stated, we can not neglect the ionized states $a(1)a(2)$ and $b(1)b(2)$ from the begining. It is to be noted that the above matrix representation of g is not hermitian because $l\neq l'$. Using these matrix elements, the secular equation can be written as

$$\begin{vmatrix} 2f_0+k_0-W & j_0 & f_1+l & f_1+l \\ j_0 & 2f_0+k_0-W & f_1+l & f_1+l \\ f_1+l' & f_1+l' & 2f_0+k_1-W & j_1 \\ f_1+l' & f_1+l' & j_1 & 2f_0+k_1-W \end{vmatrix}=0\,. \tag{3.5}$$

Now, we set $\varphi_{1,2}=1/\sqrt{2}\,(a(1)b(2)\pm b(1)a(2))$, $\psi_{1,2}=1/\sqrt{2}\,(a(1)a(2)\pm b(1)b(2))$, and use φ_2, φ_1, ψ_1, ψ_2 as a new base of the representation. Then, Eq. (3.5) becomes

$$\begin{vmatrix} 2f_0+k_0-j_0-W & 0 & 0 & 0 \\ 0 & 2f_0+k_0+j_0-W & 2(f_1+l) & 0 \\ 0 & 2(f_1+l) & 2f_0+k_1+j_1-W & 0 \\ 0 & 0 & 0 & 2f_0+k_1-j_1-W \end{vmatrix}=0. \tag{3.6}$$

Thus, the triplet state φ_2 is separated out and the energy of this state is given

$$W_t=2f_0+k_0-j_0\,. \tag{3.7}$$

(The state ψ_t is separated out also, but this is an ionized state which we are not interested in.) This arises from the fact that the state in which all spins are parallel does not interact with the ionized states in which at least one spin must be reversed, and it is due to this fact that the energy of the ferromagnetic ground state can be easily calculated.

It is also easy to calculate the energy W_s of the singlet state from Eq. (3.6), but the problem is how to get the solution which coincides with Eq. (3.2). As mentioned in § 2, to neglect the third and fourth lines in Eqs. (3.5) and (3.6) leads to a result quite different from (*a*) and (*b*).

To neglect the ionized states in the usual method, corresponds to the approximation that $(aa|H|aa)$ is set to be very large compared with $(aa|H|ab)$ etc., and that the ratios $(aa|H|ab)/(aa|H|aa)$ etc. are set equal to zero. The essential difference between $(aa|H|aa)$ and $(aa|H|ab)$ etc. is that the former involves the term $G_0\equiv(aa|g|aa)$ while the latters do not. Thus, we may also make an approximation setting $G_0\rightarrow\infty$ in the method (II). G_0 corresponds to the ionization energy in the treatment in which the atomic orbitals are not changed even when the atom is ionized.

According to Eq. (2.8), the matrix elements involving G_0 are k_1, j_1 and l'. Thus, we may set

$$\left.\begin{aligned} k_1&=g_{aa,aa}\sim t_{a,a}^2G_0\ ,\\ j_1&=g_{bb,aa}\sim t_{b,a}^2G_0\ ,\\ l'&=g_{ab,aa}\sim t_{a,a}t_{b,a}G_0\ .\end{aligned}\right\}\tag{3.8}$$

That is to say, $g_{kl,ij}$ involves the term proportional to G_0 when and only when $i=j$, and we can set

$$g_{kl.ij}\sim t_{k,i}t_{l,j}G_0\ .\tag{3.8'}$$

The relation will be used in the general case considered in § 4.

Thus, in the limit of $G_0\rightarrow\infty$, the equation, determining the single energy W_s, can be written as

$$\begin{vmatrix} 2f_0+k_0+j_0-W_s & 2(f_1+l)\\ 2t_{a,a}t_{b,a}G_0 & (t_{a,a}^2+t_{b,a}^2)G_0\end{vmatrix}=0\ ,$$

where we have used the fact that W_s does not involve G_0. Solving this equation, we get

$$W_s=2f_0+k_0+j_0-\frac{4(f_1+l)t_{aa,}t_{b,a}}{(t_{a,a}^2+t_{b,a}^2)}\ .\tag{3.9}$$

of course, we also get this solution by solving Eq. (3.6) exactly and then setting $G_0\rightarrow\infty$.

Now, t is the inverse matrix of $\begin{pmatrix}1 & \alpha\\ \alpha & 1\end{pmatrix}$, so that

$$t=\frac{1}{1-\alpha^2}\begin{pmatrix}1 & -\alpha\\ -\alpha & 1\end{pmatrix}\ .\tag{3.10}$$

Substitution of Eq. (3.10) into Eq. (3.9) gives

$$W_s=2f_0+k_0+j_0+\frac{4\alpha(f_1+l)}{1+\alpha^2}\ .\tag{3.9'}$$

We can easily see that Eqs. (3.7) and (3.9′) coincide with Eq. (3.2) using the following relation;

$$f_0=\frac{1}{1-\alpha^2}(F_0-\alpha F_1)\ ,\quad f_1=\frac{1}{1-\alpha^2}(-\alpha F_0+F_1)\ ,$$

where

$$F_0\equiv(a|f|a)\ ,\quad F_1\equiv(b|f|a)$$

and

$$k_0=\frac{1}{(1-\alpha^2)^2}(K+\alpha^2J-2\alpha L)\ ,$$

$$j_0=\frac{1}{(1-\alpha^2)^2}(J+\alpha^2K-2\alpha L)\ ,$$

$$l=\frac{1}{(1-\alpha^2)^2}((1+\alpha^2)L-\alpha(K+J))\ ,$$

where

$$K=(ab|g|ab)\ ,$$

$$J\equiv(ab|g|ba)\ ,$$

$$L\equiv(aa|g|ab)\ .$$

The wave function for the singlet state has a form $\varphi_1+c\psi_1$ where φ_1 is nothing but Ψ_s of Eq. (3.6). $c\psi_1$ expresses the mixing of the ionized states, but c is of the order of L/G_0 and we can set $c=0$ in our approximation. For the ionized state, the wave function is of the form as $\psi_1+c'\varphi_1$, where c' is of the order of 1 compared with L/G_0. That is, the ionized state is largely affected, but the non-ionized state is hardly affected.

From the above discussion, we can find the approximation in the method (II), which is equivalent to neglect ionized states in the usual method: We must include the ionized states at first, but, in solving the secular equation, we may set $G_0\rightarrow\infty$. G_0 is involved in the terms such as $g_{kl,ii}$ which is set $t_{k,i}t_{l,i}\ G_0$ in this approximation.

At first sight, it might appear that the method (I) is much simpler than the method (II). The above example, however, is a two-electron system, so that the dimension of the overlap matrix is $2!=2$ in the method (I), which is same as in the method (II). In a N-electron system, the dimension of the overlap matrix is much less in the method (II) than in the method (I), and the former is much simpler than the latter.

§ 4. *N*-electron System

In this section, the method (II) is applied to N-electron system. As mentioned in § 1, we treat the idealized case, in which each of N atoms has one electron. Thus, there are N atomic orbitals, which is denoted as φ_1, $\varphi_2, \cdots, \varphi_N$. The Hamiltonian of the system has a form, Eq. (2.6),

$$H=\sum_{i=1}^{N} f(r_i)+\sum_{i>j}\sum g(r_{ij}) . \tag{4.1}$$

Since there are many orbital configurations, it is convenient to write the Hamiltonian in the form of second quantization. In our case, the basic one-electron wave functions are not orthogonal to each other, but we can follow the Fock's method[6] to quantize the Hamiltonian as follows: The functions

$$\varphi_{i_1}(1)\varphi_{i_2}(2)\cdots\varphi_{i_N} . \quad (i_n=1,\, 2,\, \cdots,\, N) \tag{4.2}$$

are linearly independent with each other, though not orthogonal. We confine the space considered to that consists from these functions and expand the projection of any function to this space in terms of these functions. For the sake of simplicity we consider the orbital parts of the wave functions only, and shall attach the spin parts after a while. Thus, we can write

$$\psi=\sum_{\{i_n\}} c(\{i_n\})\varphi_{i_1}(1)\varphi_{i_2}(2)\cdots\varphi_{i_N}(N) .$$

Now, we must solve the equation

$$i\hbar\frac{\partial\psi}{\partial t}=H\psi .$$

Using the matrix elements defined in Eq. (2.7), we obtain the following relation,

$$\sum_{n=1}^{N} f(n)\varphi_{i_1}(1)\cdots\varphi_{i_N}(N)=\sum_{j}\sum_{n=1}^{N} f_{j,i_n}\varphi_{i_1}(1)\cdots\varphi_{i_{n-1}}(n-1)\varphi_j(n)\varphi_{i_{n+1}}(n+1)\cdots\varphi_{i_N}(N) ;$$

$$\tfrac{1}{2}\sum_{m\neq n}\sum g(m,\, n)\varphi_{i_1}(1)\cdots\varphi_{i_N}(N)=\tfrac{1}{2}\sum_{k}\sum_{l}\sum_{m\neq n}^{N}\sum^{N} g_{kl,i_m i_n}\varphi_{i_1}(1)\cdots\varphi_{i_{m-1}}(m-1)\varphi_k(m)\varphi_{i_{m+1}}(m+1)$$
$$\cdots\varphi_{i_{n-1}}(n-1)\varphi_l(n)\varphi_{i_{n+1}}(n+1)\cdots\varphi_{i_N}(N) .$$

Thus, the equation for the coefficients c's is obtained by equating the coefficients of $\varphi_{i_1}(1)\varphi_{i_2}(2)\cdots\varphi_{i_N}(N)$ in both sider of $i\hbar(\partial\psi/\partial t)=H\psi$,

$$i\hbar\frac{\partial c(\{i_n\})}{\partial t}=\sum_{n=1}^{N}\sum_{j} f_{i_n,j}\, c(i_1,\, \cdots,\, i_{n-1},\, j,\, i_{n+1},\, \cdots,\, i_N)$$
$$+\tfrac{1}{2}\sum_{n\neq m}^{N}\sum^{N}\sum_{k}\sum_{l} g_{i_m i_n,kl}\, c(i_1,\, \cdots,\, i_{m-1},\, k,\, i_{m+1},\, \cdots,\, i_{n-1},\, l,\, i_{n+1},\, \cdots,\, i_N) .$$

Here, we attach the spin function to each orbital, and express c's in terms of the occupation numbers of each orbital. Taking into account of Fermi statistics, we introduce the annihilation and creation operators a_{is}, a_{is}^*. Then the above equation becomes

$$i\hbar\frac{\partial c(\{n_{i,s}\})}{\partial t}=\mathscr{H}\, c(\{n_{i,s}\}) ,$$

where

$$\mathscr{H}=\sum_{i,j}\sum_{s} f_{j,i}a_{js}^*a_{is}+\tfrac{1}{2}\sum_{k,l}\sum_{i,j}\sum_{s,s'} g_{kl,ij}a_{ks}^*a_{is'}^*a_{js'}a_{is} , \tag{4.3}$$

and

$$[a_{is}^*a_{j,s'}]_+=\delta_{i,j}\delta_{s,s'} , \qquad [a_{i,s},\, a_{j,s'}]_+=0 \qquad \text{etc.} \tag{4.4}$$

Eqs. (4.3) and (4.4) are completely same in form as in the case of orthogonal orbitals. In our case, the orbitals are not orthogonal. So that, if we use the inner products to define the matrix elements, the Hamiltonian involves much higher powers of a, a^* and is much complicated than Eq. (4.3). As was proved above, if we use the expansion coefficients instead of the inner products, we obtain the same form of Hamiltonian as in the case of orthogonal orbits. The only difference between orthogonal and non-orthogonal orbitals is the coefficients $f_{j,i}$ and $g_{kl,ij}$ which become $(j|f|i)$ and $(kl|g|ij)$ in the case of orthogonal orbitals. As mentioned in § 3, the special care must be taken if the configurations considered are limited.

In the following, we shall calculate the energy eigenvalues of $\mathscr{H}$, Eq. (4.3), in the case of ferromagnet. The approximation used must be equivalent to that in the usual method in which we neglect the ionized states.

(a) *Ground State*

The energy of the state Φ_0 in which all spins are parallel can be calculated very easily. In this state, each orbital is occupied by one electron and there are neither empty nor doubly occupied orbitals. Let the spins of all electrons are oriented to z direction, which is denoted by $s=+$. Then

$$a_{i+}^*\Phi_0=0\,, \qquad a_{i-}\Phi_0=0 \qquad \text{for all } i\,.$$

Using these properties, we obtain immediately

$$\mathscr{H}\Phi_0=\left\{\sum_{i=1}^{N} f_{i,i}+\tfrac{1}{2}\sum_{i=1}^{N}\sum_{j=1}^{N}(g_{ij,ij}-g_{ij,ji})\right\}\Phi_0=W_0\Phi_0\,. \tag{4.5}$$

If we express W_0 in terms of $(j|f|i)$'s and $(kl|g|ij)$'s we get

$$W_0=\sum_{i,j} t_{i,j}(j|f|i)+\tfrac{1}{2}\sum_{ij}\sum_{kl}(t_{i,k}t_{j,l}-t_{i,l}t_{j,k})(kl|g|ij)\,, \tag{4.6}$$

which completely coincides with the result which Löwdin$^{4)}$ obtained by the usual method.

(b) *Excited States* (*Energy Spectrum of Spin Waves*)

In order to consider the excited states, we define the operator which transfers an electron at j site to l site reversing its spin,

$$B_{l,j}^*=a_{l-}^*a_{j+}\,. \tag{4.7}$$

$B_{l,j}^*\Phi_0=\Phi_{l,j}$ is the state in which there are two electrons with $+$ and $-$ spins at l site and a hole at j when $l\neq j$. $\Phi_{l,l}$ is the state in which each atom has one electron but the spin at l site is reversed.

First, we calculate $\mathscr{H}\Phi_{l,j}$

$$\mathscr{H}\Phi_{l,j}=W_0\Phi_{l,j}+[\mathscr{H},\,B_{l,j}^*]\Phi_0 \tag{4.8}$$

The second term of this equation becomes

$$\begin{aligned}[\mathscr{H},\,B_{l,j}^*]\Phi_0=\{&\sum_m(f_{m,l}+\sum_n g_{mn,ln})B_{m,j}^*\\ &-\sum_i(f_{j,i}+\sum_n(g_{nj,ni}-g_{nj,in}))B_{l,i}^*-\sum_m\sum_i g_{mj,li}B_{l,i}^*\}\Phi_0\,.\end{aligned} \tag{4.9}$$

The physical meaning of each term on the right hand side is obvious as follows; The first term represents the transition of negative spin at l site to m, the second of positive spin at i to j, that is, of the hole at j to i. While the negative spin moves in the first term, the positive spin moves in the second, so that there is the exchange term with other spins $\sum g_{nj,in}$. The last term represents the transitions of negative spin at l to m and positive spin at i to j.

It is very difficult to solve Eq. (4.9) exactly. However, we need not solve it exactly. As mentioned in § 3, we adopt the approximation which is equivalent to neglect the ionized states in the usual method. This approximation is to set $(jj|g|jj)\equiv G_0\to\infty$. Now, we pick up the term proportional to G_0 in Eq. (4.9),

$$(\mathscr{H}-W_0)\Phi_{l,j}=[\mathscr{H},\,B_{l,j}^*]\Phi_0\sim G_0\sum_m\{t_{m,l}t_{l,l}B_{m,j}^*-t_{m,l}t_{j,l}B_{m,l}^*\}\Phi_0\,. \tag{4.10}$$

For the ionized state, $l \neq j$, the right hand side of this equation does not vanish, so that the other terms which was not written in Eq. (4.10) may be neglected. For the non-ionized state, $l=j$, Eq. (4.10) vanishes and the rigorous expression of $[\mathscr{H}, B_{l,j}^*]\Phi_0$ must be used.

Taking the Fourier transform for the motion of the center of gravity, we define

$$B_{K,j}^* \equiv \frac{1}{\sqrt{N}} \sum_l e^{iKl} B_{l,l-j}^* , \qquad \Phi_{K,j} = B_{K,j}^* \Phi_0 , \tag{4.11}$$

where the states $j \neq 0$ correspond to ionized states. The inverse transformation of Eq. (4.11) is

$$B_{l,j}^* = \frac{1}{\sqrt{N}} \sum_K e^{-iKl} B_{K,l-j}^* , \qquad \Phi_{l,j} = \frac{1}{\sqrt{N}} \sum_K e^{-iKl} \Phi_{K,l-j} . \tag{4.11'}$$

Using Eqs. (4.11) and (4.11′), we obtain from Eqs. (4.9) and (4.10),

$$\begin{aligned}(\mathscr{H}-W_0)\Phi_{K,0} &= \sum_n g_{0n,n0}(1-e^{iKn})\Phi_{K,0} \\ &\quad + \sum_{j\neq 0} \{f_{j,0}(e^{-iKj}-1) - \sum_n (g_{jn,0n}-g_{jn,n0}) + e^{-iKj} \sum_n (g_{jn,0n}-g_{nj,0n}e^{-iKn})\}\Phi_{K,j} \\ &\equiv \mathcal{E}'(K)\Phi_{K,j} + \sum_{j\neq 0} \beta_K(j)\Phi_{K,j}\end{aligned} \tag{4.12}$$

$$(\mathscr{H}-W_0)\Phi_{K,j} = G_0\{t_0 t_j(e^{iKj}-1)\Phi_{K,0} + \sum_{j'\neq 0}(t_0 t_{j-j'}e^{iK(j-j')} - t_j t_{-j'}e^{-iKj'})\Phi_{K,j'}\} , \qquad (j \neq 0) , \tag{4.13}$$

where we have used the property of the translational symmetry, that is,

$$t_{m,m+j} = t_{0,j} \equiv t_j , \qquad f_{m,m+j} = f_{0,j} , \qquad g_{m+k,m+l,m+i,m+j} = g_{kl,ij} .$$

We need the energy eigenvalue of the non-ionized state $\Phi_{K,0}$. If we neglect the state $\Phi_{K,j}$ $(j \neq 0)$ in Eqs. (4.12) and (4.13), the result is quite different from the usual approximation, as was mentioned in § 3. Since $(\mathscr{H}-W_0)\Phi_{K,j}$ $(j \neq 0)$ involves $\Phi_{K,0}$ in the order of G_0, we cannot neglect $\Phi_{K,j}$ in the right hand side of Eq. (4.12). This is the only complicated feature of this method.

Now, we consider the transformation which eliminates $\Phi_{K,0}$ from Eq. (4.13). To do this, we may set

$$\Psi_{K,j} = \Phi_{K,j} - \alpha_K(j)\Phi_{K,0} , \qquad (j \neq 0) . \tag{4.14}$$

The transformation is not unitary. We need not use, however, the unitary transformation, because our Hamiltonian, Eq. (4.3), is not hermitic. Since, $(\mathscr{H}+W_0)\Phi_{K,0}$ is lower order compared with $(\mathscr{H}-W_0)\Phi_{K,j}$, we get

$$(\mathscr{H}-W_0)\Psi_{K,j} \simeq (\mathscr{H}-W_0)\Phi_{K,j} .$$

We use Eq. (4.14) to express the right hand side of Eq. (4.13) in terms of $\Psi_{K,j}$ instead of $\Phi_{K,j}$ and determine $\alpha_K(j)$ in such a way that the coefficient of $\Phi_{K,0}$ may vanish. Then, the equation for $\alpha_K(j)$ becomes

$$t_0 t_j(e^{iKj}-1) + \sum_{j'\neq 0} \alpha_K(j')[t_0 t_{j-j'}e^{iK(j-j')} - t_j t_{-j'}e^{-iKj'}] = 0 . \tag{4.15}$$

This can be solved easily,

$$\alpha_K(j) = c_K \sum_{j_1} s_{j_1} e^{iKj_1} t_{j_1,j} , \tag{4.16}$$

where c_K is determined from the condition $\alpha_K(0)=1$, which gives

$$(c_K)^{-1} = \sum_{j_1} s_{j_1} e^{iKj_1} t_{-j_1} . \tag{4.17}$$

s_j is the overlap integral $s_j \equiv s_{0,j} = (\varphi_0, \varphi_j)$. Eqs. (4.16) and (4.17) can be written in another form,

$$\alpha_K(j) = \frac{c_K}{N} \sum_{K_i} e^{-iK_i j} \frac{t(K_i)}{t(K+K_i)} = \frac{c_K}{N} \sum_{K_i} e^{-iK_i j} \frac{s(K+K_i)}{s(K_i)} , \tag{4.16'}$$

$$(c_K)^{-1} = \frac{1}{N} \sum_{K_i} \frac{t(K_i)}{t(K+K_i)} = \frac{1}{N} \sum_{i} \frac{s(K+K_i)}{s(K_i)} , \tag{4.17'}$$

where $s(K)$ and $t(K)$ are the Fourier transforms of s_j and t_j, respectively,

$$s(K) = \sum_j s_j e^{iKj} , \qquad t(K) = \sum_j t_j e^{iKj} . \tag{4.18}$$

These $s(K)$ and $t(K)$ are eigenvalues of the matrices $(s_{i,j})$ and $(t_{i,j})$ respectively, and we have the relation

$$s(K)t(K) = 1 . \tag{4.19}$$

It is clear from Eq. (4.16) that when $K=0$, we have

$$\alpha_0(j) = \delta_{j,0} . \tag{4.20}$$

Now, substituting Eq. (4.14) into Eq. (4.12), we obtain

$$(\mathscr{H} - W_0)\Phi_{K,0} = [\mathcal{E}'(K) + \sum_{j \neq 0} \alpha_K(j)\beta_K(j)]\Phi_{K,0} + \sum_{j \neq 0} \beta_K(j)\Psi_{K,j} . \tag{4.21}$$

Since $(\mathscr{H} - W_0)\Psi_{K,j}$ does not contain $\Phi_{K,0}$ in the order of G_0, we can neglect $\Psi_{K,j}$ on the right hand side of Eq. (4.21), and we have the energy of the state $\Phi_{K,0}$, given by

$$\mathcal{E}(K) = \mathcal{E}'(K) + \sum_{j \neq 0} \alpha_K(j)\beta_K(j) , \tag{4.22}$$

or using the relation $\alpha_K(0)=1$, $\beta_K(0)=\mathcal{E}'(K)$

$$\mathcal{E}(K) = \sum_j \alpha_K(j)\beta_K(j) . \tag{4.22'}$$

Thus, the energy eigenvalue of the state in which one spin is reversed is obtained in the approximation neglecting the ionized states. This is just the energy spectrum of spin waves. The above expression is valid irrespective of the value of the overlap integral. The only approximation made is to set $G_0 \to \infty$, that is, to neglect the ionized states in usual method.

The calculation of the energy of the state, in which more than two spins are reversed, is necessary in order to discuss the interaction between spin waves, but there is a mathematical difficulty, as will be discussed later. Before doing this, we shall discuss a little more about the energy spectrum in the next section.

§ 5. Concrete Expression for Energy Spectrum of Spin Waves

The expression for energy spectrum of spin waves, given above has the form

$$\mathcal{E}(K) = \sum_j \alpha_K(j)\beta_K(j) , \tag{5.1}$$

where $\alpha_K(j)$ and $\beta_K(j)$ are given by Eqs. (4.16) and (4.12), respectively,

$$\alpha_K(j) = c_K \sum_{j_1} s_{j_1} e^{iKj_1} t_{j_1,j} = \frac{c_K}{N} \sum_{K_i} e^{-iK_i j} \frac{s(K+K_i)}{s(K_i)} \tag{5.2}$$

$$\beta_K(j) = f_{j,0}(e^{-iKj} - 1) - \sum_n (g_{jn,0n} - g_{nj,0n}) + e^{-iKj} \sum_n (g_{jn,0n} - g_{nj,0n} e^{-iKn}) . \tag{5.3}$$

First, we can see, immediately,

$$\mathcal{E}(0)=0\,, \tag{5.4}$$

since $\alpha_0(j)=\delta_{j,0}$ and $\beta_0(j)=0$. This is an expected result, because for $K=0$ the wave function has the same symmetry as the ground state.

The above expression is rigorous, as mentioned in § 4, how large the overlap integral may be, but contains unfamiliar quantities such as $f_{j,0}$, $g_{jn,0n}$, etc. These quantities can be expressed in terms of familiar quantities such as $(j|f|0)$, $(jn|g|0n)$, etc. using Eq. (2.8). In so doing, however, we obtain very complicated expression, so we make further assumptions not unreasonable in order to get a simple expression.

The first assumption is that the atomic orbitals overlap only between nearest neighbours. Then, we can set

$$\left.\begin{aligned}(\varphi_i,\,\varphi_j)\equiv s_{i,j}&=1\,, &&\text{for }\ i=j\,,\\ &=\alpha\,, &&\text{for }\ i=j+\delta\ (i\text{ and }j\text{ are nearest neighbours of each other})\,,\\ &=0\,, &&\text{otherwise}\,,\end{aligned}\right\} \tag{5.5}$$

and

$$\left.\begin{aligned}(\varphi_i,\,f\varphi_j)&=F_0\,, &&\text{for }\ i=j\,,\\ &=F_1\,, &&\text{for }\ i=j+\delta\,,\\ &=0\,, &&\text{otherwise}\,,\end{aligned}\right\} \tag{5.6}$$

and, finally, $(kl|g|ij)$ vanishes except the following elements,

$$(0\delta|g|0\delta)=K\,,\qquad (0\delta|g|\delta 0)=J\,,\qquad (00|g|0\delta)=L\,,\qquad (00|g|00)=G_0\,. \tag{5.7}$$

Here, we have assumed that the overlap integral between nearest neighbours has no directional dependence.

Secondly, we assume that $z\alpha^2<1$, where z is the number of nearest neighbours.

Under these assumptions, we expand $\mathcal{E}(K)$ in power series of α and keep the terms up to α^2. This can be calculated very easily, but the calculation of the next term of α^3 becomes very complicated. This expansion converges if the second assumption is valid. If α is so large that $z\alpha^2>1$, the expansion loses its meaning. In such a case, however, our basic assumption that the ionized states can be neglected becomes invalid, and the band approximation becomes better than the Heitler-London approximation, as was mentioned in § 2. Since we have implicity assumed that the Heitler-London approximation is good, the second assumption can be permitted.

Under these assumptions, we obtain the eigenvalue $s(K)$, Eq. (4.18) of the matrix $(s_{i,j})$,

$$s(K)=1+\alpha\gamma(K)\,,\qquad \gamma(K)\equiv\sum_{\delta}e^{iK\delta}\,, \tag{5.8}$$

where the summation in $\gamma(K)$ is extended over the lattice points of nearest neighbours.

After a long but straightfoward calculation, we obtain for the energy spectrum of spin waves,

$$\mathcal{E}(K)=(\gamma(0)-\gamma(K))\{J-2\alpha F_1-2\alpha^2F_0+\alpha^2(1-2\gamma(0))K-\alpha^2[2-\gamma(0)-2\gamma(K)]J\}+0(\alpha^3)\,, \tag{5.9}$$

where $\gamma(0)=\sum 1$ is equal to the number z of nearest neighbours.

In the case of orthogonal orbitals, we obtain

$$\mathcal{E}(K)=J(\gamma(0)-\gamma(K))$$

setting $\alpha=0$. This is a results expected from the Hamiltonian

$$\mathscr{H}=-2J\sum_{<i,j>}S_i\cdot S_j\,,$$

where the summation is extended over all pairs of nearest neighbours.

§ 6. Interactions Among Spin Waves

Let us consider the states, in which more than two spins are reversed. An example of such states can be written as

$$\Phi_{l_1 l_2 \cdots l_n ; j_1 j_2 \cdots j_n} = a^*_{l_1 -} a^*_{l_2 -} \cdots a^*_{l_n -} a_{j_n +} \cdots a_{j_2 +} a_{j_1 +} \Phi_0 \, . \tag{6.1}$$

This is a state in which the up spins at j_1, j_2, $\cdots$, j_n are reversed and moved to l_1, l_2, $\cdots$, l_n. This can be expressed by using the operator $B^*_{l,j}$ defined in Eq. (4.7),

$$\Phi_{l_1 l_2 \cdots l_n ; j_1 j_2 \cdots j_n} = B^*_{l_1, j_1} B^*_{l_2, j_2} \cdots B^*_{l_n, j_n} \Phi_0 \, , \tag{6.1$'$}$$

although this division into the product of $B^*_{l,j}$ is not unique.

When operating $\mathscr{H}$ on this state, we obtain

$$(\mathscr{H} - W_0) \Phi_{l_1 l_2 \cdots l_n ; j_1 j_2 \cdots j_n} = \sum_{p=1}^{n} \prod_{i \neq p} B^*_{l_i, j_i} [\mathscr{H}, B^*_{l_p, j_p}] \Phi_0 + \sum_{p>q=1}^{n} \sum^{n} \prod_{i \neq p,q} B^*_{l_i, j_i} [[\mathscr{H}, B^*_{l_p, j_p}] B^*_{l_q, j_q}] \Phi_0 \, , \tag{6.2}$$

because $[[[\mathscr{H}, B^*] B^*] B^*] = 0$. This expression, of course, is independent of the method of division Eq. (6.1$'$). Now, the single commutator in the first term of Eq. (6.2) was calculated in § 4, Eq. (4.9), and the double commutator in the second term can be calculated as

$$\begin{aligned} [[\mathscr{H}, B^*_{l,j}] B^*_{l',j'}] = \sum_{mn} \{ & g_{mn, ll'} a^*_{m-} a^*_{n-} a_{j'+} a_{j+} \\ & + g_{jj', mn} a^*_{l-} a^*_{l'-} a_{n+} a_{m+} - g_{mj', ln} a^*_{m-} a^*_{l'-} a_{n+} a_{j+} - g_{mj, l'n} a^*_{m-} a^*_{l-} a_{n+} a_{j'+} \} \, . \end{aligned} \tag{6.3}$$

The terms which are proportional to G_0 in Eq. (6.3) is

$$-G_0 \sum (t_{m,l} t_{j',l} a^*_{m-} a^*_{l'-} a_{l+} a_{j+} + t_{m,l'} t_{j,l'} a^*_{m-} a^*_{l-} a_{l'+} a_{j'+}) \, . \tag{6.4}$$

Since Eqs. (6.3) and (6.4) are of 4-th power of a^*_- and a_+, we can write these as quadratic forms of $B^*_{l',j}$. The way of expressing these in such forms, however, is not unique, as mentioned above. For example, we can write

$$a^*_{l-} a^*_{l'-} a_{j'+} a_{j+} = B^*_{l\,j} B^*_{l',j'}$$

or

$$= -B^*_{l,j'} B^*_{l',j} \, .$$

Now proceding the discussion as in § 4, we first calculate $[[\mathscr{H}, B^*_{K,j}] B^*_{K',j'}]$ and properly express the terms corresponding to Eq. (6.4) in terms of $B^*_{K_1,j_1}$. Then, we make the transformation given by Eq. (4.14), i.e.,

$$B^*_{K,j} = C^*_{K,j} + \alpha_K(j) B^*_{K,0} \, . \tag{6.5}$$

If the expression for the ionized states does not contain the non-ionized states at all, we can carry out the similar calculation as in § 4, and we get the interaction terms between non-ionized spin waves. These express the scatterings between two spin waves and the direct interactions among more than three spin waves do not appear.

Unfortunately, this is not the case. The transformation (6.5) can not eliminate the effect of the ionized states on non-ionized states, when more than two spins are reversed. This transformation can be used only in the case of one spin reversed. So that, we must find another method than that of § 4.

This, however, is very difficult. For example, consider the state in which two spins are reversed. From Eqs. (4.9) and (6.4), we obtain

$$\begin{aligned} (\mathscr{H} - W_0) \Phi_{ll', jj'} & \\ = G_0 \sum_{m} \{ & t_0 t_{m,l'} \Phi_{lm, jj'} + t_0 t_{m,l} \Phi_{ml, jj'} \\ & - t_{m,l'} t_{j',l'} \Phi_{lm, jl'} - t_{m,l} t_{j,l} \Phi_{l'm, j'l} \\ & - t_{m,l'} t_{j,l'} \Phi_{lm, l'j'} - t_{m,l} t_{j',l} \Phi_{l'm, jl} \} \, . \end{aligned} \tag{6.6}$$

For the non-ionized states, that is, when $(l, l') = (j, j')$ (this means that $l = j$, $l' = j'$ or $l = j'$, $l' = j$), the right hand side of this equation vanishes, so that the rigorous expression must be used. In other cases, we may pick up the non-ionized states from the right hand side, and must find the method to eliminate these states from Eq. (6.6). Obviously, when $l, l' \neq j, j'$ (this means that $l \neq j, j'$ and $l' \neq j, j'$), Eq. (6.6) does not contain the non-ionized state. When one of the pairs is equal, for example $l=j,\ l'\neq j'$, the non-ionized states appear in a following form

$$G_0 t_0 t_{j',l}(\Phi_{lj',lj'}-\Phi_{ll',ll'})$$

This term can be eliminated by the transformation (6.5) or Eq. (4.14). However, when this transformation is applied to the case $l,\ l'\neq j,\ j'$, $(\mathscr{H}-W_0)\Phi_{ll',jj'}$ becomes to involve non-ionized states. These states appear from the term $\Phi_{ll',lj'}$ involved in $(\mathscr{H}-W_0)\Phi_{ll',jj'}$. So, we must proceed in a following way: First, we mix the one hole states ($l=j,\ l'\neq j'$, for example) in the two-hole states, $l,\ l'\neq j,\ j'$ to eliminate the former from the equation for the latter. Next, we mix the non-ionized states $(l,\ l')=(j,\ j')$ in the one-hole states to eliminate the former from the equation for the latter. Finally, we express $(\mathscr{H}-W_0)\Phi_{ll',ll'}$ in terms of these new ionized states and pick up the non-ionized states.

This procedure, however, can not be applied in practice, because Eq. (6.6) involves four indices in the right hand side and we must solve about N^4 equations. Of course, the motion of the center of gravity can be separated out, so that the number of the effective states is reduced to about N^3, which is still very large and the rigorous calculation is nearly hopeless. The more the number of the reversed spins is, the more this difficulty increased. We can not find the approximate treatment, so that the discussion about this point is deferred to another occasion.

§ 7. Conclusions and Discussions

We have developed a general method to treat the non-orthogonal wave functions and applied this to Heisenberg model in magnetic problems. This method was previously applied to liquid Helium by the author, who obtained the modified phonon-roton model which showed the phase transition of second order due to Bose condensation. In the magnetic case treated in this paper, we calculated the energy eigenvalues of the ferromagnetic ground state and of the excited state in which one spin is reversed. This latter represents the energy spectrum of spin waves. These results are rigorous for any values of the overlap integrals. Only approximation made is that we have neglected the ionized states. This is a reasonable approximation if the treatment of Heitler-London type is valid.

The energy spectrum of spin waves has a very simple form but it contains unfamiliar quantities, such as $f_{j,i}$ or $g_{kl,ij}$. If these quantities are expressed by familiar ones $(j|f|i)$ or $(kl|g|ij)$ the expression becomes very complicated, so that we have calculated it under the two assumptions mentioned in § 5.

We have treated an idealized case only, that is, each atom is assumed to have only one electron. The extension to more realistic case is possible, but the result will be much more complicated. Although the problem treated in this paper is considered to be rather academic, so that it is questionable whether such an extension to realistic cases has any physical meaning, and the results obtained here can be considered to give a qualitatively correct conclusions even in the realistic cases. These are the reasons why we do not attempt to extend the discussion to more realistic cases.

We have wished to calculate the interactions among spin waves, but the mathematical complexity has prevented it. It is certain, however, that, in order to describe the scatterings between spin waves, the Hamiltonian such as Eq. (1.1) is not sufficient. The terms which involve more than three spin variables are necessary. Thus, when the atomic orbitals are not orthogonal to each other, it is still questionable whether the interactions between spin waves deduced from Eq. (1.1) have any physical meaning. The energy spectrum of spin waves, deduced from Eq. (1.1), has a physical meaning, however, if the values of the exchange integrals $J_{i,j}$ are taken properly. For example, we can use the coefficient of $(\gamma(0)-\gamma(K))$ in Eq. (5.6) as J_δ in Eq. (1.1).

The higher order terms, which are necessary to discuss the interactions among spin waves, may be of higher order of α. Therefore, if the overlap integral α is so small that the higher terms of α can be neglected, the Hamiltonian, Eq. (1.1), may be used as a first approximation.

As was mentioned in § 1, the method used in this paper is very powerful in the case in which a set of non-orthogonal functions plays an important role. In the case treated here, it is possible to calculate the energy spectrum of spin waves by the usual method under certain assumptions[7], so that it might appear somewhat troublesome, to use this method in order to obtain the results mentioned above. The Hamiltonian, Eq. (4.3), in our method, however, has a very simple form and we can say that our method is much easier than the usual method. For example, the superexchange interactions which are discussed by several authors[8] may also be discussed by using our Hamiltonian.

The author wishes to express his sincere thanks to Prof. R. Kubo in Tokyo University and Prof. M. Toda in this university for their valuable discussions.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 14, No. 3, MARCH, 1959

On Quantitative Measurement of Turbulence by Means of a Constant Resistance Hot-wire Anemometer

By Nisiki HAYASI

Transportation Technical Research Institute, Mitaka, Tokyo

(Received November 14, 1958)

Constant resistance hot-wire anemometry has been improved to measure velocity fluctuation quantitatively. For this purpose, the effects of the resistance of the galvanometer circuit and current variation due to resistance variation of hot-wire are calculated for general case. The values of the turbulent energy reached by the older method would be several part of correct ones in our experiment. A direct calibration method using alternating current has been devised. This method is easy to apply. Experiments show that the results obtained by the two methods completely agree with each other. Owing to the possibility of the calibration in the actual circuit, the constant resistance method would be superior to the constant current method.

§ 1. Introduction

Since H. L. Dryden[1] carried out his pioneer work for the hot-wire anemometer technique, many authors have developed and refined this powerful equipment for the studying of turbulence. Most investigators, however, have dealt with the constant current method, while few authors[2),6),7] have used the constant resistance method. In either method, the effect of the variations of electric current and heat transfer due to the variation of hot-wire resistance and other effects scattered the experimental results when the temperature of hot-wire was varied, thus permitting in general only qualitative measurements to be done.

Simmons and Salter[7] showed the effect of current variation due to resistance variation in a special version of constant resistance method. Kovásznay[4] pointed out this effect in the constant current method. Shigemitsu[6] neglected this effect in the simplest one of constant resistance method. Ruetenik[5] showed the main effect of the heat transfer variation due to resistance variation.

In this paper, the first effect is evaluated for the general case of the constant resistance method. Moreover it is pointed out that, in general, the effect of the finite resistance of the galvanometer circuit cannot be ignored. When these effects are taken into account, the results are independent of the wire temperature.

Further, the direct calibration method for the dynamic characteristics using alternating current is developed to save calculation. This calibration is easy to apply. The experimental results obtained by the use of the calculation method and the direct calibration method completely agree with each other. Owing to the possibility of the calibration in the actual circuit, the constant resistance hot-wire anemometer would be superior to the constant current hot-wire anemometer.

§ 2. Measurement of Turbulent Intensity by Calculation Method

The equation of cooling of the hot-wire is

$$\frac{dH}{dt}=i^2r-f(u,\ r)(T-\Theta)\ , \qquad (1)$$

where H and T are the heat energy and the absolute temperature of the wire, u and Θ are the velocity and the absolute temperature of air, i is the electric current, r is the resistance of the wire, and

$$\left.\begin{aligned} &f(u,\ r)=K(r)+D(r)u^m\ ,\\ &K(r)=akL\ ,\\ &D(r)=bkL(d/\nu)^m\ , \end{aligned}\right\} \qquad (2)$$

where a and b are constants, k and ν are the thermal conductivity and the kinematic viscosity of air, and L and d are the length and the diameter of the wire.

On the other hand

$$\frac{dH}{dt}=ms\frac{dT}{dt}\ , \qquad (3)$$

where m and s are the mass and the specific heat of the wire, respectively. If we use the temperature coefficient of resistance α, we have

$$\left.\begin{aligned} &T-\Theta=\frac{r-r_0}{\alpha r_0}\ ,\\ &\frac{dT}{dt}=\frac{1}{\alpha r_0}\frac{dr}{dt}\ , \end{aligned}\right\} \qquad (4)$$

where r_0 is the resistance of the wire at air temperature. From (1), (3) and (4),

$$\frac{ms}{\alpha r_0}\frac{dr}{dt}=i^2r-f(u,r)\frac{r-r_0}{\alpha r_0}\ . \qquad (5)$$

In the case of stationary state with constant wind velocity U, we have

$$i_e{}^2\bar{r}=f(U,\ \bar{r})\frac{\bar{r}-r_0}{\alpha r_0}\ , \qquad (6)$$

where $\bar{r}$ is the resistance of the wire and i_e is the electric current through it. To keep the wire resistance constant, it is convenient to use a Wheatstone bridge.

When the air speed fluctuates,

$$u=U+u'\ ,\quad r=\bar{r}+r'\ . \qquad (7)$$

If we can neglect small quantities of $O(u'/U)^2$, $O(u'r'/U\bar{r})$ and $O(r'/\bar{r})^2$, we have from (5) and (7)

$$\begin{aligned} \frac{ms}{\alpha r_0}\frac{dr'}{dt}=i^2(\bar{r}+r')&\\ -\{f(U,\ \bar{r})+f_u(U,\ \bar{r})u'+f_r(U,\ \bar{r})r'\}&\\ \times\frac{\bar{r}-r_0}{\alpha r_0}-\frac{f(U,\ \bar{r})}{\alpha r_0}r'\ ,& \qquad (8) \end{aligned}$$

where suffices u and r represent partial differentiation. If the circuit constants are such as shown in Fig. 1,

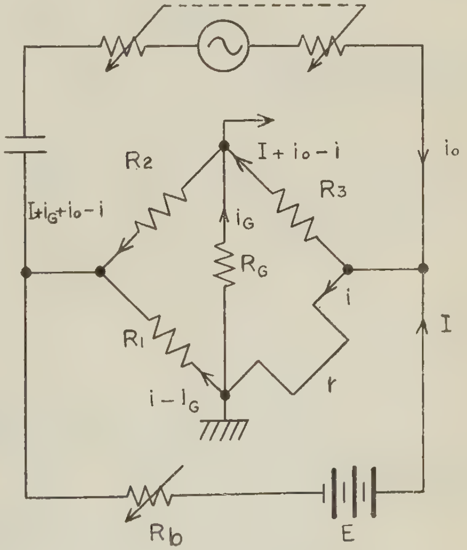

Fig. 1. Bridge circuit.

$$\begin{aligned} &\bar{r}R_2=R_1R_3\ ,\\ &i=(E+i_0R_b)R_3G/(\bar{r}\Delta)\ ,\\ &i_e=ER_3/B\ ,\\ &I=[\{E(\bar{r}+R_3)-i_0R_3(\bar{r}+R_1)\}G\\ &\qquad+E(G-R_1R_G)r']/(\bar{r}\Delta)\ , \end{aligned}$$

where small quantities of $O(i_0r'/E)$ are neglected and

$$\Delta=\Delta_1+\Delta_2r'\ ,$$

$$\Delta_1 = BG/\bar{r}\ ,$$
$$\Delta_2 = \{G(R_b+R_3)+R_1(R_1R_3-R_bR_G)\}/\bar{r},$$
$$B = R_b(\bar{r}+R_3)+R_3(\bar{r}+R_1)\ ,$$
$$G = R_G(\bar{r}+R_1)+R_1(\bar{r}+R_3)\ .$$

If we choose $i_e \gg |i_0|$, then we have, neglecting small quantities,

$$\left.\begin{aligned} &\bar{i} = i_e\ ,\\ &\bar{I} = i_e(1+\bar{r}/R_3)\ ,\\ &i^2(\bar{r}+r') = i_e^2\{\bar{r}+2i_0\bar{r}R_b/E+(1-\rho)r'\}\ , \end{aligned}\right\} \quad (9)$$

where bar denotes the time average and

$$\rho = 2\bar{r}\Delta_2/\Delta_1\ .$$

Hence from (6), (8) and (9), we have

$$M\frac{dr'}{dt}+r' = c_1u'+c_2i_0\ , \qquad (10)$$

where M is the time constant of the wire defined as

$$\left.\begin{aligned} &M = ms/(i_e^2r_0\alpha A)\ ,\\ &c_1 = -(\bar{r}-r_0)f_u/(i_e^2r_0\alpha A)\ ,\\ &c_2 = 2R_b\bar{r}/(EA)\ ,\\ &A = \frac{r_0}{\bar{r}-r_0}+\rho+\frac{\bar{r}-r_0}{i_e^2\alpha r_0}f_r\ . \end{aligned}\right\} \quad (11)$$

From (6) and (9), we have

$$f_u(U,\ \bar{r}) = \frac{\alpha r_0\bar{r}}{2\sqrt{U}(\bar{r}-r_0)}\left(\frac{R_3}{\bar{r}+R_3}\right)^2\frac{\partial\overline{I^2}}{\partial\sqrt{U}}\ . \qquad (12)$$

Also (2) gives

$$f_r = K'+D'u^m\ .$$

In this equation,

$$K = ak_1L_1\left(\frac{\theta}{\theta_1}\right)^\omega\left\{1+\frac{\beta}{\alpha}\left(\frac{r}{r_1}-1\right)\right\}\ ,$$

where θ is the effective temperature of air, suffix 1 represents the standard state,

$$\theta = \frac{1}{2}(T+\Theta),\quad \theta_1 = \frac{1}{2}(T_1+\Theta)\ ,$$

and β is the coefficient of linear expansion of the wire. Thus

$$K = ak_1L_1\left\{\frac{T_1+\Theta+(r-r_1)/\alpha r_1}{T_1+\Theta}\right\}^\omega\left\{1+B\left(\frac{r}{r_1}-1\right)\right\}\ ,$$

where $B = \beta/\alpha$. Hence

$$K' = K\left\{\frac{\omega}{\alpha r_1(T_1+\Theta)+r-r_1}+\frac{1}{r-r_1+r_1/B}\right\}\ ,$$

On the other hand,

$$D = bk_1L_1\left(\frac{d_1}{\nu_1}\right)^m\{1+\beta(T-T_1)\}^{m+1}\left(\frac{\theta}{\theta_1}\right)^{\omega-5m/2}\left(\frac{\theta+C}{\theta_1+C}\right)^m,$$

where $C = 107$°C. Then

$$D' = D\left\{\frac{m+1}{r-r_1+r_1/B}+\frac{\omega-5m/2}{\alpha r_1(T_1+\Theta)+r-r_1}+\frac{m}{\alpha r_1(T_1+\Theta+2C)+r-r_1}\right\}\ .$$

If we choose $r = r_1 = \bar{r}$, $T_1 = \bar{T}$,

$$f_r(U,\ \bar{r}) = \frac{f}{\bar{r}}\left\{\frac{\omega}{\alpha(\bar{T}+\Theta)}+B\right\}+\frac{mDU^m}{\bar{r}}\left\{B-\frac{5}{2}\,\frac{1}{\alpha(\bar{T}+\Theta)}+\frac{1}{\alpha(\bar{T}+\Theta+2C)}\right\}\ .$$

But from (2), we have

$$mDU^m = Uf_u\ .$$

Therefore, considering that B is negligible (0.0023 for platinum, 0.00083 for tungsten), we obtain, from (6) and (12),

$$f_r = \frac{\overline{I^2}r_0R_3^2}{(\bar{r}-r_0)(\bar{T}+\Theta)(R_3+\bar{r})^2}\left[\omega-\frac{3\sqrt{U}\,\partial\overline{I^2}}{4I^2\,\partial\sqrt{U}}\left\{1+\frac{4}{3}\,\frac{C}{\bar{T}+\Theta+2C}\right\}\right]\ . \qquad (13)$$

Usually, ω can be taken as 3/4.

On the other hand, the output voltage of the bridge is

$$e=\sigma r' , \tag{14}$$

where

$$\sigma=-i_e R_1 R_G/G ,$$

When we use the hot-wire in fluctuating air flow, $i_0=0$. Then

$$M\frac{dr'}{dt}+r'=c_1 u' . \tag{15}$$

To find the relation between r' and u', these are expressed as time-dependent Fourier series

$$u'=\sum_n (A_n \cos \omega_n t+B_n \sin \omega_n t) ,$$

$$r'=\sum_n (C_n \cos \omega_n t+D_n \sin \omega_n t) .$$

If we put these formulas in (15), we get

$$r'=\sum_n \frac{c_1}{\sqrt{1+M^2\omega_n^2}}\left\{A_n \cos(\omega_n t-\phi_n)+B_n \sin(\omega_n t-\phi_n)\right\} ,$$

$$\phi_n=\tan^{-1}(M\omega_n) .$$

That is, the fluctuation of the wire resistance is reduced in the ratio of $|c_1|/\sqrt{1+M^2\omega^2}$ in amplitude, and retarded by an amount of $\tan^{-1}(M\omega)$ in phase. When this effect is eliminated by use of a compensating amplifier, the equivalent bridge output becomes

$$e=\sigma c_1 u'. \tag{16}$$

σc_1 is the sensitivity of the hot-wire anemometer.

As c_1 can be calculated by (11), (12) and (13), the turbulent intensity $\sqrt{\overline{u'^2}}$ can be found by means of (16) by measuring $\sqrt{\overline{e^2}}$.

From (9), it is clear that ρ represents the effect of current variation due to resistance variation. By definition ρ is always positive, and hence, by (11), A is increased, so that M, c_1 and c_2 are decreased. Thus the time constant of the wire decreases with the sacrifice of the sensitivity.

§ 3. Measurement of Turbulent Intensity by Calibration Method

For the calibration of the hot-wire, we place it in the wind at constant speed without fluctuation, and superpose an alternating current on the direct current through the wire:

$$i_0=a\cos\omega t . \tag{17}$$

Then

$$M\frac{dr'}{dt}+r'=c_2 i_0,$$

$$r'=\frac{c_2}{\sqrt{1+M^2\omega^2}}a\cos(\omega t-\phi) ,$$

$\phi=\tan^{-1}(M\omega)$. If we use such ω as $M\omega\ll 1$, $r'=c_2 i_0$, so that the bridge output becomes

$$e_c=\sigma c_2 i_0 . \tag{18}$$

When the dynamic calibration has been performed, c_2 can be obtained by (18). Now, from (11) and (12), we have

$$c_1=-\frac{1}{4I\sqrt{U}}\frac{\partial\overline{I}^2}{\partial\sqrt{U}}c_2 .$$

Thus

$$e=-\frac{e_c}{4Ii_0\sqrt{U}}\frac{\partial\overline{I}^2}{\partial\sqrt{U}}u' . \tag{19}$$

From this equation, measurement of turbulent intensity can be immediately carried out without complicated calculation.

§ 4. Comparison with Experiment

To investigate the effectiveness of the above-mentioned methods, a series of measurements of the same turbulence with various hot-wires were performed. For this purpose, the decay of turbulence behind a square mesh grid at air speed of 4 m/s was investigated. The grid was $2.8\times2.5\,\mathrm{mm}^2$, made with circular rods of 0.75 mm diameter. This grid was placed in an N.P.L. type wind tunnel with $20\times30\,\mathrm{cm}^2$ rectangular test section. Turbulent intensity was measured at the center line of the test section. The hot-wire was Wollaston processed platinum wire whose diameter was 2.5 micron. We used an equal arm Wheatstone bridge in the same manner as Shigemitsu[6] had done. In this case, R_b can be far greater than $\bar{r}$, and the output voltage over the hot-wire is approximately $1.5+\bar{r}/R_G$ times that over the galvanometer without superposed alternating current[3]. This point is important for the measurement of small velocity fluctuation, although, in this case, the calibration method cannot be used.

The output of the bridge was led to a compensating amplifier and mean-square unit[3].

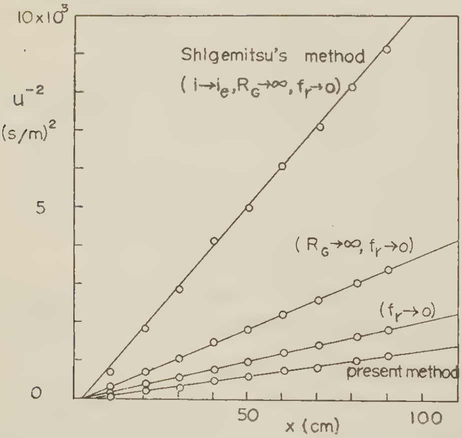

Fig. 2. Error due to various simplified assumptions.

The temperature of the wire was varied from 175°C to 413°C. In Fig. 2, the result at 413°C is plotted using the calculation method—(16)—and the calibration method—(19). In this figure, the result obtained by the use of Shigemitsu's method[6] is also shown for comparison. The latter is about ten times as large as other two results.

Shigemitsu assumes that the current and heat transfer variations due to the resistance variation are infinitesimal and the resistance of the galvanometer circuit infinite. So the above-mentioned difference may be deemed due to the effects of these variations and of the finite resistance of the galvanometer circuit. In order to clarify this, the result calculated by the assumption of infinitesimal heat transfer variation and the result calculated by further assumption of infinite resistance of the galvanometer circuit are also plotted in this figure. From this figure, it is clear that the main cause of the difference is the current variation due to the resistance variation, nevertheless the effects of the finite resistance of the galvanometer circuit and heat transfer variation cannot be ignored.

In Fig. 3 is shown the effect of temperature variation for Shigemitsu's method. The scatter of the results is due to the temperature variation of this effect.

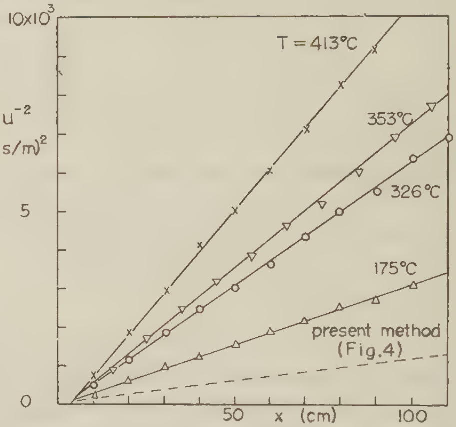

Fig. 3. Temperature dependence of the result obtained by the old method.

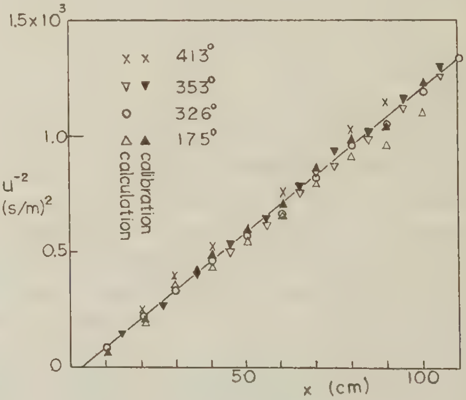

Fig. 4. Temperature independence of the result obtained by the present method.

In Fig. 4, the results obtained by using our two methods are presented. It will be seen that the temperature effect is completely eliminated, and further, all the experimental points lie on a single line. Thus we may safely state that the present results are quantitatively correct.

§ 5. Summary

Two experimental methods for quantitative measurement of turbulence are described. These two methods have been applied to investigate the decay of the turbulent energy behind a grid. In spite of the variation of the temperature of the hot-wire, results obtained were in complete agreement with each other. It is remarked that the older method which neglects the effects of the finite resistance of the galvanometer circuit and the current variation due to resistance variation of hot-wire would lead to values about ten times as large as correct ones at the highest wire temperature in our experiment.

In conclusion, the author wishes to express his hearty gratitude to Dr. Masando Hanajima and Mr. Yutaka Shigemitsu for their kind support. His cordial thanks are also due to Professor Itiro Tani, Professor Isao Imai and Mr. Junji Iwayanagi for the interest shown to this work.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN Vol. 14, No. 3, MARCH, 1959

The Effect of the Room Shape on the Sound Field in Rooms (Studies on the Measurement of Absorption Coefficient by the Reverberation Chamber Method I)

By Kozi SATO and Masaru KOYASU

Kobayasi Institute of Physical Research, Kokubunji,
Tokyo, Japan

(Received August 18, 1958)

In order to carry out accurate measurements of absorption coefficient by Sabine formula, the assumption of diffuse distribution of sound energy in the reverberation chamber must be fulfilled. Thus, this work was started from the basic researches of the sound field in the two and three dimensional model rooms.

The standing wave pattern of each normal mode was investigated using the dust figures and other methods.

At low frequencies, normal mode of vibration existed even when the room shape was made adequately irregular, and for each normal mode, spatial variation of sound pressure did not depend on room shape.

However, as the room shape becomes irregular, the nodal lines of successive normal modes distribute at random in space. Also, in the properly irregular room, the variation of decay rate for each normal mode was much smaller than that of a rectangular room.

§ 1. Introduction

The acoustics of the theatres, concert halls, auditoria, etc. and the noise reduction in factories, offices, houses have recently become a significant problem. One of the important problems in these cases lies in measuring an accurate absorption coefficient of acoustic materials and furnitures by the reverberation chamber method.

A large number of literatures have been published as to the measurement of absorption coefficient by the reverberation chamber method[1]. And it is believed that the sound field in the chamber forms the most important problem. Namely, the reverberation chamber formulae presuppose the following two conditions as premises:

1. To obtain the uniform distribution of sound energy throughout the reverberation chamber.
2. To secure the equal transfer of sound energy in all directions throughout the reverberation chamber.

Thus it is essential that the assumption of uniform distribution of sound energy should hold in the reverberation chamber.

Generally it is accepted that, as the frequency of sound becomes lower and the wavelength of sound draws closer to the size of the reverberation chamber, the sound field goes against the assumption mentioned above. Such being the case, many attempts have been made to approach to the premised conditions by considering the room shapes, use of microphones and loudspeakers, the position of a sample material and so on. Since most of the typical reverberation chambers had been set up before the aforementioned condition of uniform sound field was apprehended from the viewpoint of the present wave theory of acoustics[2], these counterplans have mostly been taken up empirically.

As far as the rectangular reverberation chamber is concerned, the relation between the room size and the sound field has been thoroughly investigated by Hunt *et al*[3]. However, full investigations on general room shape have not yet been made in relation to the characteristics of the reverberation chamber. Although Venzke recently submitted a report on the relation between the shape of the reverberation chamber and the measured decay curve[4], the results alone are believed not necessarily to bear witness to the irregular chamber with plane walls being the same with the rectangular one. Also, Nimura and Shibayama are conducting analyses and experiments on the subject of the relation between room shape and steady-state characteristics[5]. However, consideration from another angle is now urged for the reverberation chamber.

In a sense as mentioned above, we thought it most desirable to start off with the basic studies on the sound field within the room. Since the number of normal modes decreases particularly at low frequencies, it would be necessary to consider the characteristics of individual normal modes which participate with the sound field at those frequencies. Even when the room shape is extremely irregular, there exist distinct normal modes determined by room shape. This fact is well-known at least from theoretical considerations. In this case, we believe that the spatial distribution of nodal lines of successive normal modes and the direction of propagation of the wave front would play an important role.

This paper intends to report the results of model room experiments relating the effect of the shape and size of the room on the steady-state and transient characteristics of sound waves in it, within the range of comparatively low frequencies. As a result of these experiments, it was made sure that, in a properly irregular room, nodal lines of successive normal modes distributed at random throughout the room. It was also confirmed that the fluctuation in decay rate of all the normal modes became smaller in this case than in the case of rectangular room.

§ 2. Two-Dimensional Model Room Experiments

The shape and size of two-dimensional model rooms are shown in Fig. 1. Side walls were 5 cm in height. The bottom and side walls were made of wood with a thickness

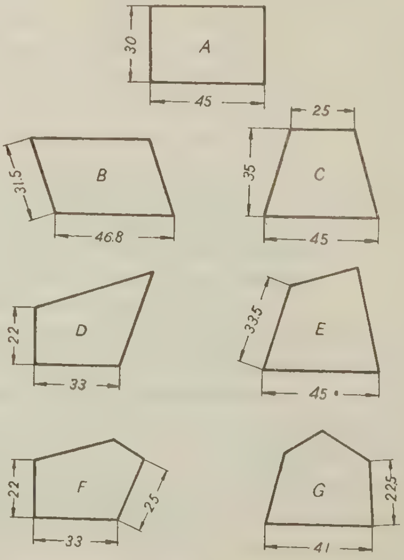

Fig. 1. Plan of two dimensional models. Size in centimeter.

of 3 cm, and a glass plate with a thickness 1 cm was used for the upper surface so that we can look into dust figures to be mentioned later. Although every considerations were taken to make each area of model equal, it was impossible to attain the perfect equality of all areas under the various conditions including the experimental apparatus. However, since the comparison among the same mode of vibration was the main purpose of these experiments, the difference of areas in some measure was believed to be allowable after all.

2.1. Spectrum of normal modes

With a view to obtaining a spectrum of normal mode of vibration, sound from the loudspeaker was sent into the model room through the hole made in the side walls, changing continually the frequencies of the oscillator. Sound pressure received by the microphone which was fixed on the other point was amplified and registered by the level recorder.

Attaching a tube with a length of 30 cm (in which aluminum wires were heavily stuffed) to the driver unit, and letting sound go into the model room through the orifices made at the end, we had the loudspeaker suffer from reaction as little as possible. Loudspeaker and microphone were placed in the different corners of the model room. Exchanging their positions from the one to the other, spectrum of several combinations was measured for each model room.

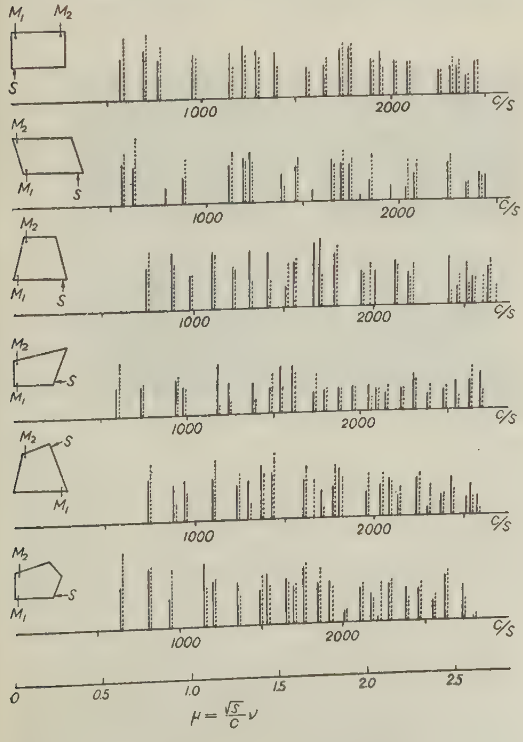

Fig. 2. Spectrum of normal mode of vibration. microphone position: —— M_1, - - - M_2

Spectrum of normal modes for each model room is shown in Fig. 2 as an example. The scale seen at the bottom of the illustration for the purpose of correcting the area difference is the non-dimensional frequency μ whose relation with frequency ν is as follows:

$$\mu=\frac{\sqrt{S}}{c}\nu\,. \tag{1}$$

Here S is the area of the model and c is the velocity of sound[6]. For the convenience of comparison, the abscissa of spectrum in each model room was made to match on μ.

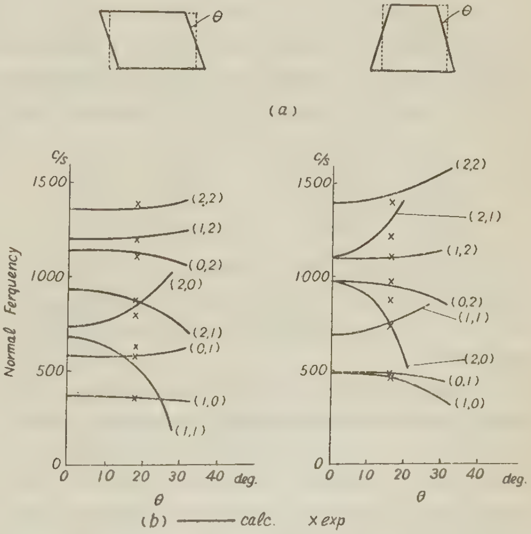

Fig. 3. Normal frequencies of parallelogram and trapezoid.

(i) *The normal frequency in parallelogram and trapezoid*

Since parallelogram and trapezoid are the simplest transformation from rectangle, the change in the normal frequency is considered to form the basis of general transformations. Furthermore, the calculation in this case was comparatively easy by Feshbach's perturbation method, and so the comparison with that was also made.

When the transformation as shown in Fig. 3 (a) takes place, frequency ν_N of normal mode of vibration $N\ (n_x, n_y)$ is given in the following formula[7].

$$\nu_N^2=\nu_{N0}^2-\frac{c^4}{16\pi^4}\sum{}'\frac{A_{KN}^2}{\nu_{K0}^2-\nu_{N0}^2} \tag{2}$$

ν_{N0} and ν_{K0} are the normal frequencies in $N(n_x, n_y)$, $K(k_x, k_y)$ mode of the original rectangle and the sum of the second term equals the answer with $K=N$ excluded. Bolt and others calculated on the trapezoid room[8]. Here we further calculate the A_{KN} of parallelogram room, which is carried out as follows:

$$A_{KN}=(-1)^{(k_x+k_y+n_x+n_y-2)/2}\cdot 4\alpha M_K M_N \times\left\{\left(\frac{b}{a}\right)^2\frac{n_x^2(k_y^2+n_y^2)}{(k_y^2-n_y^2)^2}-\frac{n_y^2}{k_y^2-n_y^2}\right\}. \tag{3}$$

In this case

$$M_N=\left\{\frac{(2-\delta_{0n_x})(2-\delta_{0n_y})}{4ab}\right\}^{1/2},$$

$$\delta_{0n}=\begin{cases}1 & n=0\\ 0 & n\neq 0\end{cases}$$

$\alpha=\tan\theta$, $2a$ and $2b$ are lengths of the sides of the original rectangular room. And in this case k_x and k_y obey different combination rules for n_x, n_y from those of trapezoid room.

n_x	k_x	n_y	k_y
even	odd	even	odd
odd	even	odd	even

Fig. 3 (b) shows the change of normal frequencies with θ as calculated from Eqs. (2) and (3), and compared with the result of experiments.

In some of the normal modes, the calculation and experiments show so large a disagreement that the approximation by the perturbation method does not seem to hold good, as shown in the figure. However, the figure will serve to tell the tendency of variation.

Some modes in the illustration show the same normal frequency with that in the rectangular room, while others are considerably different. For the case of parallegram and trapezoid shown in Fig. 3 (a), the distance between one pair of opposite sides is the same with that of the original rectangular room. The shift of normal frequency is very small for those modes which form nodal lines parallel to these sides.

The mode of vibration with nodal lines extending in only one direction in the rectangle results from plane waves going back and forth in the direction perpendicular to nodal lines. It follows from this that when the distance between the opposite sides does not change by transformation, the frequency comes under little influence.

(ii) *The distribution of adjacent normal frequencies*

Next, for the convenience of comparison of differences in the distribution of normal frequencies which occur to each room shape, the differences were arranged into Fig. 4 which is based upon Bolt's *frequency spacing index* Ψ[6]. Using the aforementioned non-dimensional frequency μ, Ψ is given by the following formula.

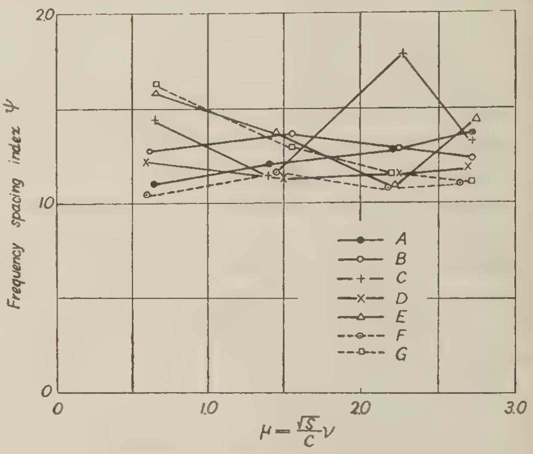

Fig. 4. Frequency distribution of normal mode (expressed by frequency spacing index).

$$\Psi=N\sum_{\mu_a}^{\mu_b}\delta_N^2/(\mu_b-\mu_a)^2 \tag{4}$$

In this case, N is the number of spaces in the normal modes between μ_a and μ_b, and $\delta_N=\mu_{N+1}-\mu_N$. If the distribution of normal modes is at equal intervals, the formula becomes $\Psi=1$. It follows from this that the modes D, F, etc. in Fig. 1 are the nearest to the formula $\Psi=1$ throughout the range. Also, in the case of non-symmetrical polygons, when the longitudinal and latitudinal lengths are almost in the same order as in the models, E, G, etc., there is a tendency that normal modes get together into several groups. This is, of course, one of the examples. For instance, if the ratio of the longitudinal length to the latitudinal one is changed, the distribution varies even in the case of rectangle.

2.2. Mode of normal vibrations (Position of nodal lines)

The position of nodal lines of normal modes has hitherto been checked up by moving the microphone and has been figured out from the sound pressure distribution or from the phase-reversal[9]. This method becomes extremely troublesome when the nodal lines get complicated due to the irregularity of the room shape. And it takes a lot of time just to examine one mode. Under the circumstances, we took up the dust figures for the investigation of normal modes. Since experimental methods and the details of results will be given in another report, we mention here in this report only the results used in these model room experiments.

Cork dust was scattered on the floor of model room, and a horn speaker unit was fixed at the hole made in the side wall through which sound was let in. When the frequency of sound is brought in line with that of the normal vibrations of the room, the dust starts to move and forms a stripe pattern. This pattern is formed around the position of maximum particle velocity, in the same manner as in one dimensional Kundt tube experiment. Therefore, it is possible to locate the rough position of nodal lines.

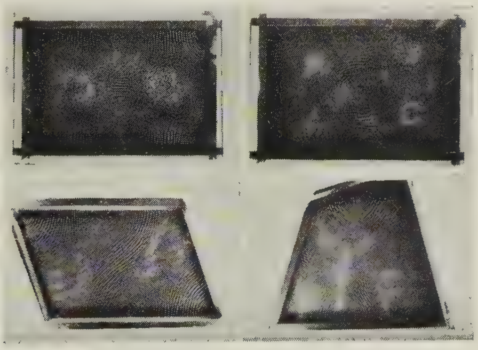

Fig. 5. Dust figures of normal mode of vibration.

Photos in Fig. 5 show examples of the dust figures of normal modes obtained by this method, while Fig. 6 shows schematically the variation of nodal lines with room shape, based upon these dust figures.

When there are parallel walls or symmetry as in the case of parallelogram or trapezoid, the variation of nodal lines has a certain regularity. On the other hand, the more the room shape becomes irregular, the more complicated the nodal lines become. This seems to be an important factor for obtaining the uniformity of sound field. Sound field after sound source is off is obtained by the superposition of the decaying normal modes excited at the time of cut off[10]. The nodal lines in the rectangular room are so regular that nodal lines of different modes overlap one another to some extent. In such a case the normal modes taking part in decay become extremely different in nature (axial, tangential or oblique modes) in different parts of the room. On the other hand, when the room shape and so the position of nodal lines are irregular, the superposition of decaying normal modes would show nearly the same nature throughout any part of the room.

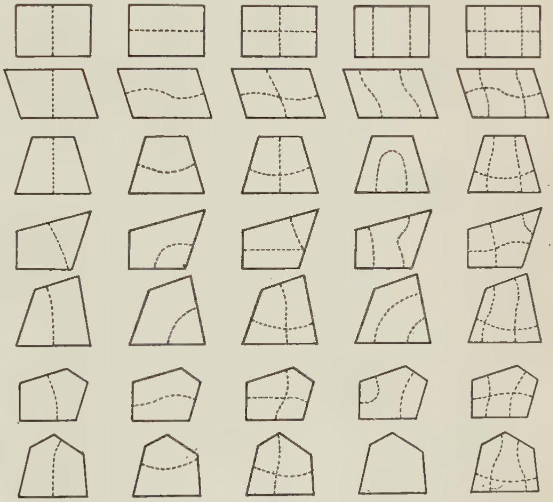

Fig. 6. Schematic representation of nodal lines obtained from dust figures.

2.3. Sound pressure distribution of normal modes

Letting sound into the model room in the same way as in the spectrum measurements, we measured the sound pressure distribution by probe tube microphone.

Fig. 7 shows sound pressure distribution of some normal modes for each model room in the range of low frequencies. The direction of the microphone movement and the position of nodal lines found from dust figures are shown in the illustration.

Sound pressure level is different in different corners except in those of rectangular model. This was rather an expected result, since nodal lines found by dust figures become asymmetric and approach the corners in some cases.

Next, the ratios between maximum and minimum values of sound pressure level in the room showed no apparent difference for different room shapes. The results thus attained accord also with those of Bolt's experiments which was done for a slightly deformed rectangular room[9].

§ 3. Three-Dimensional Model Room Experiments

A three dimensional model room was constructed with nonparallel walls and the sound field of this model was compared with that of three-dimensional rectangular models. The shape of the bottom of the irregular room is a non-symmetrical pentagon based upon the model F in Fig. 1. Its shape and size are shown in Fig. 8. On the other hand, the rectangular models used for comparison comprised two kinds; the model I had the same base area and volume with irregular model (48 cm × 37 cm × 35 cm), while the model II was relatively large in size and volume (125 cm × 75 cm × 50 cm).

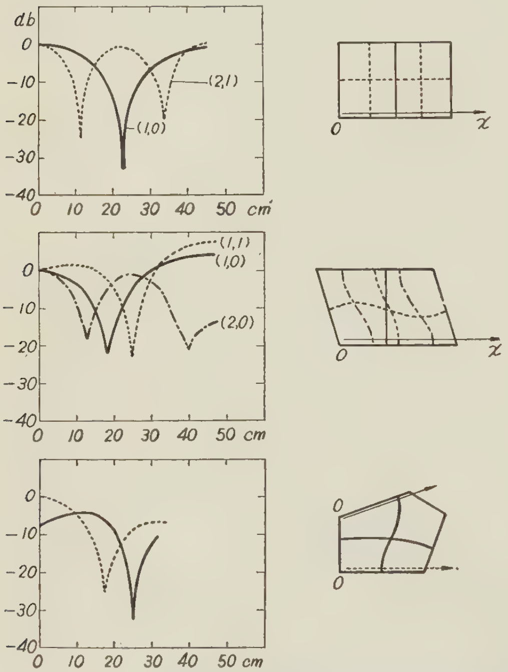

Fig. 7. Sound pressure distribution along a line parallel to the wall.

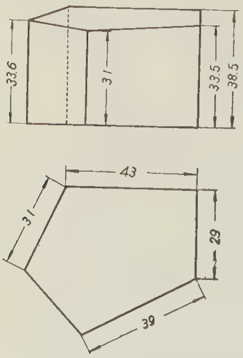

Fig. 8. Three-dimensional model with non-parallel walls. Size in centimeter

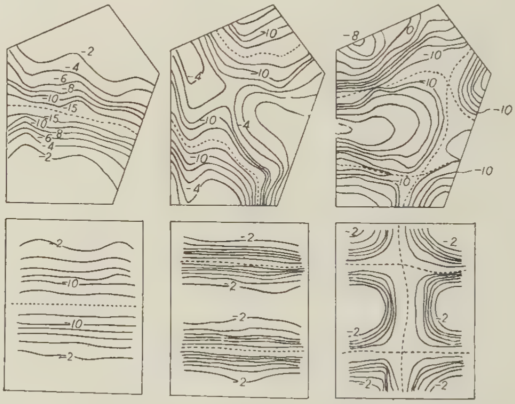

Fig. 9. Sound pressure distribution of normal modes. Figures show relative level in decibel and dotted line shows the nodal line.

3.1. Sound pressure distribution

(i) *Sound pressure distribution by pure tone*

Fig. 9 shows an example of the sound pressure distribution of normal modes for the irregular model and the rectangular model I on the plane parallel to the floor. The sound pressure distribution is shown with contour lines drawn at the intervals of 2 decibels from the position of maximum sound pressure. The dotted lines in the illustration indicate the minimum sound pressure (nodal lines). Since sound pressure contour lines get close together around the nodal lines, only the lines of −15 and −20 decibels and the nodal lines are shown for pressure levels lower than −10 decibels. The ratios between maximum and minimum values of sound pressure level were 30 to 40 decibels in either case of model rooms.

(ii) *Sound pressure distribution by warble tone*

Next, we investigated sound pressure distribution when various normal modes were excited at the same time. Since the size of the actual reverberation chamber that was to be designed would be 10 to 20 times as large as the model in linear dimensions (chamber volume: 250∼500 m^3), we adopted 1000∼2000 cycles per second for the center frequency of warble tone. As an example Fig. 10 shows the comparison of sound pressure distribution between the irregular room and rectangular model I, with 1260 cycles per second as its center. While the sound pressure of irregular room changes intricately in different parts, that of rectangular one is distributed almost symmetrically and becomes minimum in the center of the room. But the range of variations of sound pressure level was almost the same in each room shape. This value is extremely small as compared with the difference of the sound pressure levels for each normal mode by pure tone, which tells the fact that the warble tone has the effect of uniformizing the sound field.

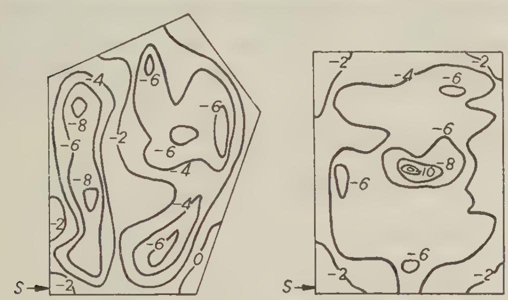

Fig. 10. Sound pressure distribution by warble tone. $\nu_0 = 1260$ c/s, $\Delta\nu = 250$ c/s

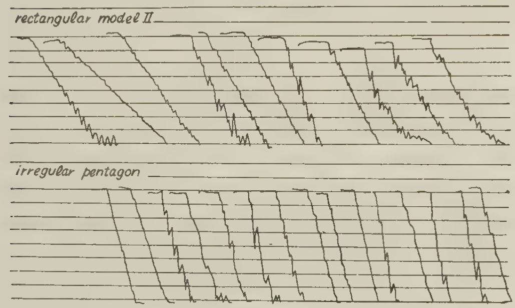

Fig. 11. Decay curves for each normal mode.

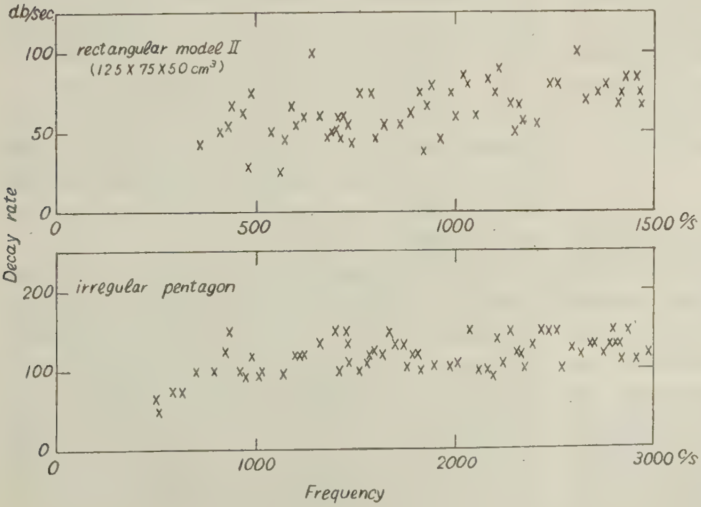

Fig. 12. Decay rate for each normal mode.

3.2. The effect of room shape on the decay of sound

(i) *Decay curve for each normal mode*

We further investigated the decay of each normal mode in the irregular model and rectangular model room II by pure tone. Fig. 11 shows one of the example of decay curves recorded in order from low to high frequencies.

Since the rectangular model had eight times as large volume as the irregular one, it would be safe to suppose that the normal mode of the irregular model that corresponds to a certain normal mode of the rectangular model has about twice the frequency as that of the rectangular room. Therefore, when the comparison on decay was made as in the case of Fig. 11, we made the frequencies in case of rectangular room correspond to twofold frequencies in case of irregular room.

Next, we determined from this record the decay rate of each decay curve, which is shown in Fig. 12. In this case, due to the large volume of the rectangular room, the reverberation time becomes about twofold in the average (one-half in decay rate). So the ordinate was doubled for the rectangular model for the convenience of comparison. What is evident from the results of the two model rooms is that the fluctuations in the decay rate of irregular room are much smaller than those in the rectangular model. This applies to all the normal modes except to some normal modes with low frequencies. Namely, at frequencies higher than 700 cycles per second in the irregular room, the ratio of the fastest to the slowest of the decay rate is only one and a half. On the other hand, in the case of rectangular room, normal modes which are extremely slow in decay rate are found below about 1000 cycles per second (which corresponds to 2000 cycles per second in the irregular room.)

In the case of rectangular room, all the normal modes whose decay is extremely slow correspond to the normal modes caused by sound waves reflecting back and forth between a pair of walls which stand opposite each other (*axial mode*) or to similar ones, while in the case of non-symmetrical rooms as this irregular room which has no parallel walls, the average difference of reflection distance between the walls becomes small for all the normal modes. For this reason, it is quite natural to think that the fluctuations of the reverberation time become small for irregular rooms.

(ii) *Decay curve by warble tone*

Next, using the warble tones with center frequencies of 1260 and 2650 cycles per second (620 and 1260 cycles per second in rectangular model II), we measured the decay curves from which we obtained the decay rate as shown in Table I. It is clear, when compared with the aforementioned measurements by pure tone (Fig. 12), that the decay rate in this case would be obtained by averaging the decay rates of each normal mode within the variation range of warble tone. With 1260 cycles per second for center frequency in the irregular room, the decay curve is perfectly logarithmic, while in case of 620 cycles per second for rectangular model, that corresponds to 1260 cycles per second for irregular room, the decay curve is bent and the decay rate at the beginning part of the decay curve is steeper than that at the tail. This is because the normal modes whose decay is extremely slow are included within the range.

Table I. Decay rate when warble tone is used for sound source.

Irregular model		Rectangular model II	
frequency	decay rate	frequency	decay rate
2650±300 c/s	120 db/sec	1260±150 c/s	67 db/sec
1260±250	109	620±120	50 (0∼−15 db)* 27 (from −15 db)

* This shows that the range from steady-state (0 db) to −15 db is different from the range less than the above in decay rate.

§ 4. Conclusion

One of the most important problems in measuring the absorption coefficient of acoustic materials by the reverberation chamber method depends upon the realization of uniform sound field. For this reason, we conducted the model room experiments to investigate the effects of the room shape and size upon the sound field in the room. The object we set for the basic consideration is how the normal modes depend on the room shape and size. The following is the summary of the experimental results.

(1) As was expected from theoretical consideration, there exist normal modes determined by the room shape, and the sharpness of pressure distribution for each normal mode is not affected by the room shape. But, when the room shape becomes properly irregular, the nodal lines of normal modes get distributed in a complicated manner, and so the number of normal modes taking part in decay become almost uniform in any part of the room.

(2) In this case, the fluctuation in the decay rates of each normal mode begin to decrease from the comparatively low frequencies. This fact would indicate that the distinct axial mode becomes difficult to exist in such an irregular room.

From the experimental results mentioned above, we believe that, in order to obtain a desirable sound field for a reverberation chamber, one of the advantageous way is to make the room shape properly irregular, and that this would prove far more advantageous at least than a rectangular chamber with the same volume. Moreover, in this way we can anticipate fully satisfactory results.

We express a deep gratitude to Mr. K. Kubo who participated and cooperated with us in the experiments of dust figures which formed one of the basis of our study.

Germanium-Silicon Alloy Junctions

By Yasuo MATUKURA

Electrotechnical Laboratory, Tokyo, Japan

(Received December 9, 1958)

When a germanium dot is heated on a silicon wafer, a molten alloy of the equilibrium compositions of Ge and Si is formed on the silicon wafer. As cooled with a temperature gradient, Si-enriched Ge–Si alloy is recrystallized on the adjacent pure Si, and the succeeding recrystallization produces gradually Ge-enriched Ge–Si alloy, which energy gap[1)] is abruptly modified from Si value to Ge–Si alloy's one and then gradually to Ge one. If alloy is made from Ge and Si doped with opposite type impurity of the segregation constants, k_1 and k_2, respectively, these impurities will be segregated during the successive solidification. Difference ΔC between n- and p-type impurities at any point g, where g is a fraction which has solidified, is given by the following formula[2)].

$$\Delta C = k_1 C_{01}(1-g)^{k_1-1}\left[\frac{k_1 C_{01}}{k_2 C_{02}}(1-g)^{k_2-k_1}-1\right], \quad (1)$$

where, C_{01} and C_{02} are the impurity concentrations in the initial molten phase. If C_{01}, C_{02}, k_1, k_2, and alloy temperature are suitably chosen so as to make ΔC zero at some g, then a pn junction will grow. Fig. 1 shows relations between g and ΔC calculated by Eq. (1). This estimation was made for alloying of arsenic doped n–Si and gallium doped p–Ge at 1150°C so as to produce pn junctions at $g=0$, $g=0.5$ and $g=0.8$. Donor concentrations in Si is 7.3×10^{14} cm^{-3}, and acceptor concentrations in Ge are shown in Fig. 1. The segregation constants for the alloy were assumed the same as the ones for Si at 1420°C[3)].* In the figure, the variations of the composition and of the energy gap E_g of recrystallized alloy are shown together.

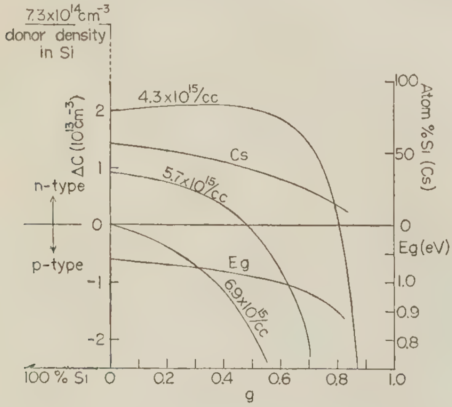

Fig. 1. The variations of ΔC, band gap, and alloy composition with the fraction of solidification. Parameter is the acceptor density in *Ga* doped *p–Ge*.

Preliminary experiments were performed by using arsenic doped 2.5 Ωcm n–Si and gallium doped 0.05 Ωcm p–Ge so as to produce a pn junction at $g=0$. A small dot of Ge was put on a Si wafer of thickness of 0.3 mm and heated at 1150°C for 30 minutes in H_2 gas, and then cooled at the rate of 2°C/min. The measurements by hot probe method and a result of etching on the section of Ge–Si alloy showed that a pn junction was formed at $g=0.1$. This result shows that the assumptions for the segregation constants is almost reasonable. The influence of impurity diffusion on ΔC was estimated to be very small.

As the total thickness of recrystallized Ge–Si alloy was about 1 mm, the gradient of ΔC, a, in Fig. 1 can be estimated at the pn junctions. If $L_a = n_i/a$ is compared with L_d[4)] by using the values of the intrinsic resistivity[5)], it is seen that these pn junctions are nearly of abrupt type rather than graded one.** In Ge–Si alloy recrystallized at high temperatures, the variation of E_g is so small that E_g at both sides of the pn junction grown at $g\neq0$ will be nearly equal, and the pn junction is localized in nonuniform semiconductor[6)]. On the other hand, the variation of E_g will be increased by low temperature alloying. In this case, it is seen that E_g at both sides of a pn junction is not equal. At $g=0$, it is considered that one side of the pn junction has E_g of Si and the other side smaller E_g. This tendency will be increased by decreasing alloy temperature. Further investigations on the characteristics of these particular pn junction will be reported later.

The author is indebted to Mr. M. Kikuchi for helpful discussions.

Electronmicroscopic Observation of the KCl Crystal Containing Potassium Colloid Particles

By Tadatosi Hibi
Research Institute of Scientific Measurements
and Tetsuhiko Tomiki*
The Research Institute of Iron, Steel and Other Metals, Tohoku University, Sendai, Japan

(Received January 20, 1959)

As reported previously[1], electronmicroscopic observations on the additively coloured KCl crystals illuminated with green light showed that the small hemispherical humps having a spongy structure appeared on the illuminated surface. It was suggested there that these structures might be caused by the coagulation of potassium metal. This experiment was started to observe colloidal particles in KCl crystal electronmicroscopically. When KCl single crystal was heated in the atmosphere of potassium vapour for 4 hours at 550°C, followed by the furnace cooling to room temperature in about 12 hours, the crystal was decorated with potassium particles along the dislocation lines. Fig. 1 is the *optical* microscopic photograph of such a crystal. Since the crystal in this case was *not* deformed mechanically beforehand, the decorated networks of dislocation are not so regular as those reported by many authors[2], but it is sure that the colloidal particles are imbedded in the crystal. When the fresh (001) cleavage plane of this crystal is observed electronmicroscopically using one stage replica technique, hemispherical pits surrounded by tiny droplets can be seen on the flat (001) plane as shown in Fig. 2. These pit structures have not been observed on the freshly cleaved (001) surface of the KCl single crystal either grown from the melt or coloured additively with excess metal. Moreover, the diameter of these pits have a mean value of 0.5 microns and, on the other hand, the colloid particles of Fig. 1 are estimated as larger than 0.4 microns in diameter. Judging from these facts, it will be reasonable to consider that these pits have a relation to the colloid particles, though Scott and his coworkers[3] had failed to observe colloid *centres* in the alkali halide crystal with an electron microscope.

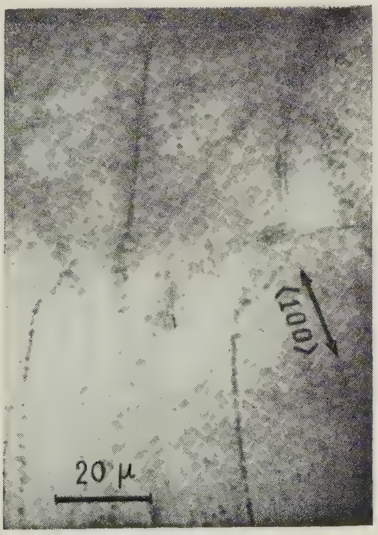

Fig. 1.

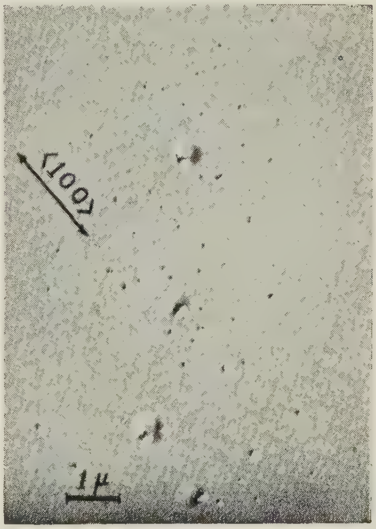

Fig. 2.

If the above explanation is valid, the pit will probably be produced by the scattering of the colloidal metal, under the actions of cleaving process, etc., arround the position at which it was located, thus leading to the formation of tiny droplets of colloid as satellites of the pit. Usually, etching techniques[4] provide the "etch" pits on the surface where dislocations exist, but the surface layer of several microns in thickness is removed from the crystal at the same time. This is one of the disadvantages in achieving the electronmicroscopic observation on the relation between the pattern of cleavage steps and dislocations. It has generally been accepted that the points where colloid particles exist have a close relationship to the crystal imperfections. Then the pit reported here may also offer one of the useful means for the electronmicroscopic studies of the crystal imperfections as the chemical or thermal etch pit did for optical microscopy. The experiments are now in progress with the deformed crystal which was decorated with excess metals.

Etch Patterns on Ferroelectric Triglycine Sulfate

By Hiroo TOYODA

Electrical Communication Laboratory,
Nippon Telegraph and Telephone
Public Corporation, Tokyo

(Received January 16, 1959)

Etch patterns are useful to investigate the domain structure of ferroelectric crystals and to study their polarization reversal, as has been demonstrated by the special etch pits exhibited by barium titanate etched in various acids[1)-4)]. Researches on the etch pits of GASH have been also reported[5),6)], though the correspondence to domain structure was not clear. The author has examined the effect of various etchants on triglycine sulfate and found out obvious correlation between the etch pits and the polarization of ferroelectric domains.

Etchants examined are methyl alcohol, ethyl alcohol, n-butyl alcohol, ethylene glycol, ethylene glycol mono-methyl ether, water, acetone, ether, carboxyl acids, and some alcohols containing potassium hydroxide, etc...

Mono-valent alcohols examined gave similar etch pits, though the etching rate decreased with the increase of molecular weight. Methanol gives clear patterns in a relatively short time. By applying an electric field to a thin crystal, cut perpendicularly to b-axis, it was confirmed that negative pole surface has a compapatively flat appearance, while positive end becomes very uneven. Fig. 1 shows a pattern on a crystal etched in methanol at 27°C for four hours, after removing the evaporated gold electrodes. Natural cleavage surfaces exhibit various etch patterns with either rectilinear or irregular boundaries. Most of the rectilinear patterns penetrate throughout the crystal parallelly to b-axis, while this is not the case for irregular ones. When re-etched in methanol after applying an electric field above Curie temperature, complete disappearance of all kinds of boundaries proves that the crystal has turned into a single domain.

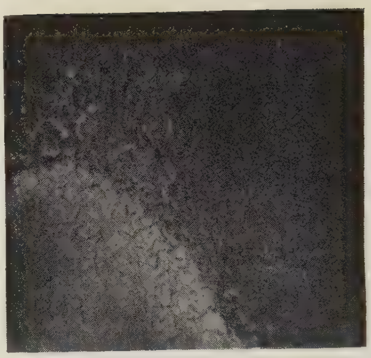

Fig. 1. Etch pits produced by methyl alcohol. (Darker area in the flat part is the silhouette of the electrode on the back surface). (×53).

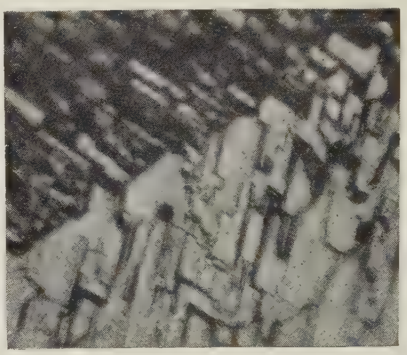

Fig. 2. Etch pattern produced by methyl cellosolve. (×180)

Alcohols containing KOH give sharp striped patterns. Ethylene glycol gives different rectilinear markings. Ethylene glycol mono-methyl ether, the so-called methyl cellosolve, etches the surfaces in a somewhat characteristic manner. Fig. 2 shows an example of a natural b-plane of the crystal immersed in this etchant for two weeks at room temperature. The figure again shows a twin boundary, which was ascertained to correspond to a domain boundary.

More comprehensive description will be published elsewhere.

The Proton Magnetic Resonance Absorption of the Trichloroacetic Acid in Solid Phase

By Masashi Yagi and Masayasu Ueta

Department of Physics, The Faculty of Science, University of Tohoku

(Received December 20, 1958)

Simple chain monocarbonic acids RCOOH has been confirmed by the several experimental results[1–4] and by the proton magnetic absorption[5] to take the coagulation state of dimers which are formed through the bridge with two hydrogen bonds in the liquid phase. But in the solid state, the crystal structures are not well known except for the formic acid which has been observed to have the chain structure[6].

One of the present authors[7] has studied the acetic acid CH_3COOH with the proton magnetic resonance method at the temperatures ranging from the room temperature to about −180°C. In this material, however, R contains three hydrogen atoms and the resonance due to these hydrogen atoms in the COOH radical, therefore, it was difficult to talk definitely about the situation of the hydrogen bonding between two radicals. This ambiguity is avoided by the investigation using the trichloro-acetic acid: CCl_3COOH. The melting point of this material is 57°C.

Samples of the commercial guaranteed reagent (purity of 99%) were redistilled and solidified in the thin glass tube. Experiments were carried out in the magnetic field of 2500 gauss with using the conventional regenerative oscillator method. The derivative curve of the resonance absorption obtained at the room temperature has a fine structure as shown in Fig. 1. The absorption curve obtained by integrating the derivative curve given in Fig. 2 indicates the symmetrical pattern consists of the main and side pairs of peaks which separated with 2.9 and 5 gauss respectively. The line shape is considered as the two proton system of the small interbroadening.

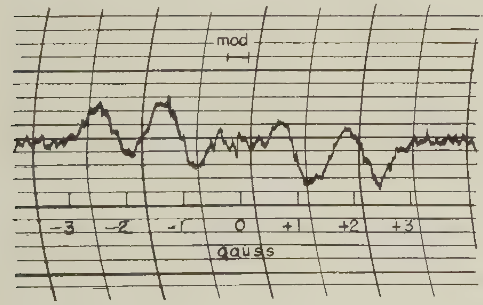

Fig. 1. The derivative of the proton magnetic resonance absorption of the trichloro-acetic acid at 16°C.

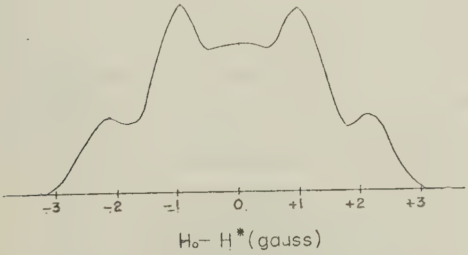

Fig. 2. The resonance absorption line obtained by integrating the derivative curve of Fig. 1.

The separation of the main peaks of the absorption line in two proton system is given as $\alpha=3\mu r^{-3}$ if the crystal lattice is assumed to be rigid and the interaction between two neighbouring two proton systems is neglected as small. When α is equated to the value of 2.9 gauss which was obtained from the derivative curve, the distance r between two protons in the solid of the trichloro-acetic acid is calculated to have the value of 2.4_7 Å. The second moment corrected against the field modulation was obtained from the derivative curve as 2.6_7 gauss^2. From this value of the second moment, the distance r of H–H was also calculated and was given the value of 2.4_5 Å, by neglecting the interaction with other neighbours. From these values the distance of two protons was determined as 2.46±0.03Å.

On the other hand, from the data in liquid and vapor phase of chain mono-carbonic acids and the formic acid, the value of the distance of H–H in dimers is estimated to have the value of 2.2∼2.5 Å. From these facts it is concluded that the trichloro-acetic acid takes the form of dimer in the solid state. Nearly the same rosonance absorption curves were kindly taken at the Laboratory of Professor Kakiuchi, The Institute for the Solid State Physics, Tokyo University.

The full report of this work will be published with the results of other chain mono-carbonic acids.

The present authors are deeply indebted to Profesor Y. Kakiuchi for his interest to this investigation.

On the Dielectric Loss of Oxidized High-Density Polyethylene

By Shigeharu OKAMOTO
Department of Applied Physics, Waseda University, Tokyo
and Keisaku TAKEUCHI
Kijima Communication Wire Co., Ltd., Tokyo

(Received January 21, 1959)

In recent papers by a number of authors, it has been reported that for branched low-density polyethylene three peaks are observed in the mechanical loss data measured as a function of temperature, while for unbranched high-density polyethylene only two loss peaks can be observed and the so-called β peak is missing.

In connection with the mechanical losses, it is of interest to observe dielectric losses as a function of temperature. But reports in this field are very few. In a recent note[1], Oakes and Robinson have reported that for one type of oxidized polyethylene (probably a low-density one) there exist three dielectric loss peaks. On the other hand, Nakajima and Saito[2] mentioned, that for oxidized high-density polyethylene two dielectric loss peaks (β and γ) could be observed, but not the so-called α peak in the temperature range below 105°C.

In view of these situations, careful observations were carried out on the temperature dependency of the dielectric loss using high-density polyethylene.

The high-density polyethylene used was Hi-zex 3500, supplied as pellets by Mitsui Chemical Industry Co., Ltd. The photo-oxidation of the polyethylene specimen has been carried out by exposure to the ultraviolet radiation from a mercury quartz lamp for 60 hrs. Dielectric measurements were made over a temperature range of −75 to +100°C and a frequency range of 30 to 10^6 c/s.

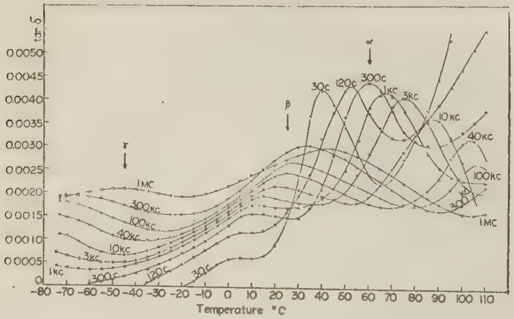

Fig. 1. The change of tan δ as a function of temperature at various frequencies for high-density polyethylene.

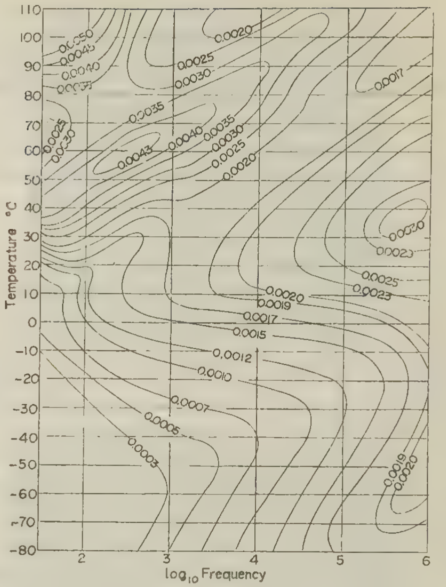

Fig. 2. Tan δ contour map for high-density polyethylene.

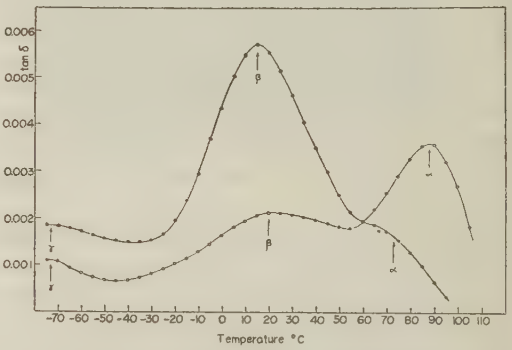

Fig. 3. Variation of tan δ of the high-density (○) and the low-density polyethylene (●) at 10 kc/s. Both samples were exposed to ultraviolet radiation for 60 hrs.

The results of dielectric loss tangent (tan δ) on the high-density polyethylene are shown in Fig. 1, 2 and 3.

As shown by Fig. 1, three loss peaks could be clearly observed also for the high-density polyethylene. Furthermore, as can be seen in Fig. 3, for the high-density polyethylene sample the α peak rises at a temperature higher by about 15°C than for the low-density sample. The shift of the α peak for high-density sample towards higher temperatures may be attributed to its high degree of crystallinity. The activation energies obtained from the results of our experiments were 25, 20 and 6 kcal/mol for the peaks α, β and γ respectively.

Nuclear Quadrupole Resonance Spectra of N^{14} in Urea Crystal

By Takehiko CHIBA, Masaharu TOYAMA
and Yonezo MORINO

*Department of Chemistry, Faculty of
Science, University of Tokyo*

(Received January 27, 1959)

There have been reported only a few papers1)–5) on the pure nuclear quadrupole resonance of N^{14}. We have observed N^{14} resonance in urea crystal. The apparatus used was a Pound-Knight-Watkins type spectrometer6) with Zeeman modulation of 230 cps. The signal was displayed on a recorder through a lock-in detector. Particular care was taken so as to apply a modulation field strong enough to cause a sufficient Zeeman shift of the resonance line even when the atom under study had a fairly large asymmetry parameter η. (The field strength of the Zeeman field in the usual run was about 60 Gauss.)

It has been established from the study of NMR7), x-ray8), neutron diffraction9), and infrared spectra10),11) that all the atoms in urea molecule are located in a plane. A transition was observed with proton resonance by Kromhout and Moulton12) in the range from about 0°C to 100°C. This transition was considered to be due to rapid reorientation of NH_2 groups around the C–N axes. If this is actually the case, it may be difficult to observe a nuclear quadrupole resonance at higher temperatures. Thus the measurement was first made at dry-ice temperature and a fairly strong absorption was found at 2.87 Mc. The asymmetrical shape of the line indicated the presence of large η. It is also examined by measuring the resonance at different field strength of modulation. At a certain weak field of modulation the absorption became very weak in urea, though still strong in hexamethylene tetramine which has $\eta=0$. The change of the shape with the change in the sweep velocity or in the sweep direction (from higher frequency to lower one or vice versa) showed an appreciable saturation effect similar to the case mentioned by Bray4). From the shape of the absorption and the change of signal strength with the modulation field it was concluded that the observed line was the higher frequency component of the doublet due to η. The other component is expected to lie somewhere around 2.6 Mc, but no attempt to find the line has been successful heretofore.

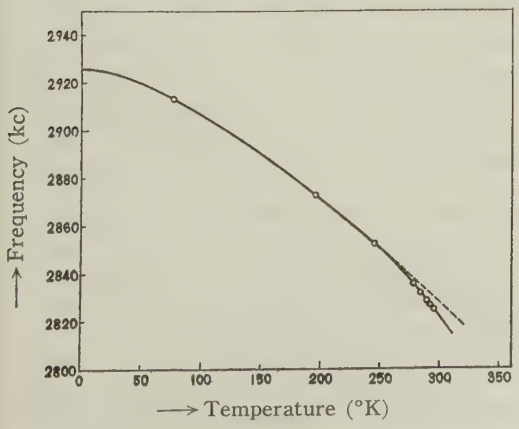

Fig. 1. Temperature dependence of N^{14}-resonance frequency in urea crystal.

The temperature dependence of the resonance line was also measured. The line became weaker with increasing temperature and was barely observable at 22°C. At this temperature the frequency of the line was definitely smaller than those at the lower temperatures, as shown in Fig. 1. The frequency change is normal at lower temperature range, the fractional change being much larger than those in the usual cases such as Cl resonance. This may be due to large amplitudes of oscillation of NH_2 groups about the C–N axes. Near 0°C the curve of the temperature dependence makes a distinct bend downward. This anomaly can be considered to be due to the setting-in of rapid reorientation of NH_2 groups, in good accord with the corresponding change in the line width of the proton resonance12).

Table I. N^{14}-resonance frequency in urea crystal.

Temperature (°K)	Frequency (kc)
177	2913.2
196	2872.8
245.5	2852.3
278.0	2835.7
284.0	2832.0
289	2828.7
292	2827
295	2825

Electrical Properties of Dilute Alloys of Zinc with Manganese at Low Temperatures

By Yoshio MUTO, Yoshio TAWARA, Yoshio SHIBUYA and Tadao FUKUROI

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received January 21, 1959)

It seems that anomalous electrical properties of dilute alloys at low temperatures are classified into two groups. The alloys of the first group such as Cu–Sn alloys have a minimum in the resistance-temperature curves in zero magnetic field and their magnetoresistance behaves similarly as the narmal alloys. The alloys of the second group such as Cu–Mn alloys have a maximum and subsequently a minimum in the resistance-temperature curves and show the decrease of the resistance in the magnetic field below the temperature corresponding to the resistance-maximum. Although no plausible explanation of the resistance-minimum has yet been given, K. Yoshida1) showed that in the case of Cu–Mn alloys the decrease of resistance below the temperature presumably corresponding to the resistance-maximum might be related to the *s–d* interaction between the conduction electrons and the *d*-electrons of Mn ions. The solvent metals of dilute alloys which exhibit the resistance-anomaly at low temperatures are confined as yet to the monovalent noble metals such as Au, Ag and Cu except for Mg, the only divalent metal in which the resistance-anomaly has been found so far. We believe that it is quite interesting to examine whether Zn is really the normal solvent metal without any resistance-anomaly as has been believed and whether dilute alloys of Zn containing a small amount of Mn does not show a spin dependent characteristic in their electrical properties.

Three specimens including pure Zn (99.96 percent) were used for the preliminary experiments. All specimens were melted under an atmosphere of argon in a high-frequency induction furnace in crucibles described below. The alloy containing 0.099 atomic percent Mn melted in an alumina crucible was contaminated with Fe included in the crucible, the quantity of Fe, however, being less than that of Mn. By using the crucibles made of S. B. glass in place of alumina, pure Zn and its alloy of 0.43 atomic percent Mn were melted. It was then confirmed that the amount of Fe contained in the above just mentioned specimens was sufficiently small.

The electrical resistance of pure Zn is constant below 5°K and the resistance increases with the intensity of magnetic field. For the alloy containing 0.099 atomic percent Mn, the resistance-minimum appears at about 14°K and its maximum does not appear down to 1.5°K as depicted in Fig. 1. The inset, however, shows more clearly that the rate of resistance-increase diminishes as the temperature becomes lower. Fig. 2 shows that, in the range of liquid hydrogen temperatures the resistance increases with the intensity of magnetic field in the same way as for pure Zn, while in the range of liquid helium temperatures the resistance decreases with the intensity of magnetic field and the rate of decrease is more enhanced with lowering temperature. For the alloy of 0.43 atmic percent Mn, a

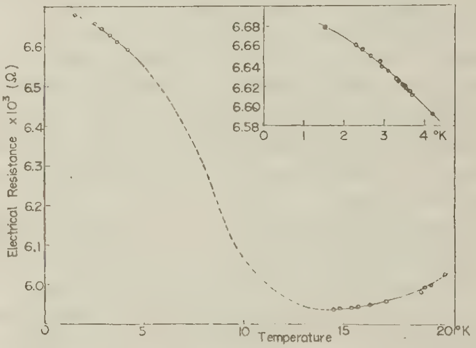

Fig. 1. Electrical resistance versus temperature of Zn alloy with 0.099 atomic percent Mn. The inset is the enlarged figure below 5°K.

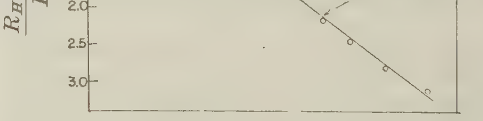

Fig. 2. $(R_H-R_0)/R_0$ versus magnetic field strength for Zn alloy with 0.099 atomic percent Mn at 20.4°K, 4.2°K and 1.54°K, respectively.

similar behaviour is also found.

Since the electrical properties of these alloys are quite similar to each other and the behaviour in magnetic field resembles to those of Cu-Mn alloys[2),3)], we are led to presume that these phenomena are closely related to the magnetic states of Mn ions. More detailed reports including electrical properties of Zn-Sn alloys will shortly be published elsewhere.

The authors wish to express their sincere thanks to Assist. Prof. S. Tanuma for his helpful suggestions and discussions. The present work was supported partly by the Grant in Aid for Fundamental Scientific Research from the Ministry of Education.

On the Growth Conditions of Germanium

By Takeo SASAKI

Research Laboratory, Nippon Electric Co., Ltd.
Kawasaki, Japan

(Received December 17, 1958)

The effect of the growth conditions of pulled, single crystal germanium on the structural and physical properties has been investigated.

The n-type germanium single crystals containing a very small amount of arsenic, are pulled in the (111) direction, and four kinds of crystals with different growth conditions shown in Table I are chosen. These conditions comply with the suggestion by F. D. Rosi and E. Billing[1)] giving the thermal stress for the pulled crystal.

The CP-4 etch pit density in the cross section perpendicular to the growth direction is found to depend on the growth condition which is represented by the growth rate for convenience, as shown in Fig. 1. But it is not apparent which factor is the most effective.

Next, it is easy to find the spiral pits among the many concentric pits by the Rhodes' etching technique[2)] as shown in Fig. 2. These spiral pits, however, are not caused from the thermal stress as shown in Fig. 1. The terrace width of the spiral

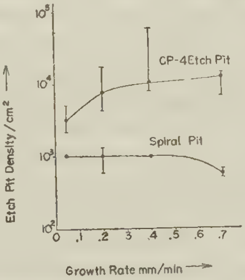

Fig. 1. The dependency of CP-4 etch pit and spiral pit density on the growth rate.

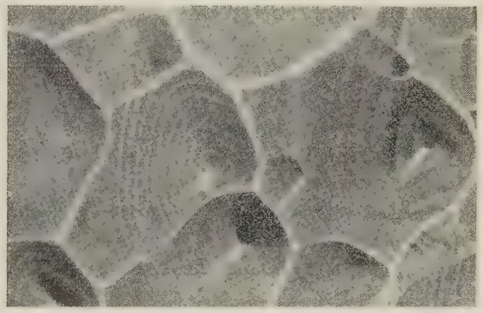

Fig. 2. The spiral etch pits in (111) surface (×960).

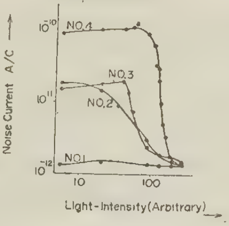

Fig. 3. The relationship between noise and light-intensity.

Table I

	sample No.	1	2	3	4
	growth rate	50	200	400	700μ/min
growth condition	temperature gradient in the liquid-solid interface*	35	35	130	130°C/cm
	temperature variation during the crystal growth**	0.5	1.0	3.0	5.0°C/min

* The temperature gradient was varied by using the crucibles which had different wall heights.

** The temperature variation was represented by the rate of the temperature decrease for maintaining the constant diameter of the pulled crystal in the initial stage of the growth.

pit is relatively large, being of the order of 0.8 μ, and has no dependency on the growth condition. The terrace width of the concentric pit, on the other hand, depends on the growth rate and from this fact the platelet growth is considered to occur in germanium[3].

To measure the noise characteristics germanium bars, each measuring $0.3\times0.3\times3$ mm are cut from these samples, and after the surfaces have been carefully treated each of them is hermetically sealed in a case having a glass window. The amount of noise has turned out to be inversely proportional to frequency within the range of from 100 c/s to 10 kc/s and it increases with increasing growth rate or dislocation density[4]. The variation of the noise when the samples are illuminated is shown in Fig. 3. The value of the noise remains constant when the light intensity is low, but it decreases suddenly when the intensity exceeds a certain value. This critical point is closely related to the growth condition. The number of photo-excited carriers at these points are calculated to be of the order of 10^{14} or 10^{15}/cm^3, which is comparable to the number of the original conduction electrons. Thus the existence of the qualitative relationship between the dislocation density and the noise has been verified. But the reason why the noise decreases abruptly is not yet explained and further experiments are now being made to clarify this phenomenon.

Finally the author would like to express his appreciation to Dr. Y. Ishikawa for his encouragement during the course of these experiments.

Non-Existence of Bound States with Positive Energy

By Tosio KATO

Department of Physics,
University of Tokyo

(Received February 3, 1959)

Consider the wave-mechanical system described by the schrödinger equation

$$\Delta\varphi+[\lambda-V(x,y,z)]\varphi=0\,. \qquad (1)$$

It has been believed that such a system has *no bound state with positive energy* if the potential V tends to zero at infinity with a certain order of rapidity. Mathematically speaking, this amounts to saying that (1) has no positive eigenvalue λ with a square-integrable eigenfunction φ.

Strangely enough, however, it seems that this fact has never been proved, except in the special case in which V is spherically symmetric and therefore permits the separation of variables. It is true that some sufficient conditions[1] have been proposed for the non-existence of positive eigenvalues in the general case, but these conditions are rather strong and restrict the behavior of V in the *whole space*. To the best of the author's knowledge, no sufficient condition has been given which restricts only the *asymptotic behavior* of V at infinity. It is to be remarked that the underlying mathematical problem is far from trivial once V is allowed to deviate from spherical symmetry even slightly.

Recently we have been able to prove the following theorem, which gives a satisfactory answer to the above question.

Theorem. *If* $V(x,y,z)$ *is continuous for* $r>0$ *and* $V=o(r^{-1})$ *for* $r\to\infty$, *then* (1) *has no positive eigenvalue with a square-integrable eigenfunction* $\varphi\not\equiv0$.

The assumption that $V=o(r^{-1})$ does not admit of any essential improvement. As is well known[2], there is an example of a potential V with the asymptotic form

$$V=-\frac{4k\sin 2kr}{r}+O\left(\frac{1}{r^2}\right), \qquad r\to\infty\,, \qquad (2)$$

for which there is a positive eigenvalue $\lambda=k^2$ with a square-integrable eigenfunction φ.

The above theorem can be extended to the differential equation of the form (1) in the n-dimensional space. The proof will be published elsewhere[3].

The Crystal Structure of $CoCl_2 \cdot 6H_2O$

By Jōji MIZUNO, Kazutoshi UKEI
and Tadashi SUGAWARA

*The Research Institute for Iron, Steel and
Other Metals, Tohoku University,
Sendai, Japan*

(Received January 28, 1959)

It was reported by Haseda and Kanda1) that the susceptibilities of powered samples of $CoCl_2 \cdot 6H_2O$ show an antiferromagnetic behavior below about 3°K. The magnetic measurement on a single crystal of this salt is in progress, and it has been found up to now that the antiferromagnetic order of spins occurs along c axis of the monoclinic lattice2). The complete structure determination of the salt has not yet been done, while it is indispensable to the elucidation of the magnetic behavior. The present work was thus undertaken.

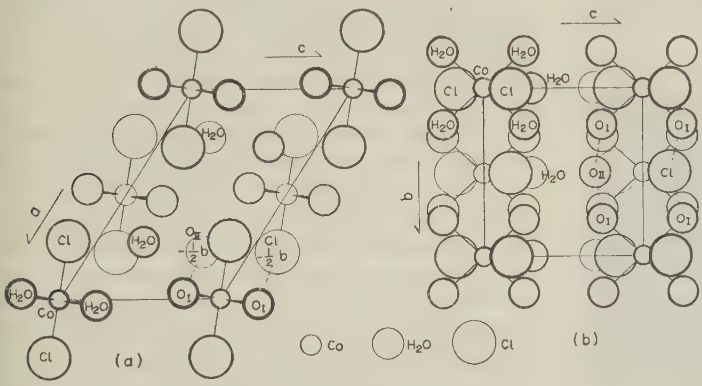

Fig. 1. The arrangement of atoms projected (*a*) on (010) and (*b*) on (100). Broken lines represent the hydrogen bond.

The single crystal used was the same (monoclinic prismatic) in its habit as Groth described3). X-ray rotation and oscillation photographs were taken about a and b axes, using Mn-filtered FeK_α and Zr-filtered MoK_α. Unit cell dimensions were given as $a=10.34$ Å, $b=7.06$ Å, $c=6.67$ Å. For the angle β and the density values found in literatures, 122°19′ and 1.924 gr/cm³, were used. These data gave two formula units per unit cell. Space group was determined as C_{2h}^3-C2/m. Atomic positions were obtained from (*hol*) Patterson map and from (*hol*) and (*okl*) Fourier maps, as given in Table I.

Table I. Atomic positions in $CoCl_2 \cdot 6H_2O$.

Kind of atom	Position	x	y	z
Co	origin	0	0	0
Cl	4(*i*)	0.278	0	0.175
O_I	8(*j*)	0.0288	±0.221	0.255
O_{II}	4(*i*)	0.275	0	0.700

The arrangement of atoms projected on (010) and (100) is shown in Fig. 1 (a) and (b), respectively. As seen from Fig. 1, two Cl^- ions and four water molecules are octahedrally coordinated to Co^{2+} ion to form the group $[CoCl_2 \cdot 4H_2O]$, and the other two water molecules of the formula unit are relatively free. The groups seem to be joined with one another by hydrogen bonds, O_I---H—O_{II}—H---O_I and O_I—H---Cl, in the plane parallel to (001). This structure leads to the perfect cleavage parallel to (001) by Groth3).

In a powdered sample of $NiCl_2 \cdot 6H_2O$ isomorphous to $CoCl_2 \cdot 6H_2O$ an anomalous magnetic behavior has been observed below 6~8°K4). According to a preliminary study on the structure analysis of this salt by one of the authors5) the arrangement of atoms seems to be similar to that in $CoCl_2 \cdot 6H_2O$. Full reports on the crystal structure of these two salts will be published later.

The authors wish to express their sincere thanks to Prof. E. Kanda and Prof. S. Ogawa for their continued encouragements throughout this work.

Change of Surface Recombination Velocity of Germanium by γ ray Irradiation, Using P-N-P Alloy Transistor

By Kiich KOMATSUBARA

Semiconductor dep. Kobe Kogyo Cop. Kobe

(Received September 6, 1958)

In this note, the change of surface recombination velocity, S, as a function of γ ray dosage is discussed. Values of S are derived from the change of α_{eb} vs. emitter current, Ie, curves of transistor.

The equation for α_{eb} as a function of Ie for p-n-p alloy junction transistor has been presented by Webster1) as follows,

$$\frac{1}{\alpha_{eb}} \approx \frac{SWA_s}{D_p A_e}\left(\frac{1+z}{1+2z}\right)+\left[\frac{\sigma_b W}{\sigma_e L_e}+\frac{W}{D_p \tau}\right](1+z)\,, \tag{1}$$

where

$$z=\frac{W\mu_e I_e}{D_p A_e \sigma_b}\,, \tag{2}$$

σ_b is conductivity, τ is the hole life time in base Germanium, D_p, μ_e, σ_e, and L_e are well known constants, W and A_e are constructional constants, and A_s is effective area for surface recombination.

This equation reduces to the asymptotic expression for large value of Z as

$$\left.\frac{1}{\alpha_{eb}}\right)_{z\to\text{large}}=\frac{SWA_s}{2D_p A_e}+\left[\frac{\sigma_b W}{\sigma_e L_e}+\frac{W}{D_p \tau}\right](1+z)\,, \tag{3}$$

and the difference between the original equation and this asymptote is

$$\left.\frac{1}{\alpha_{eb}}\right)_{\text{diff}} \approx \frac{SWA_s}{2D_p A_e}\left(\frac{1}{1+2z}\right)\equiv f(s)\,. \tag{4}$$

If the value of Ie is extrapolated to the zero value, then this equation becomes

$$f(s)\approx\frac{SWA_s}{2D_p A_e}\,.$$

This difference is the function of S only, if it is assumed that, for small carrier injection, A_s is constant independent of γ irradiation.

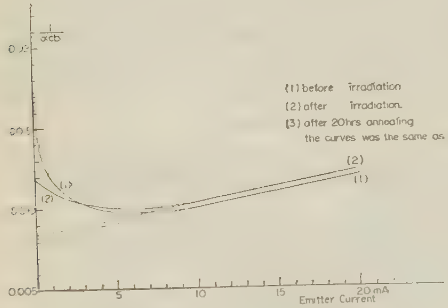

Fig. 1. The changes of $\alpha_{eb}-I_e$ curves by 2.9×10^7 röntgen γ ray dose.

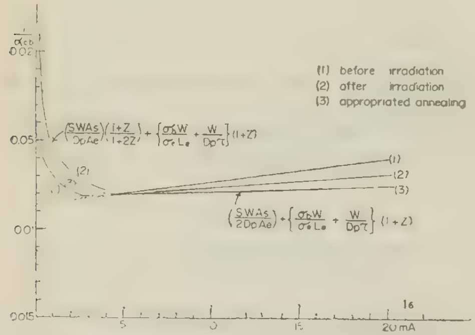

Fig. 2. The changes of $\alpha_{eb}-I_e$ curves by 5×10^7 röntgen γ ray dose.

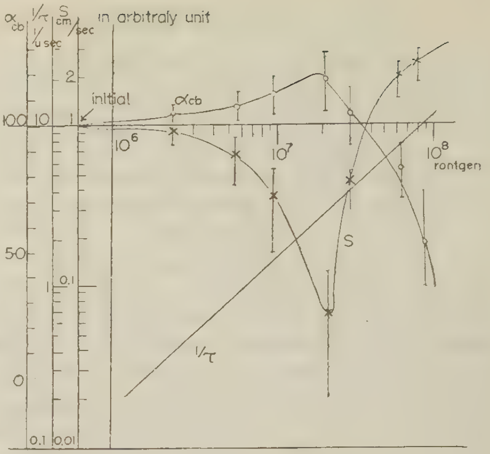

Fig. 3. The changes of S α_{cb} and $1/\tau$ by γ ray dose in p–n–p G_e alloy transistor.

The curves of α_{eb} as a function of Ie are shown in Figs. 1 and 2 as examples. Fig. 1 shows the case of 2.25 röntgen dose, and Fig. 2 shows 5.7 röntgen dose. In Fig. 3 the change of S and of α_{eb} and hole life time as a function of dose are shown. At this measurement, seven groups of several transistors each were used, and each groups were exposed to γ ray field of afout 3×10^5 röntgen per hour for different time intervals. So it was not the measurement of successive changes of same transistor, and the measurements had some troubles because of very prompt annealing effect, especially in the case of small dosages of γ ray where the changes of S were small and negative, the annealing speed of S was very large. For examples, at 2.2×10^7 röntgen dose, the value of S recovered perfectly after twenty hours from removing the γ field at about 30°C atmospheric temperature. And in the case on heavy dosage of γ rays, where the change in values of S was positive, the annealing speed was relatively small. The reason for the changes of the value of S by γ ray dosages is not yet clarified at the present stage of research. But the decrease of the conductivity in the interior of germanium should have caused the decrease of S2). The changes of S may be explained if we assume that the surface conductivity becomes gradually low and changes to P type (P type channel on N type germanium) and increases again successively by the dosage of γ rays.

This analogy to the view point of chemical impurity may have to be regarded as rough approximation, however, as the surface state density would become large by γ irradiation and deep lying vacancy level may act as recombination centers.

Preparation of Anodic Oscillator Tube using Glow Discharge

By Kazuyuki OGAWA

Matsuda Research Laboratory, Tokyo Shibaura Electric Co., Kawasaki

(Received January 8, 1959)

Generally, oscillatory phenomena in gas discharge have very complex features on the variation of its frequency, wave form, coherency, amplitude etc. Hence, there are poor reproducibilities among each experiments. Author reports some notes on the preparation of fairly stable anodic oscillator tube, with which the quantitative treatment of its characteristics is acceptable. This tube may be called "oscillatron" for convenience.

Fig. 1 illustrates the typical structure of oscillatron. A is a needle anode (about 1 mm diameter), *K* is a circular disc cathode (about 20 mm diameter) and *A*–*K* spacing is a little thicker than the Faraday dark space which is determined by the nature and pressure of gas. Both electrodes are made of pure molybdenum and are simply pinched upon the nickel poles of the glass seal. The glass envelope should be made sufficiently large so that the wall effect is negligibly small.

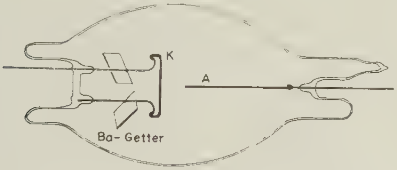

Fig. 1. Construction of oscillatron.

The evacuation and the filling processes of gas must be carried out very carefully, for the anodic oscillation is greatly affected by gaseous impurity, especially by molecular gases such as air, H_2, H_2O vapour. For example, in our laboratory, the procedures of the preparation are as follows. The electrodes were electrolytically polished, and after mounting the whole assemblage was washed up ethyl alcohol and boiling distilled water alternately. The glass tube was also cleaned beforehand and the glass work was done in an atmosphere of dry nitrogen gas in order to prevent oxidation of the metal parts. After baking out the tube at high temperature and after heating the electrodes with high frequency current, the pressure of residual gas reached to 4.5×10^{-8} mmHg. When all usual processes of evacuation were finished, the internal pressure of the tube was kept as low as 2.5×10^{-7} mmHg for 30 minutes even after the pumping was cut off. Then, the pure Ne or Ar gas, which was spectroscopically inspected, was introduced and the tube was operated by d. c. current under abnormal glow untill the glass wall was covered

Fig. 2.

(a) Oscillatron for spectroscopic analysis of anodic phenomena.

(b) Wave form of the voltage oscillation at 20 mA (Ne 50 mmHg, A–K spacing 10 mm).

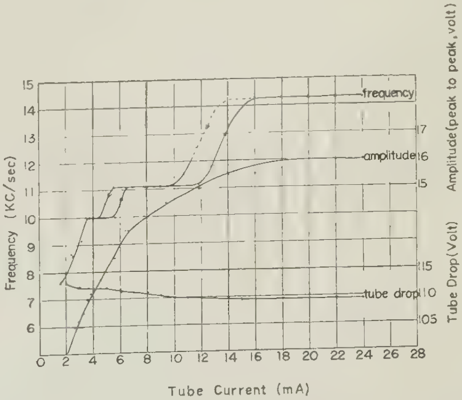

Fig. 3. Variation of the frequency, amplitude, tube drop *vs* the tube current of oscillatron (Ne 50 mmHg, A–K spacing 10 mm).

with a sufficiently thick layer of sputtered molybdenum, the polarity of d.c. source was reversed now and then in order that the both electrodes equally sputtered. The essential part of this process had been proposed by T. Jurriaanse et al.[1] with regard to production of reproducible and stable cathode drop. When it is necessary to use the tube of knotty shape or the very large one for requirement of individual experiment, conventional barium getter must be also used to absorb the gas resulting from naked parts of the glass wall. Lastly, the gas was renewed and the tube was sealed off.

Fig. 2 (a) shows a type of oscillatron which was used for spectroscopic analysis of the anodic phenomena, and (b) shows the oscillogram of its voltage oscillation between the electrodes. Fig. 3 shows the variation of frequency, average tube drop, and amplitude of the oscillation over whole range of the tube current. The oscillation includes the anodic mode only, and above 16 mA the oscillation is very stable and reproducible within a fluctuation by a few per cent. The tendency of these characteristics is almost the same for any type of oscillatron as long as the tube is prepared with great care.

Studies on the anodic oscillation using oscillatron will be reported on other papers.

Terminal Zone Cropping and Ultimate Zone Purification

By Louis GOLD

Edgerton, Germeshausen and Grier, Inc.
160 Brookline Avenue, Boston
15, Massachusetts

(Received January 8, 1959)

An aspect of zone melting which apparently has not been reported on as yet[1] concerns the explicit degree of purification achieved after any number of passes. A rather fundamental parameter, termed the purification factor, was introduced several years ago to identify the potential state of purity achieved in an ingot at any stage of the zone refinement process[2].

To apply this concept in paractice, the technique of terminal zone cropping may be employed; the initial zone serves as a sink for impurities having a distribution coefficient $k>1$, whereas the final zone accretes impurities having $k<1$. Such a procedure was found helpful in the preparation of single crystals of beryllium[3].

It is well known that as the number of passes $n\rightarrow\infty$, an equilibrium distribution of impurity in the ingot is approached. Further purification may be accomplished by removal of the terminal zone. If the back reflection of impurity from the terminal zone into the bulk of the ingot is ignored, a rather straightforward analysis of the purification becomes possible. This simplification allows ready calculation of the upper bound on the degree purification-- the actual state of purity that can be attained cannot exceed the values computed by the reduced formalism. For certain situations approximating the semi-infinite ingot, the idealized purification factor to be offered here may suffice.

Thus the cumulative total fraction of impurity potentially removable in the terminal zone can be expressed as follows:

$$P_T=1-\frac{1}{c_0L}\int_0^{L-l}c_n(x)dx \qquad (1)$$

where c_0 is the initial impurity concentration, L is the ingot length and l the zone width. $C_n(x)$ is the positional impurity concentration after the nth pass for which a number of formulae has been worked out[4)-6)]; these are of varying degrees of complexity. Still another manner of describing $c_n(x)$ has been formulated which appears particularly suited for explicit numerical computation[2]. Thus in the relation

$$c_n(x)/c_0=1-Q_n(1-k)e^{-(k/l)x} \qquad (2)$$

the quantity Q_n involves the summation

$$Q_n=\sum_{p=n}^{1}A_p\frac{((k/l)x)^{n-p}}{(n-p)\,!} \qquad (3)$$

where the A_p obtain from a certain, iterative generating function.

Purification factor data of likely practical value are to be made available at a later time when a full account of the findings will be offered.

Measurement of Bremsstrahlung Spectra with Sodium Iodide Scintillation Crystal

By Motoharu KIMURA, Naosi MUTSURO, Yuji OHNUKI, Katsufusa SHODA,
Masumi SUGAWARA, Tsutomu TOHEI and Haruo YUTA

Department of Physics, Faculty of Science,
Tohoku University

(Received August 21, 1958)

The bremsstrahlung spectra of the 8.5 MeV electrons for the forward direction were measured with a scintillation spectrometer of a sodium iodide crystal 4 in. in diameter and 4 in. in length. Be, Ni and Pt of several thickness were used as the targets. The measured spectra were compared with our semi-empirical calculation. The calculation was based upon the response function for NaI crystal which was constructed referring to the method developed by NBS group and also to the actual response curve for the monochromatic gammas of 1.12 and 6.14 MeV, instead of using Monte Carlo method which had generally been used in the former researches. The agreement is rather good if we assume Schiff's formula for the intrinsic bremsstrahlung spectra.

§ 1. Introduction

It is of importance to measure the bremsstrahlung spectrum as accurate as possible because of its extensive use in the investigation of photonuclear reactions and of the experimental check of the theory of bremsstrahlung. Many experiments have been made using a pair spectrometer and other detectors.(1)–(4) Recently, Starfelt and Koch(5) measured the bremsstrahlung spectra for the electron energies of 2.72, 4.54 and 9.66 MeV using the scintillation spectrometer of a sodium iodide crystal 5 in. in diameter and 9 in. in length. These results show that the spectral shapes obtained with the beryllium and aluminun targets agree with theories of Schiff, Sauter, and Gluckstern and Hull, for the electron energies of 2.72 and 4.54 MeV. However, the 9.66 MeV-experiment gives 20% higher value as compared with the theory at the low energy regions of photon. For gold target, the experimental cross sections at the higher photon energies were larger than the theory, the discrepancies increasing with decreasing primary electron energy.

In the present experiment, the forward bremsstrahlung spectra produced by 8.5 MeV electrons were measured by scintillation spectrometer using a sodium iodide crystal of 4 in. in diameter and 4 in. in length. Targets of beryllium ($Z=4$), nickel ($Z=28$) and platinum ($Z=78$) were used. The results show that the measurements for Z-dependence agree with the theory(6) if we neglect the effect of the target thickness. In order to obtain the target-thickness dependence of bremsstrahlung spectra, three platinum targets of 0.2, 0.08 and 0.025 mm thickness were used. These results were compared with the theory taking into account the multiple scattering of electron in the target. Complete agreement was not obtained. The discrepancy is believed to be the edge effect of the target, that is, the target in the donut presented an effective thickness less than the geometrical one because an important fraction of the radiation would originate at the target edge during the shrinkage of the betatron orbit.

For the comparison of the theory with the present experiments, the bremsstrahlung theory of Schiff(6) was used. Assuming an exponential screening law of atomic potential $Ze/r\cdot\exp(-r/a)$, Shiff integrated the Bethe-Heitler differential cross section(7) over all the outgoing electron angles and obtained the analytical expression of the intrinsic differential cross section $d^2\sigma/d\Omega\, dE$. Because of the Born approximation, his expression is restricted to energies that are large compared with m_0c^2. Taking into account the multiple scattering of electrons in the target, Hisdal(8) calculated the corrected bremsstrahlung spectra in the forward direction using Schiff's(6) and Morliere's(9) theory. His calculation was used for the comparison with our measurement of 0.2, 0.08 and 0.025 mm Pt target.

§ 2. Experimental Procedures and Results

8.5 MeV electrons were produced by the betatron acceleration of 40 MeV Synchrotron of Tohoku University. The shrinking electrons by the saturation of flux bars bombarded the target in the donut, and produced the continuous X-ray which passed through two collimators and led to the head of a scintillation spectrometer which was situated 4 meters from the target. The experimental arrangement is shown in Fig. 1.

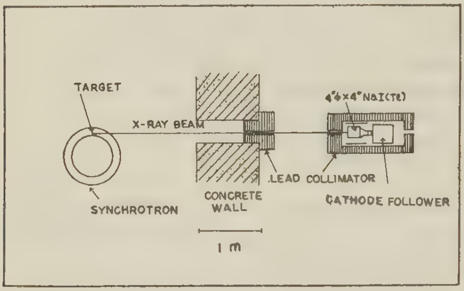

Fig. 1. Experimental arrangement for the measurement of bremsstrahlung spectra.

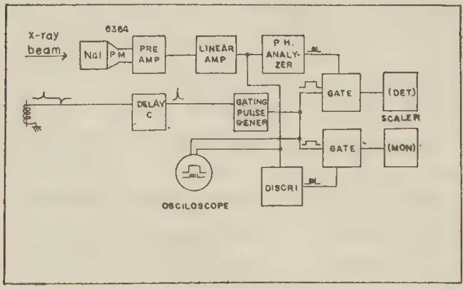

Fig. 2. Block diagram.

The block diagram of the scintillation spectrometer is given in Fig. 2. The photomultiplier DuMont 6364 and the sodium iodide crystal of 4 in. in diameter and 4 in. in length which was polished and mounted in our laboratory were used. In order to avoid the high back ground counting rate, the gate circuits were used which were open during the burst of X-ray beam. Using these gate circuits, the background countings were suppressed to about 1/30 of those when the gating was not applied. The background counts were measured under the same condition with that when the bremsstrahlung spectra was measured but with shielding the X-ray beam by a lead brick in front of the last collimator. The measured background counting rate is shown in Fig. 3. Fortunately, the background counting rate was independent of the beam intensity and was equal to the natural background, thus

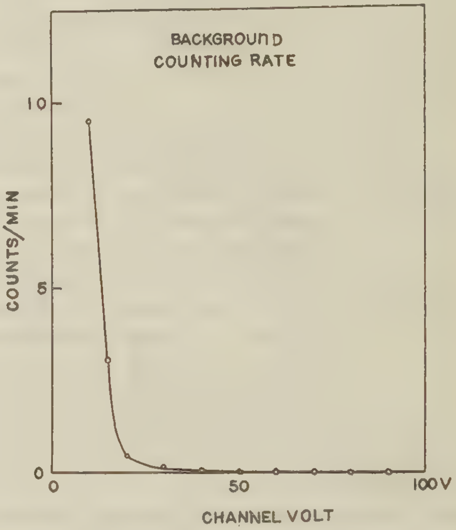

Fig. 3. Measured back-ground counting rate.

the measured spectra of the bremsstrahlung, $S(E_0, E)$ is represented by the normalized ratio, Γ as follows;

$$S(E_0, E)=\text{const}\cdot\Gamma\,, \tag{2.1}$$

where E and E_0 are the photon and the total electron energy respectively and Γ is given by

$$\Gamma=\frac{N_D-n_D t}{N_M-n_M t}\,, \tag{2.2}$$

where N_D and N_M are the measured counts of the detector and the monitor respectively and n_D and n_M their background counting rates and t the time requied for the measurement of N_D and N_M.

In order to measure the counts of the monitor, N_M, "Self monitoring" method was applied for almost all of the measurement. Using the same detector crystal for the measurement of N_D, the integral counts of pulses higher than a certain level were used as the normalization of the channel counts. As shown in Fig. 2, the monitor counts were led from the A–1 amplifier through a discriminator.

Because of the short duration of the beam, the pile up effect of the detector was expected to be important, making the normalized ratio dependent on the beam intensity. In order to avoid this effect, moderately low intensity of the beam was used for the measurements. The energy of bremsstrahlung photons was frequently checked by comparison with the 1.12 MeV gamma-ray line from Zn^{65}. The pulse height of Zn^{65} line was always measured before and after each run. The linearlity of the amplifier was checked by several gamma-ray sources of different energies. The drift of the spectrometer was within 1∼0.5% during the course of several hours' run.

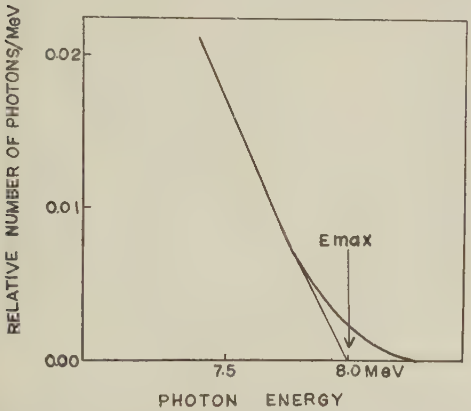

Fig. 4 (a). Calculated shape near the high energy end of the bremsstrahlung spectrum. The cross point of the tangent along the linear part of the curve with the energy axis indicates the maximum energy of photons, Emax.

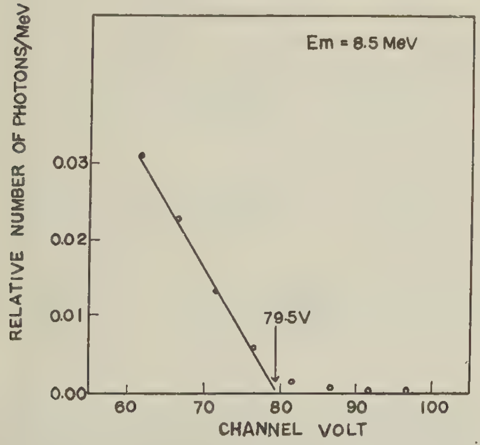

Fig. 4 (b). Measured shape near the high energy end of the bremsstrahlung spectrum.

The maximum energy of photons was determined as shown in Fig. 4. If the cross section of the bremsstrahlung are approximately given near the high energy end of the spectrum by

$$\begin{aligned} \frac{d^2\sigma}{d\Omega\, dE} &= a(E_m - E) \qquad && E_m \geq E \\ &= 0 && E_m < E\,, \end{aligned} \tag{2.3}$$

where E_m is the maximum energy of photons and a is a constant to be determined experimentally, then the curve corresponding to the measured spectrum near the high energy end of the spectrum will easily be calculated with the following assumption. We assumed that the energy spread of electrons has 4% half width with Gaussian distribution and the response function of the gamma ray as shown in section 3. The resulting curve is shown in Fig. 4 (a). Drawing a tangent along the linear part of the curve, the cross point with the photon-energy axis will indicate the maximum energy of bremsstrahlung photons, E_m. An actual example is shown in Fig. 4 (b).

Beryllium, nickel and platinum were used as the targets. The thickness was determined by micrometer as shown in Table I.

Table I.

Target material	Z	Thickness in mm	Thickness in radiation length
Be	4	0.5	0.0012
Ni	28	0.2	0.0136
Pt	78	0.2	0.0695
Pt	78	0.08	0.0278
Pt	78	0.025	0.0087

The measured bremsstrahlung spectra for various targets are shown in Figs. 5, 6, 7, 8, 9 and 10, comparing with the theory. These will be discussed in more detail in section 4.

§ 3. Calculation of Bremsstrahlung Spectra from the Response Function

1) *Differential cross section of the bremsstrahlung,* $d^2\sigma/d\Omega\, dE$

The differential cross section of the bremsstrahlung was calculated by Schiff[6] from integrated Bethe-Heitler[7] differential cross section, considering the screening effect. From his expression, differential cross section $d^2\sigma/d\Omega\, dE$ for the forward direction is given as follows;

$$\frac{d^2\sigma}{d\Omega\, dE} = \frac{4Z^2}{137} \cdot \left(\frac{e}{m_0c^2}\right)^2 \left(\frac{E_0}{m_0c^2}\right)^2 \cdot \frac{dE}{2\pi E} \cdot \left\{ -\frac{(2E_0-E)^2}{E_0^2} + \frac{E_0^2+(E_0-E)^2}{E_0^2} \ln M(0) \right\}$$

$$(E \leq E_0 - m_0c^2)\,. \tag{3.1}$$

where E_0 in the total energy of electrons and E is the photon energy, and $M(0)$ and the constant C are given by

$$\left.\begin{aligned}\frac{1}{M(0)}&=\left(\frac{m_0c^2E}{2E_0(E_0-E)}\right)^2+\frac{Z^{2/3}}{C^2}\,,\\ C&=111\,.\end{aligned}\right\}\tag{3.2}$$

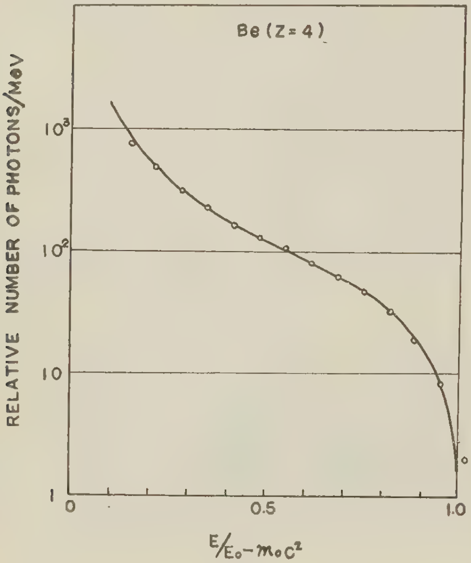

Fig. 5. Measured spectrum for Be(Z=4) of 0.5 mm thickness (open circle) and calculated curve from Schiff's formula. (solid line)
Emax=8.1 MeV

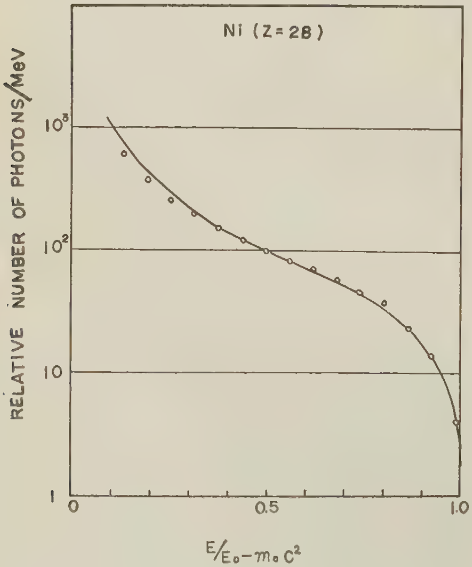

Fig. 6. Measured spectrum for Ni(Z=28) of 0.2 mm thickness (open circle) and calculated curve from Schiff's formula. (solid line)
Emax=8.6 MeV

For the convenience of remaining calculations, a following notation is used,

$$n(E_0,E)=\frac{1}{E}\left\{-\frac{(2E_0-E)^2}{E_0^2}+\frac{E_0^2+(E_0-E)^2}{E_0^2}\ln M(0)\right\}\,.\tag{3.3}$$

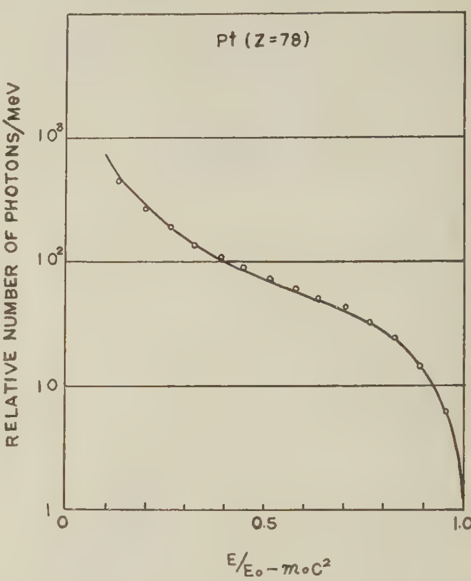

Fig. 7. Measured spectrum for Pt(Z=78) of 0.2 mm thickness (open circle) and calculated curve from Schiff's formula. (solid line)
Emax=8.5 MeV

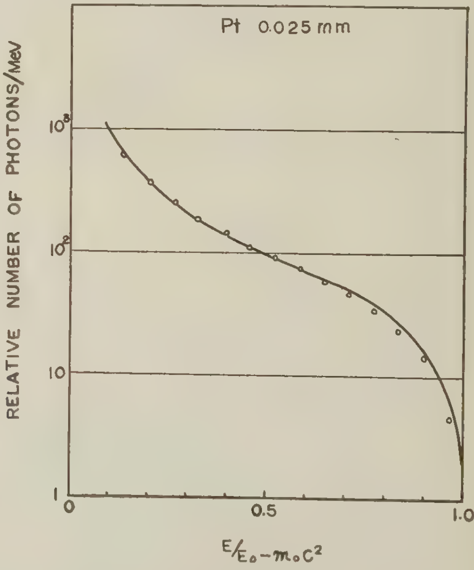

Fig. 8. Measured spectrum for Pt of 0.025 mm thickness (open circle) and calculated curve correcting the target thickness. (solid line)
Emax=8.5 MeV

Since this expression is valid in an infinitely thin target, corrections must be applied for the case of finite thickness. For a target of less than 0.1 radiation length, the effect of energy loss and absorption in the target and the double radiation process should be negligible10). Another correction comes from the multiple elastic scattering which the electrons undergo in the target before radiating. Hisdal8) evaluated the bremsstrahlung spectra in the forward direction corrected for the multiple scattering in the target of platinum. He tabulated the factors by which the intrinsic differential spectrum must be multiplied in order to obtain the relative corrected spectrum in Pt. For our calculation of the spectra of Pt target, extra and interpolated values from his table were used.

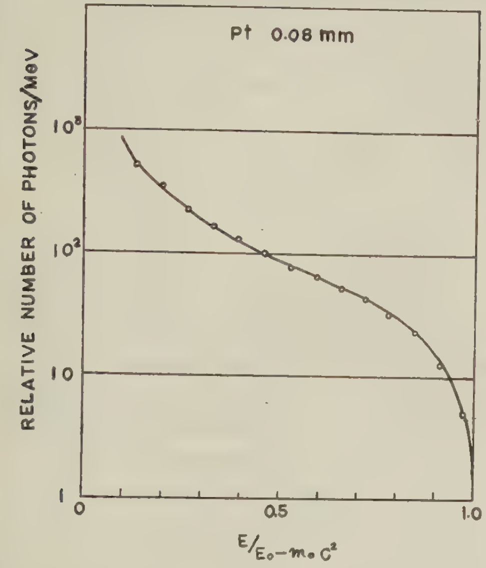

Fig. 9. Measured spectrum for Pt of 0.08 mm thickness (open circle) and calculated curve correcting the target thickness. (solid line) Emax=8.4 MeV

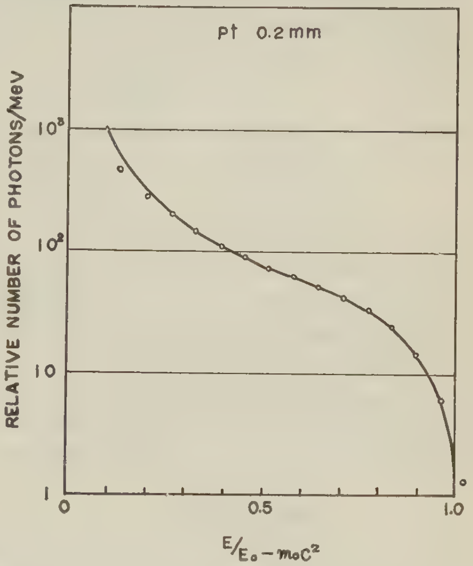

Fig. 10. Measured spectrum for Pt of 0.2 mm thickness (open circle) and calculated curve correcting the target thickness. (solid line) Emax=8.5 MeV

---

2) *Response function of sodium-iodide scintillator*

Response function $R(E, E'')$ is expressed by Berger and Doggett11) as follows;

$$R(E, E'')=Y(E)\left\{\int_0^E \frac{K(E, E')}{\sqrt{2\pi\alpha E'}} \exp\left[-\frac{(E''-E')^2}{2\alpha E'}\right] dE' + \frac{p(E)}{\sqrt{2\pi\alpha E}} \exp\left[-\frac{(E''-E)^2}{2\alpha E}\right]\right\}, \tag{3.4}$$

where E is the energy of impinging photon and E'' is the output pulse height expressed in energy scale. $Y(E)$ is the efficiency of the crystal for the photon of energy E, and 1st and 2nd term in the large blacked represent the compton tail and photo peak. The exponential factor means the Gaussian distribution of the secondary electron energy. Since the integration of $R(E, E'')$ over E'' is the efficiency of the crystal,

$$\begin{aligned}\int_0^\infty R(E, E'')\, dE'' &= Y(E)\left[\int_0^E K(E, E')\, dE + p(E)\right] \\ &= Y(E)\,,\end{aligned} \tag{3.5}$$

following normalization will be obtained;

$$\int_0^E K(E, E')\, dE' + p(E) = 1\,. \tag{3.6}$$

This means that $\int_0^E K(E, E')\,dE'$ is the fraction of Compton tail and $P(E)$ is the fraction of photo peak.

Since there are one and two quanta escapes in the response curve of 6.14 MeV photons as shown in Fig. 12, one and two quanta escape fractions, p_{π_1} and p_{π_2} must be added in our response function as follows;

$$
\begin{aligned}
R(E, E'') = Y(E)\Bigg\{ & \int_0^E \frac{K(E, E')}{\sqrt{2\pi\alpha E'}} \exp\left[-\frac{(E''-E')^2}{2\alpha E'}\right] dE' \\
& + \frac{p_{\pi_2}(E)}{\sqrt{2\pi\alpha(E-2m_0c^2)}} \exp\left[-\frac{(E''+2m_0c^2-E)^2}{2\alpha(E-2m_0c^2)}\right] \\
& + \frac{p_{\pi_1}(E)}{\sqrt{2\pi\alpha(E-m_0c^2)}} \exp\left[-\frac{(E''+m_0c^2-E)^2}{2\alpha(E-m_0c^2)}\right] + \frac{p(E)}{\sqrt{2\pi\alpha E}} \exp\left[-\frac{(E''-E)^2}{2\alpha E}\right]\Bigg\}, \qquad (3.7)
\end{aligned}
$$

where α is a constant and gives the width of Gaussian distribution and is chosen to be 0.00146.

The functions K, p_{π_2}, p_{π_1} and p can be evaluated using the Monte Carlo method. However, in the present calculation, these function were determined referring to the synthesis procedure of Koch and Wyckoff[12] which based on the experimental data obtained by monoenergetic electrons. From their synthesis procedure, these functions are expressed in terms of the photoelectric (τ), pair (π), Compton (σ) and total (μ) absorption cross sections.

$$
\left.
\begin{array}{ll}
\text{photo fraction:} & p(E) = \dfrac{\tau + a\pi + b\sigma}{\mu} \\[2ex]
\text{fraction of one quantum escape:} & p_{\pi_1}(E) = \dfrac{A_1\pi}{\mu} \\[2ex]
\text{fraction of two quanta escapes:} & p_{\pi_2}(E) = \dfrac{A_2\pi}{\mu}\,,
\end{array}
\right\} \qquad (3.8)
$$

where the constant a is the fraction of the total pair production events for which both annihilation quanta are absorbed in the crystal and the constants A_1 and A_2 are the fraction of the total pair production events for which one quantum and two quanta escape from the crystal respectively. The relation between A_1, A_2 and a is

$$A_1 + A_2 + a = 1\,. \qquad (3.9)$$

The constant b is the fraction of the Compton scattered photons that are multiply scattered and totally absorbed in the crystal. Koch and Wyckoff[12] showed that the strinking similarity exists between the Compton electron distributions for a single- and multiple-interactions for the same photon energies. Thus, the function K of the Compton tail was chosen as the Compton electron distributions for a single interaction,

$$
\begin{aligned}
K(E, E') = 0.135\,\frac{1-b}{\mu}\left(\frac{m_0c^2}{E}\right)^2 \Bigg[& \frac{E}{E-E'} - \frac{E'}{E} \\
& + \frac{1}{E^2}\,\frac{\{E^2 - E'(m_0c^2+E)\}^2}{(E-E')^2}\Bigg] \\
& \left(E' \leq \frac{E}{1+m_0c^2/2E}\right) \qquad (3.10)
\end{aligned}
$$

where the numerical coefficient 0.135 was determined to fit the total cross section of Compton scattering electrons in a sodium iodide. Instead of (3.6), the normalization of the response function, (3.7), is given in terms of p, p_{π_1}, p_{π_2} and $K(E, E')$ as follows,

$$\int_0^E K(E, E')\,dE' + p(E) + p_{\pi_1}(E) + p_{\pi_2}(E) = 1\,. \qquad (3.11)$$

The energy resoluion of the response function expressed by (3.7) is obtained as follows:

$$\frac{2\Delta E}{E} = 2\sqrt{\frac{\ln 2 . 2\alpha}{E}}\,. \qquad (3.12)$$

From the measured spectrum of 1.12 MeV gamma ray line, which gives the energy resolution 8.5%, the constant α is determined 0.00146 as stated before. The measured spectrum and the response function using the constant $\alpha = 0.00146$ give the energy resolutions 4.7% and 3.6% at 6.14 MeV respectively. This deviation comes from the difference of the distributions of the response function and the actual spectrum; the response function contains the Gaussian distribution only which comes from the statistical fluctuation as given in (3.7), whereas, the actual spectrum contains the non Gaussian part which comes from the energy loss from the crystal.

The fractions of photo-peak, one quantum, escape, two quanta escapes and Compton tail are determined from the areas of these parts in the measured spectra of 1.12 MeV and 6.14 MeV gamma-ray lines using the normalization relation (3.11). Since the constants A_1, A_2 and a are independent of the photon energies and only depend on particular geometry of the scintillator, these constants are determined from the measured fractions at 6.14 MeV using the relations (3.8) and (3.9) as follows:

$$A_1=0.500$$

$$A_2=0.083$$

$$a=0.417\,.$$

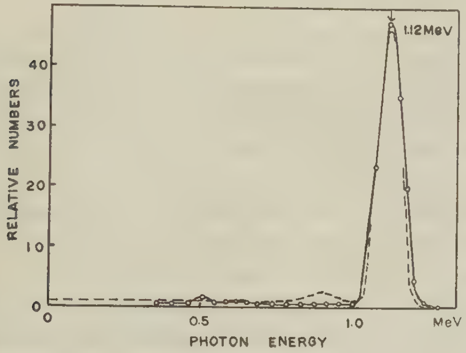

Fig. 11. Pulse height distribution produced by the 1.12 MeV gamma rays from Zn^{65} (solid) and the response function used for the calculation (dashed). The dashed curve is drawn from (3,7) using the constants as shown in the text.

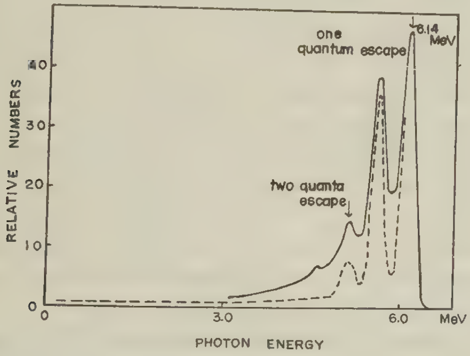

Fig. 12. Pulse height distribution produced by the 6.14 MeV gamma rays from the reaction of $F^{19}(p, \alpha)O^{16}$ (solid) and the response function used for the calculation (dashed). The dashed curve is drawn from (3,7) using the constants as shown in the text.

At the same time, the parameter b in (3.8) is determined from measured fractions. To determine p and b as the function of the gamma ray energy, the inter- and extrapolation procedure are performed along the data of Koch and Wyckoff, using p and b at 1.12 MeV and 6.14 MeV. The curves of p and b given in Fig. 13.

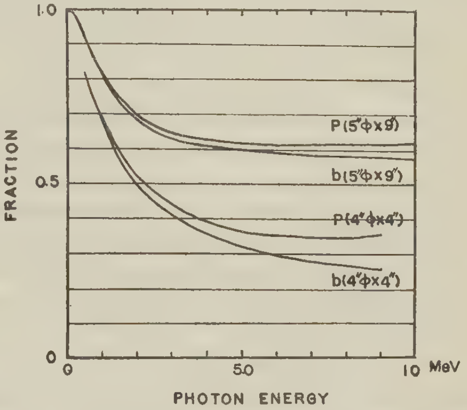

Fig. 13. Fractions of photopeak p and Compton tail b. The values of $p(5''\phi\times 9'')$ and $b(5''\phi\times 9)$ are taken from Koch and Wyckoff (reference (12)). The values of $p(4''\phi\times 4')$ and $b(4''\phi\times 4'')$ are determined experimentally and used for the present calculation.

The efficiency of the sodium iodide crystal of 4 in. in diameter and 4 in. in length was taken from the data of the sodium iodide crystal 5 in. in diameter 4 in. in length$^{11)}$. Because of long distance (4 m) between the target and the last collimator and of smallness (0.8 cmϕ) of its slit aperture, the efficiency of the crystal is given as the following;

$$Y(E)=1-\exp\left[-\mu(E)L\right] \qquad (3.13)$$

where L is the length of the crystal. This efficiency almost agrees with that of $5''\phi\times 4''$, which was used for the present calculations.

3) *Bremsstrahlung spectrum*

The bremsstrahlung spectrum converted into the measured spectrum, $S(E_0, E'')$ is given from (3.3) and (3.7), without constant factor, by

$$S(E_0, E'')=\int_0^{E_0} n(E_0, E)\cdot R(E, E'')\,dE\,. \quad (3.41)$$

This can be decomposed into four terms, that is, the integrals containning Compton tail (S_c), one quantum escape (S_{π_1}), two quanta escapes (S_{π_2}) and photo peak (S_p)

$$S(E_0, E'')=S_p(E_0, E'')+S_{\pi_1}(E_0, E'')+S_{\pi_2}(E_0, E)+S_c(E_0, E'') , \tag{3.15}$$

where

$$\left.\begin{aligned}
S_p(E_0, E'')&=\int_0^{E_0} dE\, Y(E)\frac{p(E)}{\sqrt{2\pi\alpha E}} \exp\left[-\frac{(E''-E)^2}{2\alpha E}\right] n(E_0, E)\\
S_{\pi_1}(E_0, E'')&=\int_0^{E_0} dE\, Y(E)\frac{p_{\pi_1}(E)}{\sqrt{2\pi\alpha(E-m_0c^2)}} \exp\left[-\frac{(E''-E+m_0c^2)^2}{2\alpha(E-m_0c^2)}\right] n(E_0, E)\\
S_{\pi_2}(E_0, E'')&=\int_0^{E_0} dE\, Y(E)\frac{p_{\pi_2}(E)}{\sqrt{2\pi\alpha(E-2m_0c^2)}} \exp\left[-\frac{(E''-E+2m_0c^2)^2}{2\alpha(E-2m_0c^2)}\right] n(E_0, E)\\
S_c(E_0, E'')&=\int_0^{E_0} dE\int_0^{E} dE'\, Y(E)\frac{K(E, E')}{\sqrt{2\pi\alpha E'}} \exp\left[-\frac{(E''-E')^2}{2\alpha E'}\right] n(E_0, E) .
\end{aligned}\right\} \tag{3.16}$$

These four terms were calculated to the 2nd order of approximation, the error being less than 0.5%.

The most important correction came from the absorption of photons in the glass of the donut. In this case, the corrected spectrum should be expressed by

$$S(E_0, E'')=\int_0^{E_0} \alpha(E)\cdot n(E_0, E) R(E, E'')\, dE , \tag{3.17}$$

where $\alpha(E)$ is the correction for absorption to the photon energy E. Furthermore, if the target thickness were taken into account, $S(E_0, E'')$ should be expressed in the term of the correction factor $\pi(t, E)$ for the multiple scattering in the target,

$$S(E_0, E'') =\int_0^{E_0} \alpha(E)\, \pi(t, E)\, n(E_0, E)\, R(E, E'')\, dE , \tag{3.18}$$

where t is the thickness of the target. The theoretical curves of beryllium and nickel were calculated from (3.17). The target thickness was only taken into account in the theoretical curves of platinum targets. These curves are shown in Figs. 5, 6, 7, 8, 9 and 10, together with the measured spectra.

§ 4. Discussion

The absorption of photons between the target and the head of scintillation spectrometer, the effects of the finite thickness of the targets and the effects of penetration of collimator edge and the scattering by the wall surface in the collimator must be taken into account for the theoretical curve. The absorption of photons was negligible in aluminium of the sodium iodide crystal housing and the air between the target and the head, and was the most important in the glass of the donut. This correction factor was around 10%, and was applied to the spectra. The collimator effect mainly came from the last lead collimator with the aperture of 8 mmϕ. An approximate calculation of this effect showed that both contributions of transmitted photons through the wall of the collimator and of scattered photons were about 1% in together at all energy. Because of the uncertainly of the calculation and the smallness of the magnitude, these effects were neglected. Normalizing point of theory with experiment was chosen at the point of $E/(E_0-m_0c^2)=0.5$. Near the high energy end of bremsstrahlung, statistical error became high because of low counting rate, and some deviations of the theory from experiment occurred. However, little may be said about the high energy end of bremsstrahlung. Recently, Fuller et al[13] measured the shape of the high-energy end of the bremsstrahlung spectrum, using the resonance scattering of photons by the 15.11 MeV level in C^{12}. The data indicate an excess number of photons in the tip of spectrum, when compared with Bethe-Heitler spectra corrected for target thickness.

In order to see the Z-dependence of Bremsstrahlung, the ratio Ni/Pt and Be/Pt are given Fig. 14 together with the theoretical ratios. These ratios are normalized to 1 at $E/(E_0-m_0c^2)=0.5$. If the differential cross section of bremsstrahlung with atomic number Z were given in the form of $n_Z(E_0, E)$, then the theoretical ratio $\Gamma(Z_1/Z_0)$ will be given as follows; neglecting the thickness of targets;

$$\Gamma(Z_1/Z_0)=\frac{\int_0^{E_0} \alpha(E) R(E, E'') n_{Z_1}(E_0, E)\, dE}{\int_0^{E0} \alpha(E) R(E, E'') n_{Z_0}(E_0, E)\, dE} . \tag{4.1}$$

The main contribution of $R(E, E'')$ to the integrals is photo- and one quantum escape-peak at the energy of E and $E-0.511$ (MeV). Thus the ratio $\Gamma(Z_1/Z_0)$ depends only slightly on the shapes of the response functions in the region of slow change of $n_{Zi}(E_0, E)$ with E. Therefore $\Gamma(Z_1/Z_0)$ gives us the direct knowledges for the bremsstrahlung spectra independent of the ambiguity of the shape of the response function. As shown in Fig. 14, the measured ratios agree with the theoretical ratios within the statistical error, neglecting the thickness of targets.

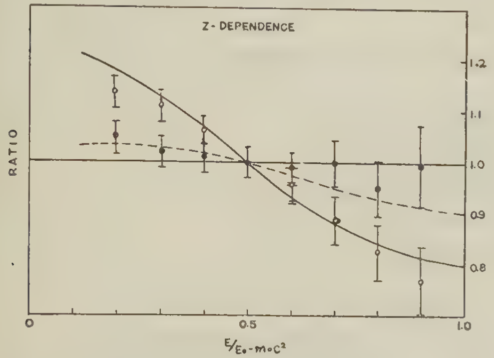

Fig. 14. *Z*-dependence of the experimental and the theoretical ratio

● : experimental point of Ni/Pt
○ : experimental point of Be/Pt
- - - -: theoretical curve of Ni/Pt
———: theoretical curve of Be/Pt

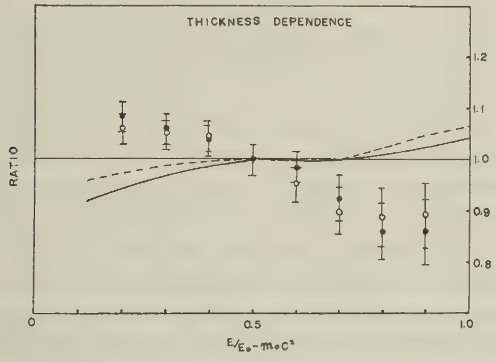

Fig. 15. Thickness dependence of the experimental and the theoretical ratio

● : experimental point of 0.025 mm/0.2 mm
○ : experimental point of 0.08 mm/0.2 mm
- - - -: theoretical curve of 0.025 mm/0.2 mm
———: experimental curve of 0.08 mm/0.2 mm

The measured spectra for the platinum targets of 0.2, 0.08 and 0.025 mm thickness are shown in Figs. 8, 9 and 10. The ratios 0.08 mm/0.2 mm and 0.025 mm/0.2 mm are shown in Fig. 15, which also shows the theoretical curve corrected for the target thickness. These ratios are normalized to 1 at $E/(E_0-m_0c^2)=0.5$. Not so good agreement was obtained. The shrinking velocity of the betatron orbit is the order of $10^{-4}\sim10^{-5}$ cm per one revolution, and the effective thickness of target will be less than the geometrical value. The effects of target thickness will be very difficult to be discussed quantitatively.

In the calculation of *Z*-dependence, the thickness of targets was neglected, that is the case of the infinitely thin target was used. There exists, however, fairly large deviations of the spectra of both experiments and calculations from standard one of 0.2 mm thickness of Pt target. Thus, we can not say much about the *Z*-dependence of the results, where the accurate estimation of the effect of target thickness is very difficult. In conclusion, though we found it rather difficult to check the theory of Schiff in full, it was a fairly useful method to calculate the shape of bremsstrahlung using the response function determined experimentally.

Acknowledgement

The authors are indebted to the Van de Graaf group in Tokyo University for their help in measuring the response of the 6.14 MeV gamma ray from $F^{19}(p, \alpha\gamma)O^{16}$ reaction. They wish to thank Mr. C. Ishii for his suggestion to the response function. The calculational help of Miss N. Komatsu will be greatly appreciated. The also should like to acknowledge The Ministry of Education for the financial support to the construction of accelerator and the measuring installations.

Scattering of Protons by Ne^{20} and Ne^{22}

By Yukiyasu ODA, Minoru TAKEDA,
Chuin HU and Shohei KATO

Department of Physics, Faculty of Science,
Osaka University, Osaka, Japan

(Received December 8, 1958)

The angular distributions of protons scattered elastically and inelastically by Ne^{20} and Ne^{22} have been observed at six energies from 4.95 to 5.50 Mev. The shape of angular distribution of inelastically scattered protons varies rapidly with incident energy in boths cases of Ne^{20} and Ne^{22}. An anomaly is found at 5.25 Mev in the reaction Ne$^{20}(p, p')$Ne^{20} ($Q=-1.63$ Mev). The elastic scatterings also exhibit the corresponding features. These results suggest that the reaction proceeds mainly through the compound nucleus formation process. The spin and parity of the compound state seem likely to be 5/2(+).

§ 1. Introduction

The present work is a study of the variation with incident energy of the differential cross sections for elastic and inelastic scattering of protons by neon nuclei. Protons of energies up to 5.5 Mev were produced by the Osaka University 44 inches cyclotron[1].

Natural neon contains three isotopes. The most abundant isotope Ne^{20} has the first excited state at 1.63 Mev above the ground state. The angular distributions of protons scattered inelastically from Ne^{20}, exciting the 1.63 Mev level, were measured by Heitler et al[2] and Freemantle, et al[3] at the proton energies of 4.2 and 9.5 Mev respectively. At present there are two types of theories that attempt to explain and predict angular distributions of product particles in nuclear reactions. The first is based on the formation and subsequent decay of a compound nucleus[4]. General theories applicable to this types of reactions are able to give information on the angular distribution[5]. If the reaction proceeds through a single level of the compound nucleus, the angular distribution is symmetric about the scattering angle $\theta=90°$ in centre-of-mass system. If some levels with different natures are involved in the reaction, the distribution may become more complex and be asymmetric about the 90° angle when the interference between outgoing waves of different parities is present. Finally if the reaction proceeds through a large number of levels of the compound nucleus which are contained within the energy spread of the incident beam in the so-called continuum region of the primary energy, the distribution is again symmetric about $\theta=90°$. In these cases interferences between the many overlapping levels are thought to be cancelled out by each other on the statistical average.

The second type of theories considers that the reaction proceeds either through a direct interaction between the incident proton and a nucleon in the target nucleus or through excitation of the nuclear rotational state[6].

It has been shown by McManus and Butler[7] that the angular distribution of inelastically scattered protons studied at 9.5 Mev by Freemantle et al is well interpreted by the direct interaction process mentioned above. On the other hand, the theoretical calculation for this experimental result based on the excitation of the rotational state has been carried out by Yoshida[8].

The experimental works described here were undertaken in order to get further information of the problem mentioned above. The results obtained at six points of incident energy from 4.95 Mev to 5.5 Mev will be shown.

§ 2. Apparatus

The Osaka University 44″ Cyclotron produced the proton beam used for the experiment. Fairly standard techniques of scattering experiment were used, some details of which are stated below. The whole layout is shown elsewhere[9] and the experimental arrangement in Fig. 1. The movable scintillation counter could be set within 0.1 degree of any angle between −70° and 164°. The protons scattered by the gas target passed through the slit system composed of two rectangular slits before counter.

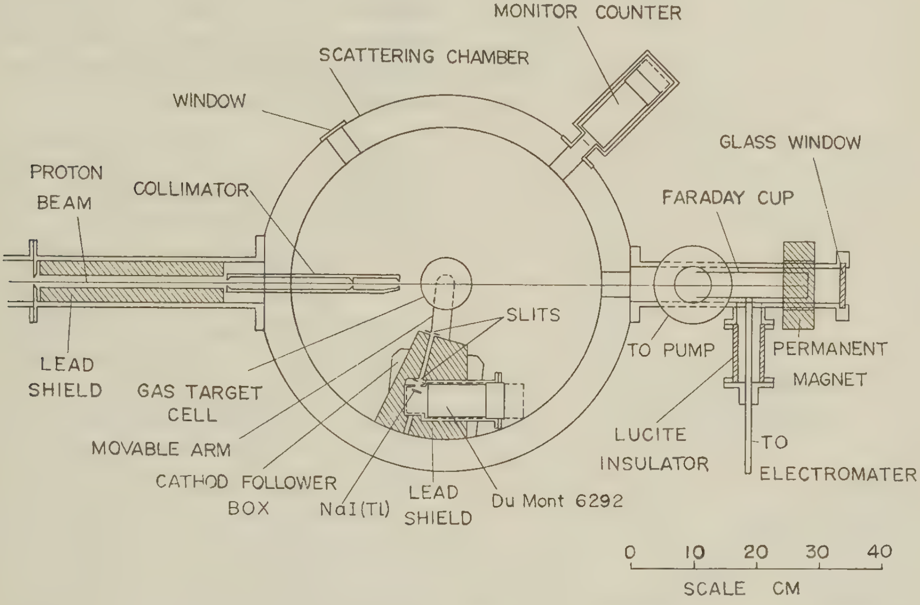

Fig. 1. The experimental arrangement.

NaI(Tl) scintillation crystals cut to the dimension of about $0.8 \times 12 \times 20$ mm³ were used as detectors with Du Mont 6291 or 6292 photomultiplier tubes. When the latter type tube was used, somewhat special arrangement as shown in Fig. 1 was adopted. Although the pulse heights of the gamma ray backgrounds in this detector were not so high, it affected fairly the accurate counting of the inelastically scattered proton groups at large scattering angles. Various efforts such as to interpose the lead gamma-ray absorbers into the beam ducts, covering the beam-exposured faces of various slits with gold foils, and the shielding of the detector with lead plate reduced these background by about a factor of thirty. The pulses generated in the scintillation detector system were amplified and analysed by an Atomic Model 510 20-channel analyzer. Some typical pulse height spectra obtained are shown later in Fig. 3 (a), (b) and (c). The energy resolution of these detectors were about 4.5%.

§ 3. Procedures of Experiment

A. *Measurements of energies of the incident proton beams*

The thickness of the aluminium absorption foils interposed to the beam in front of the scattering chamber were chosen so that the beam energies would be reduced successively by nearly 0.1 Mev. The absolute values of the beam energies corresponding to each thickness of these foils were determined as follows by referring to the excitation function for the $C^{12}(p, p)C^{12}$ reaction published by the Rice Institute group[10]. Changing the foil thickness successively, we observed the variation of the yields of the protons elastically scattered at the scattering angle $\theta=160°$ from propan target. A typical comparison is shown in Fig. 2. The values of the beam energies determined in this way were always compared reasonably with that obtained by other methods. The uncertainty of the values thus obtained seems to be within 30 Kev. The energy spread of the primary beam, on the other hand, seemed to be about 50 Kev, which would be increased gradually with reduction of the beam energy by inserting of absorption foils.

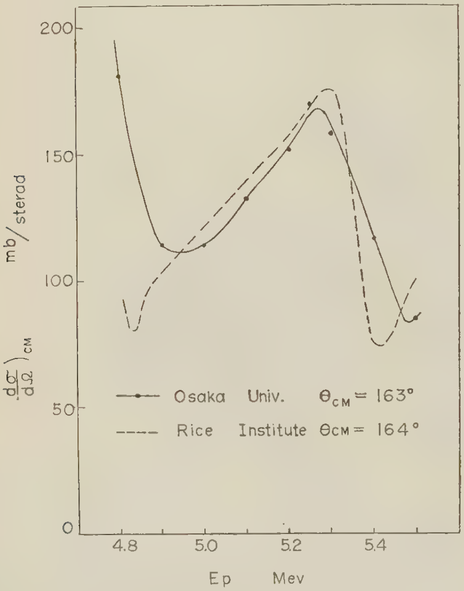

Fig. 2. Determination of the energies of the incident protons.

B. *Pulse-height spectrometry*

Fig. 3 (a) shows a typical pulse-height spectrum obtained from the detector at the scattering angle $\theta=90°$. We observed three proton groups, elastic scattering group from neon nuclei, inelastic ($Q=-1.63$ Mev) group from Ne^{20} and the inelastic scattering ($Q=-1.27$ Mev) group from Ne^{22}.

Beside these groups from neon, the elastic scattering group from helium, contamination in the target, was found a little in the region of scattering angles $\theta<100°$. It overlapped with the inelastic scattering from Ne^{22} at the angle $\theta\sim75°$ and with that from Ne^{20} at the angle $\theta\sim90°$. The corrections were about 4% for the inelastic scattering group from Ne^{20} at $\theta=90°$ and almost negligible for the elastic scattering groups at the forward angles.

The inelastic scattering groups from both neon isotopes were affected by the background at the forward angles $\theta<30°$ as is shown in Fig. 3 (b). This background seems to be produced by the slit-edge and multiple scattering of the incident and scattered beam. The intensities of this background decreased rapidly with increasing scattering angle and its effects were sufficiently small at $\theta=30°$.

At the backward scattering angles the inelastic groups from Ne^{20} suffered further from the background of gamma-rays which seemed to be produced at the collimator slits for the incident beam, (Fig. 3 (c)). In the region of medium scattering angle $40°<\theta<140°$, the amounts of background which affected the inelastic scattering groups from Ne^{20} were at most 5% in total number.

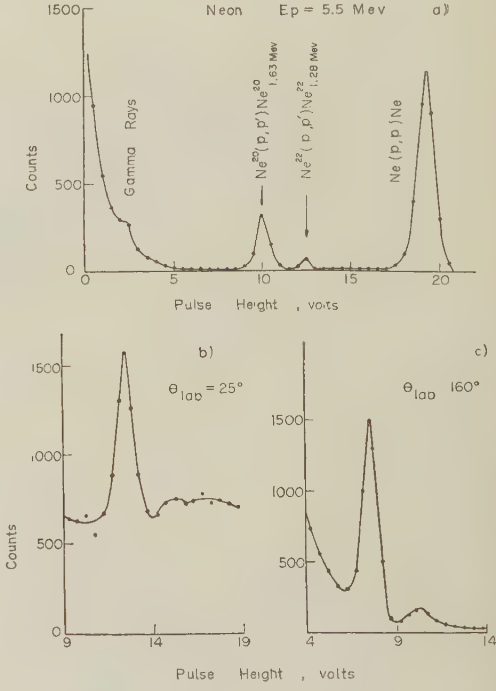

Fig. 3. The pulse-height spectra of the protons scattered from neon.

C. *Deduction of the differential cross section*

The differential cross section in laboratory system $\sigma(\theta)$ at a scattering angle θ is given in usual way. The correction owing to the finite size of the target and the beam were less than 1% even at small scattering angles. The zero of the scattering angle was checked experimentally by the comparisons of the yields at two corresponding scattering angles with respect to the incident beam ($\theta=\pm60°$, and $\pm70°$). The gas pressures were of the order of 150 mm Hg. As the intensities of protons at small angles are very large due to the elastic scattering, the counting rates were always adjusted so that the counting loss corrections would not exceed 1%.

Besides the errors for those factors stated above, there were further sources of errors. As will be shown in section 4, the measured cross sections showed remarkable variations with the change of proton energy. A change of energy by 0.1 Mev made in some extreme cases the cross sections varies by amounts of factor. Therefore we paid our attentions to the error resulting from the drift of the energy of incident beam which the small variations of the operating conditions of cyclotron might produce. However, the effects were found to be fairly small.

Considering all the factors mentioned in this section, the accuracies of our cross section measurement would be about 6% in relative values and about 10% in absolute values.

D. *Measurements*

The cyclotron were usually operated continuously for some ten hours. At every operation, the energies of the incident beam were measured as has been stated in section A. Six sets of measurements of the angular distributions for both scatterings were then performed at 5.50, 5.40, 5.30, 5.20, 5.05 and 4.95 Mev of incident proton energies. The inelastic scatterings from Ne^{22} were studied simultaneously. The angles of scattering in these measurements ranged from 20° to 164.5° in laboratory system with steps of 5° or 10°.

§ 4. Experimental Results

Fig. 4 shows the results for the elastic scattering from neon. At the smallest angle of scattering $\theta=21°$, the observed values are within 10% deviation from the calculated values based on pure Rutherford scattering.

Fig. 5 represents the results for the inelastic scattering from Ne^{20}. An anomaly is found at the energy of 5.25 Mev. Kondo, et al in our laboratory have measured also the scatterings of protons from neon by emulsion technique[11]. Both results are compatible in the position of the anomaly, the shapes of the angular distributions at corresponding energies and the feature of variations of cross sections with energy, except the relatively small differences in absolute values of cross sections especially in the region of reasonance peak.

§ 5. Discussion

As we can see in Figs. 4 and 5, the angular distributions of both elastic scattering groups from neon and inelastic scattering groups from Ne^{20} change their shapes rapidly with proton energy. At the energy of 5.25 Mev, we observe also an anomaly in the elastic scattering.

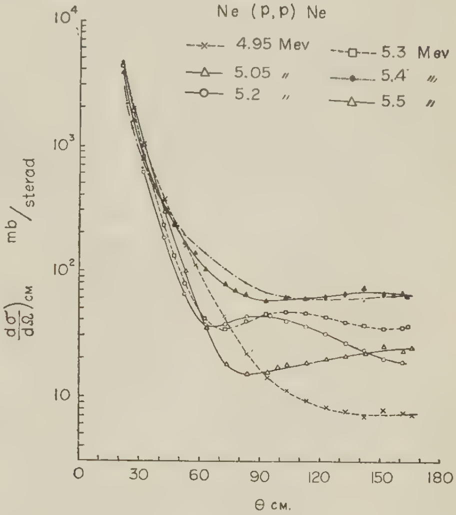

Fig. 4. The angular distributions of the elastic scatterings of protons from neon.

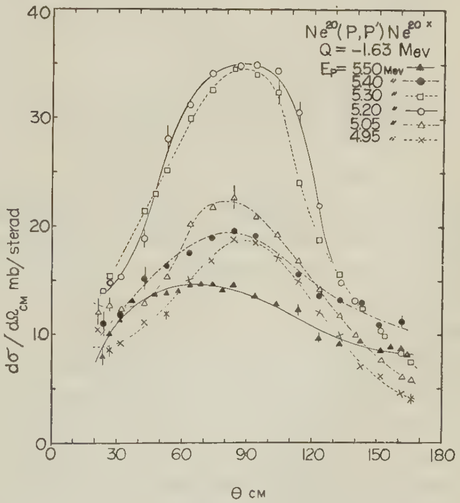

Fig. 5. The angular distributions of the reactions $Ne^{20}(p, p')Ne^{20*}$, $Q=-1.63$ Mev .

Next, as is seen in Fig. 6, the angular distributions of the inelastic scattering groups of Ne^{22} show the different shapes from those of Ne^{20} at the same enegy. The distribution shapes also change with energy.

All these features seem to support that our reactions proceed mainly through the formation of the compound nucleus. This arguments would be reasonable from the following two points. First, the energy region studied is not much higher than the so-called resonance region[12]. Thus the situations of both regions would not be different greatly. Second, the occurrence of resonance phenomena in our energy region seems to arise from the fact that the excitation energies of the compound nucleus Na^{21} are relatively low. As the separation energy of proton in Na^{21} is only 2.45 Mev, the excitation energy of Na^{21} corresponding to the proton energy of 5.5 Mev in nearly 7.8 Mev and is little higher than the excitation energy of 6.76 Mev in the mirror nucleus Ne^{21} formed by the Ne^{20} nucleus with zero energy neutron.

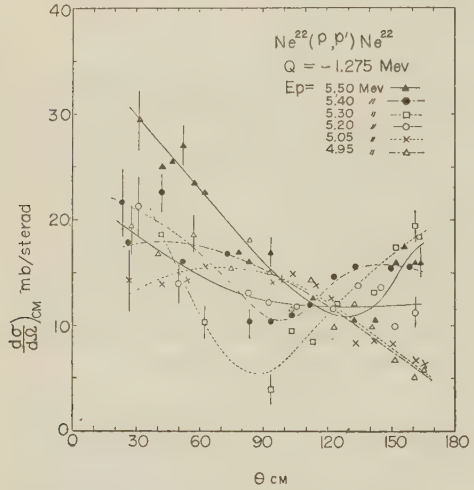

Fig. 6. The angular distributions of the reactions $Ne^{22}(p, p')Ne^{22*}$, $Q = -1.275$ Mev .

Here we should like to argue the shapes of the angular distributions of the inelastic scattering from Ne^{20}. The overall shapes of six results obtained are similar to each all and especially they are not so different from that obtained at 9. 51 Mev. As has been stated in introduction, the latter distribution shape has been interpreted by the direct interaction theory and the distribution shape is expected to vary slowly with energy. Thus, in spite of the many materials supporting the possible dominance of the compound nucleus formation process, this apparent insensitivity of the shapes to energy make ones fear that the direct process might play the main role in the energy region mentioned above. This argument is however, denied by our measurements of angular distributions which have been made at higher energies of 8.0, 9.5, 11.0, 12.5 and 14.0 Mev[13]. Among these results, the one at 9.5 Mev has showed the same distribution shape with that by Freemantle, et al. This distribution shapes at other energies have been, however, quite different from that at 9.5 Mev and also from that obtained by us in the neighborhood of 5.25 Mev. Therefore the distribution shape at 9.5 Mev is not the one which varies slowly with energy but the one which is seen rather especially in the restricted region of energy.

Now standing on the point of view that our reactions proceed through the formation of the compound nucleus, we shall discuss further our results.

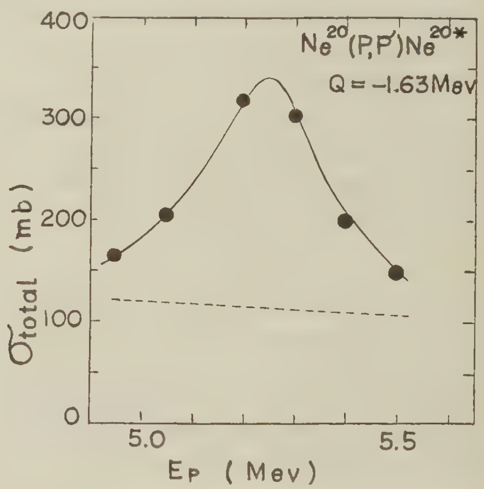

Fig. 7. The evergy dependence of the total cross sections for the reactions $Ne^{20}(p, p')Ne^{20*}$, $Q = -1.63$ Mev .

It must be emphasized that the anomaly found has a broad energy width of nearby 300 Kev. The experiments at energies below 4.4 Mev referred show that the mean level distance is about 0.2 Mev and the half widths of the nine levels observed are ranging from 12 Kev to 100 Kev, being usually some tens kilo volts[12]. The energy width observed by us is quite broader than those of lower levels. Here, we consider that this anomaly is due to a single level because the excitation curve for total cross sections vary with energy in the usual resonance behaviour as is shown in Fig. 7 and also the angular distributions do not change their shapes during the course.

Then it seems that the most parts of total cross sections are attributed to this anomaly. Fig. 7 shows that at the resonance energy of 5.25 Mev the cross section of this resonance stands for at least more than two third of the total cross section. The rest part may be attributed to the effects of some far levels or the direct process if possible. The extents to which the resonance parts amount in the total cross sections are, however, not so definite. In Fig. 7, the dotted line represents the part which varies slowly with E_p^{-1} dependence and the rest shows the resonance part which has a peak cross section of 230 mb at 5.25 Mev and a level width of 300 Kev.

The total cross section for the inelastic scattering of nucleons from a nucleus of a spin zero through a compound nucleus of spin J is given at resonance by the following well-known formula:

$$\sigma(p, p')=\frac{\pi}{k^2}\left(J+\frac{1}{2}\right)\frac{4\Gamma_{pJ}\Gamma_{p'J}}{\Gamma_J{}^2}. \qquad (1)$$

Where k is the wave number and Γ_J, Γ_{pJ} and $\Gamma_{p'J}$ are the total width, the partial width for the incident protons and that for the outgoing protons of the relevant compound level. Now $\pi/k^2=137$ mb and we may put approximately $\Gamma_J=\Gamma_{pJ}+\Gamma_{p'J}$. The factor $\pi(J+\frac{1}{2})/k^2$ in equation (1) represents the maximum value of the cross section for the reaction which proceeds through an intermediate state of spin J. Thus comparing the values of the experimental and theoretical cross sections, we can first eliminate the case $J=1/2$. In our case, the some fraction of resonance peak cross section, say 230 mb, is thought to be the result of a single level resonance. However, we must retain the possibility of $J=3/2$. As $3\pi/k^2$ is larger than $\sigma_t=340$ mb above, the cases $J\geq 5/2$ have the general possibility that even the whole of the peak total cross section are yet in the limit of the theoretical value due to a single level resonance process.

On the other hand, general consideration of the nuclear size and the incident proton energy limits the orbital angular momentum l in the incident state to $l\leq 3$ or 4 at most. Therefore $J=l\pm\frac{1}{2}$ would be limited to $J\leq 7/2$ probably.

Further selection of J among these values and assignment of parity π of the compound state must be performed under inquiring of the results for the angular distribution. The general theory of the angular distribution of product particles in a nuclear reaction which is applicable to our problem has been given in reference⁵⁾. The theoretical predictions are compared with our results, which is given by the following formula for the case of $E_p=5.20$ Mev:

$$\sigma(\theta)=\frac{\pi}{k^2}\frac{1}{2\pi}(1.14P_0+0.13P_1-0.88P_2 -0.18P_3+0.16P_4). \qquad (2)$$

Here P_n means the Legendre polynomial $P_n(\cos\theta)$. As contribution of the odd n part is relatively small, let us study tentatively one process through a compound nucleus level which can respond to the whole even parity part of the distribution formula and therefore seems to be dominant in our resonance phenomenon.

When we take into account the term P_4, we must exclude all processes with $J\leq 3/2$ because of the Yang's rule for the complexity of the angular distribution of the reaction¹⁴⁾. Then the process in which

$l=2$, $J(\pi)=5/2(+)$, $l'=0$ and 2, and $s'=5/2$

seems to be preferable. Here s' is the channel spin after the reaction, and the interference between outgoing waves has been taken into account. Next when we neglect the term P_4, the distributions of type $A-BP_2(\cos\theta)$ are reproduced respectively by the processes through $J(\pi)=3/2(-)$, $3/2(+)$ or $5/2(-)$.

Here, let us turn to the results for the elastic scattering. In order to search its anomaly, we rearrange our data shown in Fig. 4 into excitation curves at fourteen angles. Then the anomaly is found to vary with angle roughly according to the angle dependence of $-P_2(\cos\theta)$. The feature seems to support $l=2$ for the incident waves as the dominant process.

Concluding these arguments, we recommend $5/2(+)$ as the most possible state of the compound nucleus for the anomaly. As the phenomena are, however, rather complicate, the assignments $3/2(+)$, $5/2(-)$ and $3/2(-)$ have also some possibilities.

On the Coefficients of Irreversible Processes in a Highly Ionized Gas

By Taro KIHARA

Department of Physics, Faculty of Science,
University of Tokyo

(Received December 4, 1958)

An effective interparticle potential, which is a modified Debye-Hückel potential, is introduced and discussed in order to eliminate simultaneous interactions between three particles or more in an ionized gas. For this potential weak-interaction asymptotes of collision cross sections necessary for the theory of irreversible processes are calculated without making further approximations. These cross sections are applied to relaxation between ion and electron temperatures and to the coefficient of viscosity.

§ 1. Introduction

In a previous paper¹⁾ by the same author phenomenological thermodynamics of irreversible processes was applied to plasmas. In the present paper the coefficients of irreversible processes in a gaseous plasma are treated in molecular terms.

Transport and relaxation phenomena in a highly ionized gas were treated recently by many authors. Their methods can be divided into two types. The one is the treatment by Cowling²⁾, Landshoff³⁾ and Chapman⁴⁾. It starts from the Boltzmann equation for dilute gases. The other is due to Spitzer and his coworkers⁵⁾,⁶⁾ who treat the problem as a stochastic process. To avoid divergence of cross sections these authors use a cut-off procedure or similar. When the cut-off is made at a length of the order of Debye shielding length, conclusions drawn from these two types are the same so far as the weak-interaction limits are concerned which do not depend on the length of cut-off.

In the present paper we are interested not only in the weak-interaction limits but in the asymptotic forms for weak interaction.

It is impossible at present to obtain exact expressions of the asymptotes. Hence all we can do is to make calculations in a least arbitrary way. Use of an effective interparticle potential is less arbitrary than the cut-off procedure, when the effective potential seems to be adequate.

In §§ 2 and 3 a model of effective interparticle potential will be discussed. By use of the model, weak-interaction asymptotes of cross section necessary for the theory of relaxation and transport phenomena will be calculated in § 4 without making further approximations. These cross sections will be applied, in § 5, to the relaxation between ion and electron temperatures. They will further applied, in § 6, to the coefficient of viscosity, for which accurate value even at the weak-interaction limit was not obtained before.

§ 2. Potential of Average Force between Two Particles

We first consider a highly ionized gas in thermal equillibrium composed of several species of particles with electric charges e_j and number densities n_j ($j=1, 2, \cdots$). The gas is supposed to be neutral

$$\sum n_j e_j = 0 \,. \tag{2.1}$$

All the particles is assumed to have no internal structure.

The charge of any particle in the plasma is shielded by surrounding charged particles. Our essential assumption is that the shielding is shared by many particles within a sphere of shielding radius. In other words, the plasma is assumed to be close to an ideal gas; or the absolute value of potential energy between two particles at the mean distance is assumed to be much smaller than the particle kinetic energy.

Then the electrostatic potential φ around a particle in the plasma satisfies, in the time average, the linear differential equation (the Poisson-Boltzmann equation)[7),8)]

$$\nabla^2\varphi = \kappa^2\varphi \tag{2.2}$$

with the Debye-Hückel characteristic constant κ defined by

$$\kappa^2 = 4\pi \sum n_j e_j^2 / kT \,, \tag{2.3}$$

kT being the Boltzmann constant times the temperature. The electrostatic potential around a particle with charge e_1 is given by its well-known solution

$$\varphi = e_j \exp(-\kappa r)/r \,, \tag{2.4}$$

r being the distance from the particle.

Now, let us consider the potential of average force between two charged particles shielded in the plasma. Relative position of the two particles is assumed to be fixed. Then the electric potential φ in the time average around the two-particle system is a solution

$$\varphi = \frac{e_1}{r_1}\exp(-\kappa r_1) + \frac{e_2}{r_2}\exp(-\kappa r_2)$$

of the equation (2.2). Here e_1 and e_2 are particle charges; r_1 and r_2 are distances from 1 and 2, respectively. If we multiply the φ at the position 1 by e_1 and the φ at 2 by e_2, sum up these, divide the sum by two, and take out the term depending on the distance r between the two particles, then we obtain

$$e_1 e_2 \exp(-\kappa r)/r \tag{2.5}$$

as the potential of average force. This is an elementary derivation of the result obtained by Kirkwood and Poirier[8)].

§ 3. Mayer's Theory and Effective Interparticle Potential

The free energy of an ordinary gas composed of N particles in volume V can be expanded into

$$F = F_{\text{ideal}} - NkT \sum_{\nu=1}^{\infty} \frac{\beta_\nu}{\nu+1} v^{-\nu} \,, \tag{3.1}$$

where $v=V/N$, and F_{ideal} means the free energy of an ideal gas. The coefficients β_ν's are given by Mayer's irreducible cluster integrals. When the interparticle potential is a function of the interparticle distance r only, β_1 in particular is given by

$$\beta_1 = 4\pi \sum_i \sum_j \frac{N_i}{N}\frac{N_j}{N} \int_0^\infty \left[\exp\left(-\frac{\psi_{ij}(r)}{kT}\right) - 1\right] r^2\,dr \,, \tag{3.2}$$

where N_j/N is the mole fraction of jth species and $\psi_{ij}(r)$ is the potential between ith and jth species.

In our case of plasma $\psi(r)$ is a Coulomb potential; hence the integral (3.2) for β_1 and corresponding integrals for $\beta_2, \beta_3, \cdots$ all diverge. Replacing first the Coulomb potential $1/r$ by $\exp(-\alpha r)/r$ with $\alpha>0$ and taking the limit $\alpha\to 0$ at the end, Mayer, in his paper on ionic solutions[9], found however that the asymptotic form of (3.1) for weak interaction agrees with the Debye-Hückel law

$$F=F_{\text{ideal}}-\frac{V}{3}\frac{\kappa^3 kT}{4\pi}\,, \qquad (3.3)$$

κ being the Debye-Hückel characteristic constant.

As a trial let us put

$$\Phi_{ij}(r)=e_i e_j \exp(-\kappa' r)/r \qquad (3.4)$$

in pace of $\psi_{ij}(r)$ in (3.2) and replace the right-hand side of (3.1) by its first two terms

$$F_{\text{ideal}}-NkT\cdot 2\pi v^{-1}\sum_i\sum_j \frac{N_i}{N}\frac{N_j}{N}$$
$$\times\int_0^\infty\left[\exp\left(-\frac{\Phi_{ij}(r)}{kT}\right)-1\right]r^2\,dr\,.$$

Here κ' is a positive constant. This becomes, when we take the weak interaction limit and use (2.1),

$$F_{\text{ideal}}-\frac{2\pi N}{vkT}\sum_i\sum_j\frac{N_i}{N}\frac{N_j}{N}$$
$$\times\int_0^\infty\frac{1}{2}\left(\frac{e_i e_j}{r}\right)^2\exp(-2\kappa' r)r^2\,dr$$

or

$$F_{\text{ideal}}-NkTv\kappa^4/32\pi\kappa'\,.$$

The last expression coincides with (3.3) when

$$\kappa'=3\kappa/8\,. \qquad (3.5)$$

Hence the Mayer series, the right-hand side of (3.1), is equal to the sum of its first two terms in which the Coulomb potential $e_i e_j/r$ are changed to $e_i e_j \exp(-\kappa' r)/r$ with an effective shielding constant $\kappa'=3\kappa/8$.

This fact may have some physical meaning. The νth term of the Mayer series comes from configurations in which ν particles interact simultaneously. *Interactions between three particles or more can be eliminated by use of a shielded interparticles potential instead of the Coulomb.* This effective interparticle potential (3.4) is not far from the potential (2.5) of the average force. The effective shielding constant is somewhat smaller than the Debye constant.

We have so far discussed in order to find a basis for using an effective interparticle potential in the calculation of coefficients of irreversible processes. For irreversible phenomena, unlike equilibrium properties, it is extremely difficult to calculate simultaneous interactions between three particles or more. Hence we shall neglect these interactions by use of an interparticle potential of the type

$$\Phi_{ij}(r)=e_i e_j \exp(-\kappa_{ij} r)/r\,. \qquad (3.6)$$

Here κ_{ij}'s are shielding constants which are assumed, for example, to be $3\kappa/8$. Although we can not exactly give the values of the shielding constants, final results do not sensitively depend on these values.

Only the case of weak interaction

$$\zeta_{ij}\equiv|e_i e_j|\kappa_{ij}/kT\ll 1 \qquad \text{for any } i, j \qquad (3.7)$$

will be treated in the following. In this case many particles may be present in a sphere of shielding radius. One might therefore think that, in such a situation, negligence of simultaneous interactions between three particles or more would not be permitted. This is not necessarily so. Let us consider, for example, diffraction of a light particle by two heavy particles according to a Coulomb field. Then it is true that in a configuration as shown in Fig. 1a the comming particles does not suffer diffraction although its effect will be counted twice in our approximation. However, there is also such a configuration as shown in Fig. 1b, where the scattering is four times as large as a single encounter. Since both configurations occur with equal probability, and since more general configurations are alike in this respect, the interference effect may be mostly cancelled in the average.

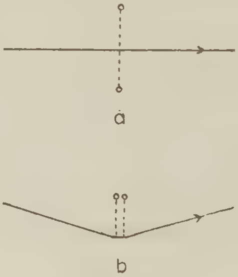

Fig. 1.

§ 4. Collision Cross Sections for the Shielded Potential

Having reduced the plasma to a "dilute" gas with the interparticle potential (3.6) we adopt Enskog-Chapman-Cowling's methods[10] of solving the Boltzmann equation. It is first necessary to calculate effective cross sections

$$\phi^{(l)}=\int_0^\infty(1-\cos^l\theta)gb\,db\qquad(l=1,2,\cdots)\quad(4.1)$$

for encounters between ith and jth species having particle masses m_i and m_j. Here θ is diffraction angle for the orbit of relative motion with the relative speed g and the impact parameter b. Then we have to know their statistical averages

$$\Omega_{ij}^{(l)}(r)=\sqrt{\pi}\int_0^\infty\phi^{(l)}\,\tilde{g}^{2r+2}\exp(-\tilde{g}^2)\,d\tilde{g}\,,\quad(4.2)$$

$(r=l,\ l+1,\cdots)$ where

$$\tilde{g}\equiv(m_{ij}/2kT)^{1/2}g\,,$$

and m_{ij} is the reduced mass,

$$m_{ij}=m_im_j(m_i+m_j)^{-1}\,.$$

The $\cos\theta$ in (4.1) is a function of

$$x\equiv\kappa_{ij}b\quad\text{and}\quad y\equiv m_{ij}g^2/2|e_ie_j|\kappa_{ij}\,.\quad(4.3)$$

By use of a dimensionless parameter

$$\zeta_{ij}\equiv|e_ie_j|\kappa_{ij}/kT=\tilde{g}^2/y\,,\qquad(4.4)$$

Ω can be expressed in the form

$$\Omega_{ij}^{(l)}(r)=\left(\frac{2\pi kT}{m_{ij}}\right)^{1/2}\left(\frac{e_ie_j}{2kT}\right)^2F_r^l(\zeta_{ij})\,,\qquad(4.5)$$

$$F_r^l(\zeta)=2\zeta^r\int_0^\infty\left[\int_0^\infty(1-\cos^l\theta)x\,dx\right]y^{r+1}\exp(-\zeta y)\,dy\,.\qquad(4.6)$$

What we need is the asymptotic forms of $F_r^l(\zeta)$'s for weak interaction, $\zeta\ll1$ (compare (3.7)). It will be shown in the following that these asymptotes are

$$F_r^l(\zeta)\approx(r-1)!\ \ l[\ln(3/4\zeta)-B_l+C_r]\,,\qquad(4.7)$$

where

$$B_1=0\,,\quad B_2=\frac{1}{2}\,,\quad B_3=\frac{2}{3}\,,\quad B_4=\frac{5}{6}\,,\ \cdots,$$

$$C_1=0\,,\quad C_2=1\,,\quad C_3=\frac{3}{2}\,,\quad C_4=\frac{11}{6}\,,\ \cdots.$$

The asymptote of the integral (4.6) is determined by the integrand with $y\gg1$. Hence the asymptote of $\int(1-\cos^l\theta)x\,dx$ for $y\gg1$ will be first evaluated. When two particles encounter with sufficiently large relative speed, effects of the shielding are negligible unless $\theta\ll1$. Hence we have

$$\tan(\theta/2)=e_ie_j/m_{ij}g^2b\qquad\text{unless}\quad\theta\ll1\,.$$

For $\theta\ll1$, a treatment similar to the perturbation method in classical dynamics can be applied:

$$\tan\frac{\theta}{2}=-\frac{1}{g}\int_b^\infty\frac{b}{r}\,\frac{1}{m_{ij}}\,\frac{d\Phi_{ij}}{dr}\left(\frac{dr}{dt}\right)^{-1}dr\,,$$

where t is the time and $dr/dt=g\sqrt{r^2-b^2}/r$. Hence

$$\tan\frac{\theta}{2}=-\frac{e_ie_j}{m_{ij}g^2}b\int_0^\infty\frac{d}{dr}\left(\frac{\exp(-\kappa_{ij}r)}{r}\right)(r^2-b^2)^{-1/2}\,dr=\frac{e_ie_j}{m_{ij}g^2b}f(x)\,,$$

where x is given by (4.3),

$$f(x)=-\int_1^\infty\frac{d}{d\rho}\left(\frac{\exp(-x\rho)}{\rho}\right)(\rho^2-1)^{-1/2}\,d\rho\,.$$

The function $f(x)$ decreases continuously from $f(0)=1$ to $f(\infty)=0$ as shown in Fig. 2. For all θ, therefore, we obtain, when $y\gg1$,

$$\tan\frac{\theta}{2}=\frac{e_ie_j}{m_{ij}g^2b}f(x)=\frac{f(x)}{2xy}$$

or

$$\cos\theta=\frac{(2xy)^2-f(x)^2}{(2xy)^2+f(x)^2}\,.$$

Let us choose an x_1 satisfying $y^{-1}\ll x_1\ll1$ and divide the domain of

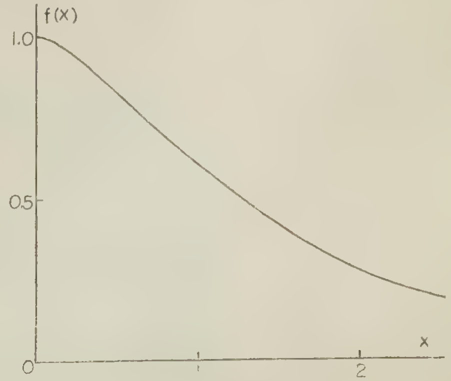

Fig. 2.

$$\int_0^\infty (1-\cos^l \theta) x\,dx \qquad \text{into} \qquad \int_0^{x_1} + \int_{x_1}^1 + \int_1^\infty .$$

Then

$$\int_0^{x_1} \approx \int_0^{x_1} \left[1-\left(\frac{(2xy)^2-1}{(2xy)^2+1}\right)^l\right] x\,dx$$

$$= \frac{1}{8y^2}\int_0^{(2x_1y)^2} \left[1-\left(\frac{\xi-1}{\xi+1}\right)^l\right] d\xi$$

$$= \frac{1}{8y^2}\int_0^{(2x_1y)^2} \sum_{p=1}^{l} (-1)^{p-1} \frac{l!}{p!(l-p)!}\left(\frac{2}{\xi+1}\right)^p d\xi$$

$$\approx \frac{l}{2y^2}[\ln(2x_1 y)-B_l]$$

where

$$B_1=0\,, \qquad B_l=\sum_{p=2}^{l}(-1)^p \frac{(l-1)!\,2^{p-2}}{p!\,(l-p)!\,(p-1)} \qquad \text{for} \quad l \geqq 2\,;$$

$$\int_{x_1}^1 \approx \int_{x_1}^1 2l\left[\frac{f(x)}{2xy}\right]^2 x\,dx = \frac{l}{2y^2}\int_{x_1}^1 \frac{f(x)^2}{x}dx$$

$$\approx \frac{l}{2y^2}\left[\ln\frac{1}{x_1} - \int_0^1 \frac{1-f(x)^2}{x}dx\right];$$

$$\int_1^\infty \approx \frac{l}{2y^2}\int_1^\infty \frac{f(x)^2}{x}dx .$$

Hence for $y \gg 1$ we obtain

$$\int_0^\infty (1-\cos^l\theta)x\,dx \approx \frac{l}{2y^2}\left[\ln\frac{2y}{\gamma'} - B_l\right],$$

where

$$\ln\gamma' = \int_0^1 \frac{1-f(x)^2}{x}dx - \int_1^\infty \frac{f(x)^2}{x}dx = 0.384 .$$

Substituting the result into (4.6) we have

$$F_r^l(\zeta) \approx l\zeta^r \int_0^\infty \left(\ln\frac{2y}{\gamma'} - B_l\right) y^{r-1}\exp(-\zeta y)\,dy$$

$$= (r-1)!\,l\left(\ln\frac{2}{\gamma'\zeta} - B_l\right) + l\int_0^\infty \ln\eta\cdot\eta^{r-1}\exp(-\eta)\,d\eta .$$

Let the last integral be $(r-1)!\,I_r$, then holds the recurrence formula

$$I_{r+1} = I_r + r^{-1} \qquad \text{for} \quad r \geqq 1\,,$$

and

$$I_1 = \lim_{\delta\to 0}\int_\delta^\infty \ln\eta\cdot\exp(-\eta)\,d\eta$$

$$= \lim\left[-\left\{\ln\eta\cdot\exp(-\eta)\right\}_\delta^\infty + \int_\delta^\infty \frac{\exp(-\eta)}{\eta}d\eta\right]$$

$$= -\int_0^1 \frac{1-\exp(-\eta)}{\eta}d\eta + \int_1^\infty \frac{\exp(-\eta)}{\eta}d\eta$$

$$= \ln(1/\gamma)\,,$$

where $\ln\gamma$ is the Euler constant 0.577. Our final result for the asymptotic form is, therefore,

$$F_r^l(\zeta) \approx (r-1)!\,l\,[\ln(2/\gamma\gamma'\zeta) - B_l + C_r]\,,$$

where

$$C_1=0\,,\qquad C_r=\frac{1}{r-1}+\frac{1}{r-2}+\cdots+1\qquad\text{for}\quad r\geqq 2\,.$$

This is equivalent to (4.7) since the constant $2/\gamma\gamma'$ is close to 3/4.

§ 5. Ion-Electron Relaxation

In this and next sections we consider a plasma composed of one type of positive ion (species 1) and electrons (species 2). The mass, charge and number density of the ion will be denoted by m_1, $e_1=Ze$ and n_1 and those of the electron by m_2, $e_2=-e$ and n_2, respectively. We assume $Zn_1=n_2$ and $Z\ll(m_1/m_2)^{1/2}$.

Since the mass ratio is far from unity, energy transfer per unit time is much smaller between an electron and an ion than between electrons or between ions. Hence the ion temperature T_1 and the electron temperature T_2 are often different although the velocity ditributions are both uniform and Maxwellian:

$$f_i(\boldsymbol{c}_j)=n_j\left(\frac{m_j}{2\pi kT_j}\right)^{3/2}\exp\left(-\frac{m_jc_j^2}{2kT_j}\right)\tag{5.1}$$

($j=1$ and 2) $\boldsymbol{c}_j$ being the particle velocities. These velocity distributions vary with time t through the temperatures only:

$$\frac{\partial f_j}{\partial t}=\left(\frac{m_jc_j^2}{2kT_j}-\frac{3}{2}\right)\frac{f_j}{T_j}\frac{dT_j}{dt}\,,\tag{5.2}$$

Our aim is to calculate the rate of relaxation between ion and electron temperatures.

The $\partial f_1/\partial t$ for ions is given by its time rate of increase due to encounters with electrons:

$$\left(\frac{m_1c_1^2}{2kT_1}-\frac{3}{2}\right)\frac{f_1}{T_1}\frac{dT_1}{dt}=\iiint(f_1'f_2'-f_1f_2)gb\,db\,d\varepsilon\,d\boldsymbol{c}_2\,,$$

in which $g=|\boldsymbol{c}_1-\boldsymbol{c}_2|$ as in § 4. Here $f_1'f_2'-f_1f_2$ is the abbreviation for $f_1(\boldsymbol{c}_1')f_2(\boldsymbol{c}_2')-f_1(\boldsymbol{c}_1)f_2(\boldsymbol{c}_2)$; $\boldsymbol{c}_1'$ and $\boldsymbol{c}_2'$ are the final velocities of an ion and an electron encountering with the initial velocities $\boldsymbol{c}_1$, $\boldsymbol{c}_2$, the impact parameter b and the diffraction azimuth ε for the orbit of relative motion. Multiplying both sides by $(m_1c_1^2/2kT_1)-(3/2)$ and integrating with respect to $\boldsymbol{c}_1$, we obtain

$$\frac{3}{2}n_1\frac{1}{T_1}\frac{dT_1}{dt}=\iiiint\left(\frac{m_1c_1^2}{2kT_1}-\frac{3}{2}\right)(f_1'f_2'-f_1f_2)gb\,db\,d\varepsilon\,d\boldsymbol{c}_1\,d\boldsymbol{c}_2\,.$$

The right-hand side can be transformed into

$$-\frac{m_1}{2kT_1}\iiiint(c_1^2-c_1'^2)f_1f_2\,gb\,db\,d\varepsilon\,d\boldsymbol{c}_1\,d\boldsymbol{c}_2$$

by use of the inverse encounters for $f_1'f_2'$. Introducing the center-of-mass velocity $\boldsymbol{G}$ and the relative velocity $\boldsymbol{g}$ by

$$\boldsymbol{G}=\frac{m_1}{m_1+m_2}\boldsymbol{c}_1+\frac{m_2}{m_1+m_2}\boldsymbol{c}_2\qquad\text{and}\qquad\boldsymbol{g}=\boldsymbol{c}_1-\boldsymbol{c}_2\,,$$

we have

$$c_1^2-c_1'^2=\frac{2m_2}{m_1+m_2}\boldsymbol{G}\cdot(\boldsymbol{g}-\boldsymbol{g}')\,,$$

where $\boldsymbol{g}'\equiv\boldsymbol{c}_1'-\boldsymbol{c}_2'$ is the relative velocity after encounter. Hence

$$\frac{3}{2}n_1k\frac{dT_1}{dt}=-\frac{m_1m_2}{m_1+m_2}\iiiint f_1f_2\boldsymbol{G}\cdot(\boldsymbol{g}-\boldsymbol{g}')gb\,db\,d\varepsilon\,d\boldsymbol{c}_1\,d\boldsymbol{c}_2\,.$$

Taking two unit vectors, $\boldsymbol{h}$ and $\boldsymbol{i}$, perpendicular to $\boldsymbol{g}$ and to each other, we can express $\boldsymbol{g}'$ as

$$\boldsymbol{g}'=\boldsymbol{g}\cos\theta+g\boldsymbol{h}\sin\theta\cos\varepsilon+g\boldsymbol{i}\sin\theta\sin\varepsilon\ .$$

Hence

$$\iint(\boldsymbol{g}-\boldsymbol{g}')gb\,db\,d\varepsilon=2\pi\int_0^\infty\boldsymbol{g}(1-\cos\theta)gb\,db=2\pi\phi^{(1)}\boldsymbol{g}$$

by the definition (4.1) for $\phi^{(1)}$. Thus we have

$$n_1k\frac{dT_1}{dt}=-\frac{4\pi}{3}\frac{m_1m_2}{m_1+m_2}\iint f_1f_2\boldsymbol{G}\cdot\boldsymbol{g}\phi^{(1)}\,d\boldsymbol{c}_1\,d\boldsymbol{c}_2\ .$$

Similarly

$$n_2k\frac{dT_2}{dt}=\frac{4\pi}{3}\frac{m_1m_2}{m_1+m_2}\iint f_1f_2\boldsymbol{G}\cdot\boldsymbol{g}\phi^{(1)}\,d\boldsymbol{c}_1\,d\boldsymbol{c}_2\ .$$

From these two relations we obtain

$$k\frac{d}{dt}(T_2-T_1)=\frac{4\pi}{3}\frac{n_1+n_2}{n_1n_2}\frac{m_1m_2}{m_1+m_2}\iint f_1f_2\boldsymbol{G}\cdot\boldsymbol{g}\phi^{(1)}\,d\boldsymbol{c}_1\,d\boldsymbol{c}_2\ . \tag{5.3}$$

The cross section $\phi^{(1)}$ is a function of the reduced mass $m_1m_2/(m_1+m_2)$ and the relative speed g. In the present case the former can be put equal to m_2, and the latter is

$$g=(c_1^2-2\boldsymbol{c}_1\cdot\boldsymbol{c}_2+c_2^2)^{1/2}\doteqdot c_2-\boldsymbol{c}_1\cdot\boldsymbol{c}_2/c_2\ ,$$

Hence the cross section becomes

$$\phi^{(1)}(g)=\phi^{(1)}(c_2)-\frac{\boldsymbol{c}_1\cdot\boldsymbol{c}_2}{c_2}\frac{\partial\phi^{(1)}}{\partial c_2}\ .$$

Inserting this into (5.3) with $\boldsymbol{G}$ and $\boldsymbol{g}$ expressed in terms of $\boldsymbol{c}_1$ and $\boldsymbol{c}_2$, denoting $\phi^{(1)}(\boldsymbol{c}_2)$ by $\phi^{(1)}$ anew, and neglecting small quantities we have

$$\begin{aligned}k\frac{d}{dt}(T_2-T_1)&=\frac{4\pi}{3}\frac{n_1+n_2}{n_1n_2}\frac{m_2}{m_1}\iint f_1f_2\left[(m_1c_1^2-m_2c_2^2)\phi^{(1)}+\frac{1}{3}m_1c_1^2c_2\frac{\partial\phi^{(1)}}{\partial c_2}\right]d\boldsymbol{c}_1\,d\boldsymbol{c}_2\\&=\frac{(4\pi)^2}{3}\frac{n_1+n_2}{n_2}\frac{m_2}{m_1}\int_0^\infty f_2\left[(3kT_1-m_2c_2^2)\phi^{(1)}+kT_1c_2\frac{\partial\phi^{(1)}}{\partial c_2}\right]c_2^2\,dc_2\ ,\end{aligned}$$

which can be reduced, after integration by parts, to

$$k\frac{d}{dt}(T_2-T_1)=-\frac{(4\pi)^2}{3}\frac{n_1+n_2}{n_2}\frac{(m_2)^2}{m_1}\frac{T_2-T_1}{T_2}\int_0^\infty f_2\phi^{(1)}c_2^4\,dc_2$$

or

$$-\frac{1}{T_2-T_1}\frac{d}{dt}(T_2-T_1)=\frac{32}{3}(n_1+n_2)\frac{m_2}{m_1}\sqrt{\pi}\int_0^\infty\exp(-\tilde{c}_2^2)\phi^{(1)}\tilde{c}_2^4\,d\tilde{c}_2$$

with $\tilde{c}=(m_2/2kT_2)^{1/2}c_2$. Hence, by the definition (4.2) for Ω, we finally obtain

$$-\frac{1}{T_2-T_1}\frac{d}{dt}(T_2-T_1)=\frac{32}{3}(n_1+n_2)\frac{m_2}{m_1}\Omega_{12}^{(1)}(1)\ . \tag{5.4}$$

Here $\Omega_{12}^{(1)}(1)$ is given by (4.2) with (4.7), but it refers to the electron temperature:

$$\Omega_{12}^{(1)}(1)=\left(\frac{2\pi kT_2}{m_2}\right)^{1/2}\left(\frac{Ze_2}{2kT_2}\right)^2\ln\frac{3kT_2}{4Ze^2\kappa_{12}}\ . \tag{5.5}$$

This is an improvement of the corresponding result by previous authors (Compare Spitzer's tract⁶⁾ Eq. (5.31)).

In the particular case where the temperature difference is small, the rate of relaxation, the right-hand side of (5.4), is independent of the time, and $|T_2-T_1|$ is proportional to exp $(-t/\tau)$ with a constant relaxation time τ.

Appendix to § 5.

It is interesting to note that a similar conclusion can be drawn from the viewpoint of the collective motion of plasma oscillation with the thermal energy. The collection of electrons is considered to make thermal oscillations of the wave length greater than the order of the Debye shielding length κ^{-1} (compare Pines and Bohm¹¹⁾). The collective motion in unit volume therefore has approximately κ^3 degrees of freedom. Since each mode of oscillation has the energy of order kT, the electric field due to one mode of oscillation is $(kT)^{1/2}$. Hence the total electric field acting on an ion is of the order of $(\kappa^3 kT)^{1/2}$, the acceleration being $(Ze/m_1)(\kappa^3 kT)^{1/2}$ with the ion mass m_1. The velocity which a rest ion has after one period τ_p of the plasma oscillation is therefore $(Ze/m_1)(\kappa^3 kT)^{1/2}\tau_p$, and after $N(\gg 1)$ periods, $N^{1/2}$ times this quantity. The relaxation time τ is given by the relationship

$$\frac{m_1}{2}\left[\left(\frac{\tau}{\tau_p}\right)^{1/2}\frac{Ze}{m_1}(\kappa^3 kT)^{1/2}\tau_p\right]^2 \sim \frac{1}{2}kT$$

or

$$\tau^{-1} \sim \frac{(Ze)^2}{m_1}\kappa^3\tau_p\,.$$

Since $\kappa^2 \sim ne^2/kT$ and $\tau_p \sim (m_2/ne^2)^{1/2}$ with the number density n and the mass m_2 of electrons, we finally obtain

$$\tau^{-1} \sim n(Ze^2)(kT)^{-3/2} m_2^{1/2} m_1^{-1}\,,$$

which agrees with the previous result so far as the order of magnitude is concerned.

§ 6. Viscosity

Chapman-Cowling's¹⁰⁾ scheme, slightly modified by the present author¹²⁾, of approximation to the coefficient of viscosity will be used in the following. We are to take into account the fact that the ion mass m_1 is much larger than the electron mass m_2, and hence the momentum is transported only through ions.

Thus, first approximation η_{I} to the viscosity η is given by

$$\eta_{\text{I}} = 5kT/8\Omega_{11}^{(2)}(2)\,.$$

Substituting our expression for Ω, (4.5) with (4.7), we obtain

$$\eta_{\text{I}} = \frac{5}{8}\left(\frac{m_1 kT}{\pi}\right)^{1/2}\left(\frac{kT}{Z^2e^2}\right)^2\left(\ln\frac{3kT}{4Z^2e^2\kappa_{11}}+\frac{1}{2}\right)^{-1}. \tag{6.1}$$

A second approximation η_{II} is of the form

$$\eta_{\text{II}} = \eta_{\text{I}}(1+\mathcal{E})\,, \tag{6.2}$$

where

$$\begin{aligned}\mathcal{E} &= \frac{3}{49}\left(\frac{7}{2}-\frac{\Omega_{11}^{(2)}(3)}{\Omega_{11}^{(2)}(2)}\right)^2\\ &= \frac{3}{49}\left(\frac{3}{2}-\frac{1}{\ln(3kT/4Z^2e^2\kappa_{11})+\frac{1}{2}}\right)^2.\end{aligned} \tag{6.3}$$

Since $\mathcal{E}$ is small, it is natural to expect that higher approximations are close to the second. In fact, at the weak-interaction limit where $\ln(kT/Z^2e^2\kappa_{11})\gg 1$, η is equal to $1.16\eta_{\text{I}}$, while $\eta_{\text{II}}=1.14\eta_{\text{I}}$.

Coefficients of other transport phenomena can be treated likewise, although first approximations are not accurate enough and higher ones are complicated.

The author wishes to thank Mr. Y. Midzuno for helpful discussions.

Note added in proof. Collision cross sections for the shielded Coulomb potential have just been treated in a similar manner by R.L. Liboff: Phys. Fluids **2** (1959) 40.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 14, No. 4, APRIL, 1959

The General Theory of Transport: The Difference between Electric Field and Density Gradient

By Tadao KASUYA

Physical Institute, Nagoya University

(Received August 4, 1958)

The difference between the electric currents due to the external electric field and the gradient of the chemical potential is discussed based on the general theory of transport coefficients. In the limit of weak magnetic field ($\hbar w \ll \kappa T$, where ω is Larmor frequency, κ Boltzmann constant, T absolute temperature) and weak collision ($\hbar/\tau \ll \kappa T$, where τ means the relaxation time), Einstein relation is applicable. In the limit of strong magnetic field, the current due to the gradient of the chemical potential exhibits the oscillatory behaviour similar to that of diamagnetism.

§ 1. Introduction

In the previous paper titled "A Theory of Impurity Conduction I1)" (hereafter refered to as [I] for brevity), we discussed the general theory of transport equation and emphasized that under the strong magnetic field the well-known Einstein relation is not applicable. That is, the electrical currents due to the external electric field and the gradient of the chemical potential are different in general, because the former is induced by the motion due to the external force and the latter is induced by that due to the internal strain of the system.

In this paper, we discuss this problem in more detail in the case that the Hamiltonian of the system is written by the sum of one electron Hamiltonian, namely in the case of impurity scattering. In the case that the many body correlation is essentially important, the situation is fairly complicated and is not treated in this paper.

§ 2. General Discussions

As was treated in [I], when the external force is written in terms of the potential $\varphi(\boldsymbol{r}, t)$, the expectation value of the electrical current density operator $\boldsymbol{j}(\boldsymbol{r})$ at position $\boldsymbol{r}$ and time t is given by

$$\langle \boldsymbol{j}(\boldsymbol{r}, t)\rangle = \mathrm{Tr}\exp(-\beta\mathscr{H})\left\{\boldsymbol{j}(\boldsymbol{r}) + \frac{1}{e}\int_0^t dt_1\int_0^\beta d\lambda\int d\boldsymbol{r}'\nabla'\varphi(\boldsymbol{r}', t)\cdot\boldsymbol{j}(\boldsymbol{r}')\boldsymbol{j}(\boldsymbol{r}, t_1 + i\hbar\lambda)\right\} \tag{1}$$

where

$$\beta = \frac{1}{\kappa T}, \tag{2}$$

$$\boldsymbol{j}(\boldsymbol{r}, t) = \exp(i\mathscr{H}t/\hbar)\frac{e}{2}\sum_i\{\boldsymbol{v}_i\delta(\boldsymbol{r}-\boldsymbol{r}_i) + \delta(\boldsymbol{r}-\boldsymbol{r}_i)\boldsymbol{v}_i\}\exp(-i\mathscr{H}t/\hbar), \tag{3}$$

and $\mathscr{H}$ is the Hamiltonian of the system.

When the potential is given by

$$\varphi(\boldsymbol{r}, t) = \varphi_k\exp(i\boldsymbol{k}\boldsymbol{r}), \tag{4}$$

it is convenient to use the Fourier component of the current density operator $\boldsymbol{j}(\boldsymbol{r})$, namely

$$\begin{aligned}\boldsymbol{j}_k &= \int \boldsymbol{j}(\boldsymbol{r}) \exp(i\boldsymbol{kr})\, d\boldsymbol{r} \\ &= \frac{e}{2} \sum_i (\boldsymbol{v}_i \exp(i\boldsymbol{kr}_i) + \exp(i\boldsymbol{kr}_i)\, \boldsymbol{v}_i)\,. \end{aligned} \tag{5}$$

Then, Eq. (1) becomes

$$\langle \boldsymbol{j}_{-k}(t)\rangle_{\text{force}} = \mathrm{Tr} \exp(-\beta \mathscr{H}) \left\{ \boldsymbol{j}_{-k} + ik\varphi_k e^{-1} \int_0^t dt_1 \int_0^\beta d\lambda \cdot \boldsymbol{j}_k \boldsymbol{j}_{-k}(t_1 + i\hbar\lambda) \right\}. \tag{6}$$

On the other hand, when there exists the internal strain and it is given by the potential of stress, that is, $-\varphi_k \exp(i\boldsymbol{kr})$, the expectation value of the current density operator is given as follows as is given in [I],

$$\langle \boldsymbol{j}_{-k}(t)\rangle_{\text{strain}} = \langle \boldsymbol{j}_{-k}(t)\rangle_{\text{ad}} + \langle \boldsymbol{j}_{-k}(t)\rangle_{\text{force}}\,, \tag{7}$$

$$\langle \boldsymbol{j}_{-k}(t)\rangle_{\text{ad}} = -\mathrm{Tr} \exp(-\beta \mathscr{H}) \int_0^\beta d\lambda\, \varphi_k n_k(i\hbar\lambda)\, \boldsymbol{j}_{-k}\,, \tag{7}$$

where

$$n_k(i\hbar\lambda) = \exp(\lambda \mathscr{H}) \sum_i \exp(i\boldsymbol{kr}_i) \exp(-\lambda \mathscr{H})\,. \tag{9}$$

In Eq. (7), the second term is the same as the expression (6) and the first term, that is given by Eq. (7), is the additive term characteristic of the strain. Our main problem is how to evaluate Eq. (8).

At first, we calculate Eq. (6). We assume here that the Hamiltonian $\mathscr{H}$ is written as the sum of the one electron Hamiltonian and rewrite the operators $\boldsymbol{j}_k$ and n_k by the second quantization method taking the eigenfunction of the one electron Hamiltonian as the basic wave function. Then performing the integrations with respect to t_1 and λ, Eq. (6) becomes

$$\begin{aligned}\langle \boldsymbol{j}_{-k}(t)\rangle_{\text{force}} = \frac{ik\varphi_k}{e\kappa T} \mathrm{Tr} \exp(-\beta \mathscr{H}) \Bigg[& \sum_{s \neq s'}\sum \cdot \langle s|\boldsymbol{j}_k|s'\rangle\langle s'|\boldsymbol{j}_{-k}|s\rangle \frac{\hbar}{E-E'} \frac{e^{\mathcal{E}-\mathcal{E}'}-1}{\mathcal{E}-\mathcal{E}'} \\ & \times \left\{ \frac{1}{i}\left(1-\cos\frac{E-E'}{\hbar}t\right) + \sin\frac{E-E'}{\hbar}t \right\} \boldsymbol{n}_s(1-\boldsymbol{n}_{s'}) \\ & + \sum_s \sum_{s'} \cdot \langle s|\boldsymbol{j}_k|s\rangle\langle s'|\boldsymbol{j}_{-k}|s'\rangle t \boldsymbol{n}_s \boldsymbol{n}_{s'} \Bigg]\,, \end{aligned} \tag{10}$$

where $\boldsymbol{n}_s$ is the operator of the occupation number of the state s and has the eigenvalue 0 or 1. Performing the trace as usual, $\boldsymbol{n}_s$ is replaced by the Fermi distribution function in thermal equilibrium $f(\mathcal{E})$, that is

$$\boldsymbol{n}_s \to f(\mathcal{E}) = [e^{\mathcal{E}}+1]^{-1}\,, \qquad \mathcal{E} = \frac{E_s - \zeta}{\kappa T}\,. \tag{11}$$

In the second term, when s' is the same state as s, the relation $\boldsymbol{n}_s\boldsymbol{n}_s = \boldsymbol{n}_s$ is used. Thus Eq. (10) becomes

$$\begin{aligned}\langle \boldsymbol{j}_{-k}(t)\rangle_{\text{force}} = \frac{ik\varphi_k}{e\kappa T} \Bigg[& \sum_{s \neq s'}\sum \cdot \langle s|\boldsymbol{j}_k|s'\rangle\langle s'|\boldsymbol{j}_{-k}|s\rangle \frac{\hbar}{E-E'} F(s, s') \\ & \times \left\{ \frac{1}{i}\left(1-\cos\frac{E-E'}{\hbar}t\right) + \sin\frac{E-E'}{\hbar}t \right\} \\ & + \sum_s \sum_{s'} \cdot \langle s|\boldsymbol{j}_k|s\rangle\langle s'|\boldsymbol{j}_{-k}|s'\rangle \{f(\mathcal{E})f(\mathcal{E}') + f_1(\mathcal{E})\delta_{ss'}\} t \Bigg]\,; \end{aligned} \tag{12}$$

where

$$F(s,s')=\frac{e^{\varepsilon}-e^{\varepsilon'}}{\varepsilon-\varepsilon'}f(\varepsilon)f(\varepsilon')=F(s',s)\,, \tag{13}$$

and

$$f_1(\varepsilon)=f(\varepsilon)\{1-f(\varepsilon)\}=[(e^{\varepsilon}+1)(1+e^{-\varepsilon})]^{-1}\,. \tag{14}$$

This equation is equivalent to Eq. (22) of [I] when $\boldsymbol{j}_k$ is replaced by $\boldsymbol{j}$.

Next, we evaluate Eq. (8) by the same method as the above, then we obtain the equation

$$\langle \boldsymbol{j}_{-k}(t)\rangle_{\mathrm{ad}}=-\frac{\varphi_k}{\kappa T}\Big[\sum_{s\neq s'}\sum\langle s|n_k|s'\rangle\langle s'|\boldsymbol{j}_{-k}|s\rangle F(s,s')$$
$$+\sum_{s}\sum_{s'}\langle s|n_k|s\rangle\langle s'|\boldsymbol{j}_{-k}|s'\rangle\{f(\varepsilon)f(\varepsilon')+f_1(\varepsilon)\delta_{ss'}\}\Big]. \tag{15}$$

Considering the relations

$$\sum_{s}\langle s|n_k|s\rangle f(\varepsilon)=0\,, \tag{16}$$

and

$$F(s,s)=\lim_{E'\to E}F(s,s')=f_1(\varepsilon)\,, \tag{17}$$

Eq. (15) becomes

$$\langle \boldsymbol{j}_{-k}(t)\rangle_{\mathrm{ad}}=-\frac{\varphi_k}{\kappa T}\sum_{s}\sum_{s'}\langle s|n_k|s'\rangle\langle s'|\boldsymbol{j}_{-k}|s\rangle F(s,s')\,. \tag{18}$$

Now we assume that the external potential $\varphi(\boldsymbol{r})$ varies very slowly in space and it is sufficient to take only the linear terms of k (hereafter we choose the direction of the gradient of the potential, $\boldsymbol{k}$, as the x-axis). Then we may expand n_k as $1+i\boldsymbol{k}\sum_i \boldsymbol{r}_i+\cdots$ and take only the linear terms of k. Further replacing the matrix element of $\boldsymbol{r}_i$ by that of $\boldsymbol{j}_i$, Eq. (18) becomes

$$\langle \boldsymbol{j}_{-k}(t)\rangle_{\mathrm{ad}}=-\frac{i\varphi_k}{e\kappa T}\Big[\sum_{s\neq s'}\sum\{\boldsymbol{k}\cdot\langle s|\boldsymbol{j}|s'\rangle\langle s'|\boldsymbol{j}|s\rangle-\langle s|\boldsymbol{j}|s'\rangle\boldsymbol{k}\cdot\langle s'|\boldsymbol{j}|s\rangle\}\frac{\hbar}{E-E'}\{F(s,s')-f_1(\varepsilon)\}\Big]. \tag{19}$$

The above expansion of n_k may be allowed when the extension of the electron wave function or the mean free path of the electron is smaller than k^{-1}.

From the above equation, we can obtain easily the following result that the additive current of x direction vanishes. This result implies that the well-known Kelvin relations concerning the thermoelectricity are satisfied in general.

The additive current perpendicular to the potential gradient does not vanish in general when the system has a particular direction (say the z-direction). The typical cases are such that the external magnetic field is applied in the z-direction, or the electron spins are ordered in the z-direction. Even in these cases, however, the additive current becomes very small if $F(s,s')$ and $\frac{1}{2}\{f_1(\varepsilon)+f_1(\varepsilon')\}$ are nearly equal. From Eq. (13), the above condition is equivalent to

$$\frac{E_s-E_{s'}}{\kappa T}\ll 1\,. \tag{20}$$

In the phenomena such as the anomalous Hall current in ferromagnetic metals, where the inter-band transition is essentially important, the above condition is not applicable. Concerning this current there were some disputes and detailed discussions may be given in another paper[2].

In the phenomena where the intra-band transition is important, the above condition is written approximately as

$$\frac{\hbar\omega}{\kappa T}\ll 1\,,\qquad \frac{\hbar}{\tau\kappa T}\ll 1\,, \tag{21}$$

where ω is the Larmor frequency

$$\omega=\frac{eH}{mc}\,, \tag{22}$$

and τ is the ordinary relaxation time, because the matrix element $\langle s|\boldsymbol{j}|s'\rangle$ is nearly zero when the energy difference $E_s - E_{s'}$ is larger than $\hbar\omega$ or $\hbar/\tau$. The conditions, (21), are just equivalent to the condition that the ordinary Boltzmann equation is applicable. As was discussed in [I], the condition that the Boltzmann-Bloch equation is applicable is approximately replaced by $\hbar/\tau\zeta \ll 1$ instead of $\hbar/\tau\kappa T \ll 1$, the same situation is also seen in Eq. (19). The more qualitative discussions in the case of strong magnetic field are given in the following section.

§ 3. Hall Current in a Strong Magnetic Field

As is discussed in the above section, the Hall currents induced by the electric field and the gradient of the chemical potential differ from each other when $\hbar\omega/\kappa T$ is much lager than unity. Here, we consider this problem in more detail. For simplicity, we consider the case that the collision effect is negligibly small and the system is treated as free electron system with effective mass m.

We choose the direction of the magnetic field as the z-axis, the direction of the force as the x-axis and consider the electrical current in the y-axis. We choose the gauge to write the vector potential $\boldsymbol{A}(\boldsymbol{r})$ as

$$A_x = A_z = 0\,, \qquad A_y = Hx\,. \tag{23}$$

Then, the Hamiltonian is written as

$$\mathscr{H} = \frac{1}{2m} \sum_i \left\{ p_{xi}^2 + \left(p_{yi} + \frac{e}{c} H x_i \right)^2 + p_{zi}^2 \right\}. \tag{24}$$

The eigenfunction of this Hamiltonian is

$$\psi_{k_z k_y n}(\boldsymbol{r}) = \exp(ik_y y + ik_z z) \exp\left(-\frac{(x-x_0)^2}{2a^2} \right) H_n\left(\frac{x-x_0}{a} \right), \tag{25}$$

where $H_n(x)$ represents the function of the n-th order harmonic oscillation with the centre at $x = x_0$, and

$$a^2 = \frac{\hbar c}{eH}\,, \qquad x_0 = -\frac{\hbar c}{eH} k_y\,. \tag{26}$$

The eigenvalue of the Hamiltonian is written as

$$E_{nk_z} = n\hbar\omega + \frac{\hbar^2 k_z^2}{2m}\,, \tag{27}$$

where

$$\omega = \frac{eH}{mc}\,. \tag{28}$$

In the steady state, the Hall currents due to the electric field and the gradient of the chemical potential are written from Eqs. (19) and (12) as

$$\langle j_{y,-k} \rangle_{\text{force}} = \frac{ik\varphi_k}{2e\kappa T} \sum_{s \neq s'}\sum \{ \langle s|j_x|s'\rangle\langle s'|j_y|s\rangle - \langle s|j_y|s'\rangle\langle s'|j_x|s\rangle \} \frac{\hbar}{E-E'} F(s, s')\,. \tag{29}$$

$$\langle j_{y,-k} \rangle_{\text{strain}} = \frac{ik\varphi_k}{2e\kappa T} \sum_{s \neq s'}\sum \{ \langle s|j_x|s'\rangle\langle s'|j_y|s\rangle - \langle s|j_y|s'\rangle\langle s'|j_x|s\rangle \} \frac{\hbar}{E-E'} f_1(\mathcal{E})\,. \tag{30}$$

because, considering the conditions mentioned above, the first term of Eq. (19) cancels out the current of Eq. (12) in steady state.

Using our model, the matrix elements of j_x and j_y become

$$\left. \begin{aligned} \langle s|j_x|s'\rangle &= ie\left(\frac{\hbar\omega}{2m} \right)^{1/2} \langle s|a_+ - a_-|s'\rangle\,, \\ \langle s|j_y|s'\rangle &= e\left(\frac{\hbar\omega}{2m} \right)^{1/2} \langle s|a_+ + a_-|s'\rangle\,, \end{aligned} \right\} \tag{31}$$

where the matrix elements of $a_\pm$ are written as

$$\langle n|a_+|n-1\rangle=\langle n-1|a_-|n\rangle=\sqrt{n}\ , \tag{32}$$

other elements being zero.

Eqs. (29) and (30) become

$$\langle j_{y,-k}\rangle_{\text{force}}=ik\varphi_k\frac{\hbar e}{2m\kappa T}\sum_s\{nF(s,s-1)+(n+1)F(s,s+1)\}\ , \tag{33}$$

$$\langle j_{y,-k}\rangle_{\text{strain}}=ik\varphi_k\frac{\hbar e}{2m\kappa T}\sum_s(2n+1)f_1(\mathcal{E})\ , \tag{34}$$

where $(s-1)$ means the state $(n-1, k_y, k_z)$.

At first, we consider Eq. (33). Performing the summation of k_y and k_z replaced by integration, Eq. (33) becomes

$$\langle j_{y,-k}\rangle_{\text{force}}=ik\varphi_k\frac{\sqrt{2}}{\pi^2}\frac{em^{1/2}}{\hbar^2}\sum_{n=0}^{[\zeta/\hbar\omega]}\sqrt{\zeta-n\hbar\omega}\ , \tag{35}$$

where $[x]$ means the integral part of x. On the other hand, the chemical potential ζ is determined by

$$\sum f(\mathcal{E})=N\ , \tag{36}$$

where N is the number density of the electron. Now performing integration over k_y and k_z one obtains from Eq. (36)

$$\frac{\sqrt{2}}{\pi^2}\frac{\omega m^{3/2}}{\hbar^2}\sum_{n=0}^{[\zeta/\hbar\omega]}\sqrt{\zeta-n\hbar\omega}=N\ . \tag{37}$$

Substituting this result into Eq. (35), we get

$$\langle j_{y,-k}\rangle_{\text{force}}=ik\varphi_k\frac{c}{H}N\ . \tag{38}$$

This result means the well-known fact that when the external electric field $F=k\varphi_k/e$ is applied in the direction perpendicular to the magnetic field, each electron moves in the direction perpendicular both to the magnetic and the electric field with the velocity Fc/H.

Next, we consider Eq. (34). To perform the integration over k_z easily, we approximate the function $f_1(\mathcal{E})$ as follows

$$\begin{aligned} f_1(\mathcal{E})&=1\ , && -\tfrac{1}{2}<\mathcal{E}<\tfrac{1}{2}\\ &=0\ , && \mathcal{E}<-\tfrac{1}{2}\ \text{ or }\ \tfrac{1}{2}<\mathcal{E}\ . \end{aligned} \tag{39}$$

Then Eq. (34) becomes

$$\langle j_{y,-k}\rangle_{\text{strain}}=ik\varphi_k\frac{\sqrt{2}}{\pi^2}\frac{e(m\zeta)^{1/2}}{\hbar^2}\sum_s G_n\ , \tag{40}$$

$$\begin{aligned} G_n=(n+\tfrac{1}{2})\frac{\hbar\omega}{\kappa T\zeta^{1/2}}&\{\sqrt{P(\zeta-n\hbar\omega+\kappa T/2)}\\ &-\sqrt{P(\zeta-n\hbar\omega-\kappa T/2)}\}\ , \end{aligned} \tag{41}$$

$$\begin{aligned} P(y)&=y\ , && 0\le y\\ &=0\ , && y<0\ . \end{aligned} \tag{42}$$

In Fig. 1, $\sum_n G_n$ is plotted as a function of $x=\zeta/\hbar\omega$. When $\zeta-n\hbar\omega$ is much larger than κT, G_n is written approximately as

$$G_n=\tfrac{1}{2}(n+\tfrac{1}{2})/\sqrt{x(x-n)}\ . \tag{43}$$

This approximation is equivalent to replacing $f_1(\mathcal{E})$ by $\delta(\mathcal{E})$-function as usual which is not a good approximation when $\zeta-n\hbar\omega$ becomes smaller than κT because in this range the state density of the system becomes infinity. When the broadening of each level by the collision mechanism, namely $\hbar/\tau$, becomes larger than κT, the height of each peak of $\sum_n G_n$ becomes $(1+(1/2n))\sqrt{\zeta\tau/\hbar}$ instead of $(1+(1/2n))\sqrt{\zeta/\kappa T}$. Thus, changing the value of the magnetic field H, $\langle j_{y,-k}\rangle_{\text{strain}}$ oscillates with sharp peaks at the points where the condition

$$\sum_n G_n=\frac{\zeta}{nT}\sum_n\left(n+\frac{1}{2}\right)x^{-3/2}\times\{\sqrt{p(x-n+xnT/2\zeta)}-\sqrt{p(x-n-xnT/2\zeta)}\}$$

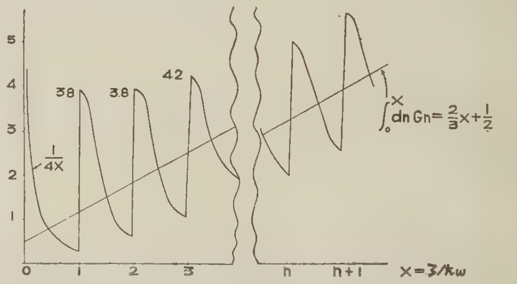

Fig. 1. The graph of $\Sigma_n G_n$ as a function of $\zeta/\hbar\omega$ $\Sigma_n G_n$ hanse peaks at points $x=n=$integer with the height of $\left(1+\frac{1}{2n}\right)\sqrt{\frac{\zeta}{nT}}$. In this graph we plot the curve by choosing the value of $\sqrt{\zeta_0/nT}$ as 3, where ζ_0 is the value of the Fermi energy when the external magnetic field is zero, and the value of ζ as a function of x is obtained in Fig. 2. The straight line is obtained by replacing Σ_n by integral $\int dn$.

$$x=\frac{\zeta}{\hbar\omega}=I=\text{integer} \tag{44}$$

is satisfied. The chemical potential ζ varies also with H as is seen from Eq. (37) and Fig. 2. When $\zeta/\hbar\omega$ is larger than unity, however, the change of ζ is much smaller than that of $\sum_n G_n$ and ζ is regarded nearly constant, namely

$$\zeta=\zeta_0=\frac{\hbar^2}{2m}(3\pi^2 N)^{2/3}, \tag{45}$$

which is the same as the value where the magnetic field is zero. When $\zeta/\hbar\omega$ becomes smaller than unity, however, the change of ζ becomes large and not negligible compared to $\sum_n G_n$. Then ζ is given by

$$\zeta=\frac{\pi^4}{2}N^2\frac{\hbar^4}{m^3\omega^2}=\frac{4}{9}\frac{\zeta_0{}^3}{(\zeta\omega)^2}, \tag{46}$$

and thus

$$\langle j_{y,-k}\rangle_{\text{strain}}=ik\varphi_k\frac{1}{2\pi^4}\frac{m^2\omega^2}{N\hbar^3}. \tag{47}$$

This character of the Hall current is recognized as follows. As is shown in Fig. 3, the current density flows in the y-direction when the magnetic field and the density gradient exist respectively in the z- and x-directions[3]. When the density gradient is induced by the gradient of the chemical potential $\nabla\zeta$, this current is proportional to the state density at the Fermi surface when the system is in Fermi degeneracy. Thus the oscillatory behaviour of the current density $j_y(\boldsymbol{r})$ is just the same as that of the state density at the Fermi surface. Thus the peculiar behaviour of $j_y(\boldsymbol{r})$ in a range of extremely strong magnetic field, namely $\zeta<\hbar\omega$, is also understandable such that the smaller N is, the smaller k_{z0} is, and the larger H is, the smaller the distance between the neighbouring states $2\pi\hbar c/eH$ is, and thus the larger the state density at the Fermi surface is.

$$\left(\frac{\zeta_0}{\zeta}\right)^{3/2}=\frac{3}{2}x^{-3/2}\sum_{n=0}^{[x]}\sqrt{x-n}$$

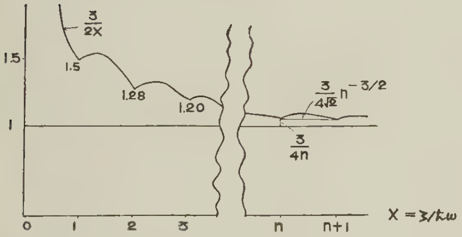

Fig. 2. The graph of $(\zeta_0/\zeta)^{3/2}$ as a function of $x=\zeta/\hbar\omega$.

$(\zeta_0/\zeta)^{3/2}$ has minima for integral values of x. If we replace the summation over n by integration, (ζ_0/ζ) becomes unity, that is, ζ becomes ζ_0. Which is the value corresponding to the case of zero external magnetic field. Each minimum of $(\zeta/\zeta^0)^{3/2}$ is larger than unity and the difference becomes $(3/4n)$ for sufficiently large value of n. The amplitude of the oscillation of $(\zeta/\zeta_0)^{3/2}$ becomes $(3/4\sqrt{2})n^{-3/2}$ for sufficiently large n as is shown in the above graph.

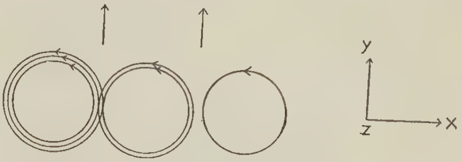

Fig. 3. A schematic explanation of the current density in the y-direction when the external magnetic field is applied in the z-direction and the density gradient exists in the x-direction.

§ 4. Concluding Remarks*

Knowing my conclusion concerning the Einstein relation S. Nakajima has reformulated this problem from the stand point of kinetic theory and obtained the same result as mine (Progr. Theor. Phys. **20** (1958) 948). Unfortunately publication of the present paper was unduly put off because of long delay in the process of reference after the receipt of the manuscript by the editorial committee.

Electrical and Thermal Conductivity of Monovalent Metals; The Influences of Coulomb Interaction

By Tadao KASUYA and Kazuo YAMADA

Physical Institute, Nagoya University

(Received October 8, 1958)

The electrical and thermal conduction phenomena are discussed by taking account of the effects of Coulomb interaction and Umklapp processes of electron-phonon collisions. The contributions of electron binary collisions through screened short range Coulomb potential to a relaxation processes are evaluated. The effect to the coupling parameter of electron-phonon interaction is also considered in the range of called Umklapp process. The effect of phonon drag is not considered in this paper.

§ 1. Introduction

The conduction phenomena of monovalent metals have been investigated by many authors, since Bloch. However, there are some ambiguous points even in alkali metals, where the theoretical treatment seems to be rather simple. In particular, how to evaluate the effects of the Coulomb interactions between electrons is one of the most serious problems and many attempts have been done so far. Recent works of D. Bohm—D. Pines[1)] and J. Bardeen—D. Pines[2)] have made it considerably clear by introducing the plasma mode. Our attempt in this paper is to see what effects should be caused by taking account of the Coulomb interactions between the conduction electrons on the conduction phenomena in metals. Here we shall confine ourselves to the case of sodium.

The problems considered are the following: i) The contribution of electron binary collisions by screened short range forces to the relaxation process. ii) The contribution of the Coulomb interactions to the effective coupling parameter of electron-phonon interactions, including the range of Umklapp process. iii) The deviation of energy spectrum from free electron approximation by the correlation effect between electrons. In turn, this may give rise to the change of electronic level density. In § 2, these problems are discussed in some detail.

In § 3 and Appendix II we shall obtain the concrete expressions for the electrical and thermal conductivity taking account of so called Umklapp process and finally these results will be compared with the experiments.

§ 2. Preliminary Discussions

i) *Electron binary collisions*

According to the theory of Bohm—Pines, the conduction electrons in metals exhibit both the collective and the individual particle motions. The long range part of the Coulomb force which corresponds to the long wave length part of the electronic density fluctuations causes the organized oscillation of the electron system as a whole. This mode is so called plasma oscillation. While, the motions corresponding to the short range part of the electronic density fluctuations are described by individual particle modes, and they interact with one another through the screened short range Coulomb forces. In this section, we shall consider the electron binary collisions by this short range potentials.

If the individual electronic state is described by a plane wave, the total wave vector is conserved in a process of electron binary collision, i.e., $\boldsymbol{k}_1+\boldsymbol{k}_2-\boldsymbol{k}_3-\boldsymbol{k}_4=0$ where the $\boldsymbol{k}_1$ and $\boldsymbol{k}_2$ mean the wave vectors of two initial electrons, $\boldsymbol{k}_3$ and $\boldsymbol{k}_4$ the wave vectors of final electrons. Therefore, these processes will not make any contribution to the electrical resistance in the first approximation. In higher approximation, of course, it might give rise to some effects even in this process because the distribution function of the electronic state undergoes a certain change by collision. However, in usual steady state in which the electrical resistance is mainly determined by electron-phonon collisions, the distribution function of Kramers type

$$[\{\exp(\hbar^2k^2/2m-\zeta)/kT+\boldsymbol{c}\cdot\boldsymbol{k}\}+1]^{-1},$$

where $\boldsymbol{c}$ is a constant vector and means a displacement of the gravity center of Fermi sphere, will be a good approximation. On the other hand, this Kramers distributions function represents the generalized equilibrium state of the system, where only the processes of electron binary collisions conserving the total energy and wave vector occurs. Thus this kind of effect also scarcely contributes to the electrical resistance. However, the electron is to be represented by Bloch's wave function, since it moves in a periodic crystalline field, and then there occur the so called Umklapp processes, say $\boldsymbol{k}_1+\boldsymbol{k}_2-\boldsymbol{k}_3-\boldsymbol{k}_4=\boldsymbol{K}_n$ where $\boldsymbol{K}_n$ means the principal wave vector of the reciprocal lattice. Thus only these Umklapp processes contributes to the electrical resistance through the electron binary collisions.

On the other hand, as to the thermal resistance, the circumstances are different, because it is determined by the relaxation mechanism of energy flow. When the electron system is in steady state under a given temperature gradient and the conditon of no electrical current, the distribution function becomes such as shown in Fig. 1. The electrons with wave vector of positive direction have a character of higher temperature range and those of negative direction have that of lower temperature range. Thus the electrons with energies higher than Fermi level flow in the positive direction and the electrons with lower energies flow in the negative directions. These two flows of the electrons are mixed together by the binary electron collision processes and the electron system approaches to the equilibrium. In consequence, these collision processes may contribute to the thermal resistance even in the plane wave approximation, as well as do the electron-phonon collision processes. It seems to us that Ginzburg and Silin³⁾, who discussed the effect of the electron binary collisions on the conduction phenomena, overlooked such a process as mentioned above.

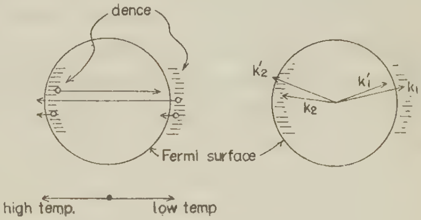

Fig. 1.

The electrons to take part in the collisions are those which fall in the energy range kT near Fermi level and hence we find that the frequency of binary collisions is proportional to T^2. On the other hand, that of the electron-phonon collisions is proportional to T at high temperature and to T^3 at low temperature. Accordingly, if we consider only the temperature tendency, the relaxation process by the electron binary collisions may dominate that of the electron-phonon collisions an sufficiently high or low temperature.

In order to calculate the resistance by the electron binary collision quantitatively, we asume the Hamiltonian of electron-electron interaction such as

$$H_{e-e}=\tfrac{1}{2}\sum_{s_1}\sum_{s_2}\sum_{s_3}\sum_{s_4}V(s_1s_2;\,s_3s_4)a_{s_1}{}^*a_{s_2}{}^*a_{s_3}a_{s_4}\delta_{\boldsymbol{k}_1+\boldsymbol{k}_2,\,\boldsymbol{k}_3+\boldsymbol{k}_4+\boldsymbol{K}_n} \tag{2.1}$$

where s means the electronic state of band l (including spin quantum number) and wave vector $\boldsymbol{k}$, $a_s{}^*$ and a_s means respectively the creation and annihilation operators of state s, and $\boldsymbol{K}_n$ the principal wave vector of the reciprocal lattice. We shall call hereafter the term of $\boldsymbol{K}_n=0$ as normal process (N-process) and one of $\boldsymbol{K}_n\neq0$ as Umklapp process (U-process). When $\boldsymbol{k}_1$, $\boldsymbol{k}_2$ and $\boldsymbol{k}_3$ are given, $\boldsymbol{k}_4$ and $\boldsymbol{K}_n$ are determined uniquely. The transition matrix element $V(s_1s_2;\,s_3s_4)$ is given by

$$V(s_1s_2;\,s_3s_4)=\sum_{\boldsymbol{K}_m}M_{\boldsymbol{k}_1-\boldsymbol{k}_4+\boldsymbol{K}_m}\left(\int_{\Omega_0}e^{-i\boldsymbol{K}_m\cdot\boldsymbol{r}}u_{s_1}{}^*(\boldsymbol{r})u_{s_4}(\boldsymbol{r})\,d\boldsymbol{r}\right)\times\left(\int_{\Omega_0}e^{-i(\boldsymbol{K}_n-\boldsymbol{K}_m)\cdot\boldsymbol{r}}u_{s_2}{}^*(\boldsymbol{r})u_{s_3}(\boldsymbol{r})\,d\boldsymbol{r}\right) \tag{2.2}$$

where Ω_0 is the volume of unit cell and M_q is the Fourier component of the interaction potential $V(|\boldsymbol{r}_i-\boldsymbol{r}_j|)$, that is

$$M_{\boldsymbol{q}}=\int e^{i\boldsymbol{q}\cdot\boldsymbol{r}}V(\boldsymbol{r})\,d\boldsymbol{r}\,. \tag{2.3}$$

If we assume that the system is represented by one band model and the electronic wave function of this band is represented by plane wave in a fairly good approximation, which means that $u_s(\boldsymbol{r})$ is nearly constant and will be applicable in monovalent metals, especially in alkali metals, then l means only the spin quantum number and in Eq. (2.2) the terms, say $\boldsymbol{K}_n=\boldsymbol{K}_m=0$ are most important. These terms, however, mean N-processes and hence no contribution to the electrical resistance. Amongst the terms corresponding to U-process, most important terms are these of $\boldsymbol{K}_n=\boldsymbol{K}_0$, $\boldsymbol{K}_m=0$ and $\boldsymbol{K}_m=\boldsymbol{K}_n=\boldsymbol{K}_0$. Then Eq. (2.2) becomes

$$(M_{k_1-k_4}+M_{k_1-k_4+K_0})A(\boldsymbol{K}_0) \tag{2.4}$$

where

$$A(\boldsymbol{K}_0)=\int_{\Omega_0} e^{-i\boldsymbol{K}_0\cdot\boldsymbol{r}}u_0^2(\boldsymbol{r})\,d\boldsymbol{r}\,, \tag{2.5}$$

where we substituted $u_0(\boldsymbol{r})$ for $u_k(\boldsymbol{r})$ by the above mentioned approximation, and the value of $A(\boldsymbol{K}_0)$ is estimated numerically by using $u_0(\boldsymbol{r})$ given by Wigner and Seitz[4].

Considering the effect of Fermi statistics, or spin quantum number of electron, the transition probability from the state $(k_1l_1;\,k_2l_2)$ to the state $(k_3l_2;\,k_4l_1)$ differs whether the spin directions of l_1 and l_2 is parallel. The squares of these matrix elements become such as

$$\left.\begin{aligned}&|W_p((\boldsymbol{k}_1\boldsymbol{k}_2);(\boldsymbol{k}_3\boldsymbol{k}_4))|^2\\&\quad=|V(\boldsymbol{k}_1\boldsymbol{k}_2;\boldsymbol{k}_3\boldsymbol{k}_4-V(\boldsymbol{k}_1\boldsymbol{k}_2;\boldsymbol{k}_4\boldsymbol{k}_3)|^2\,,\\&|W_a((\boldsymbol{k}_1\boldsymbol{k}_2);(\boldsymbol{k}_3\boldsymbol{k}_4))|^2=|V(\boldsymbol{k}_1\boldsymbol{k}_2;\boldsymbol{k}_3\boldsymbol{k}_4)|^2\,.\end{aligned}\right\} \tag{2.6}$$

The transition probability of parallel spin electrons becomes small by the effect of exchange correlation.

The main contribution to the thermal resistance comes from the N-process as mentioned above. Using again the approximation $u_k(\boldsymbol{r})\simeq u_0(\boldsymbol{r})$, Eq. (2.2) gives the matrix elements obtained by using the plane wave instead of the Bloch's function, and as well known the results agree with what computed by the Born approximation. However, as to the conduction electrons in a metal, it seems that the Born approximation is beyond the criterion of its validity, since their energies are at most a few e.v.. Therefore, we shall evaluate the exact probability of transition by using the partial wave method.

As the short-range potential we can consider the various forms as indicated in Fig. 2. Among them the following type is adopted because it is convenient for the calculation of the cross section.

$$\begin{aligned}V(r)&=\frac{e^2}{r}\left(1-\frac{r}{a}\right) &\quad r<a\\&=0 &\quad r>a\end{aligned} \tag{2.7}$$

where a is chosen as $2k_c^{-1}$. In sodium, $(k_c/k_0)\simeq 0.70$ where k_0 and k_c are respectively the magnitudes of the Fermi maximum and of

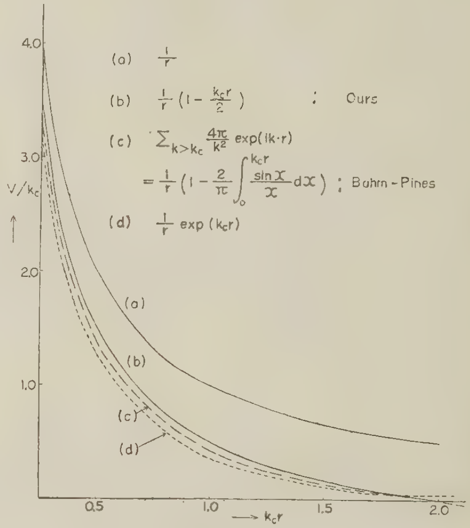

Fig. 2.

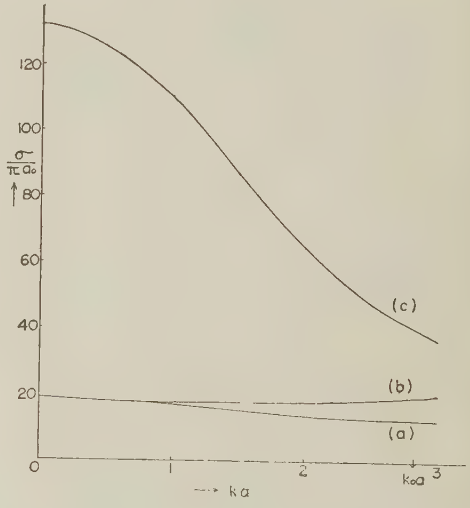

Fig. 3.

(a) Partial wave method neglecting spin effect

$$\frac{\sigma}{\pi a_0{}^2}=\frac{4}{(ka)^2}\left(\frac{a}{a_0}\right)^2(\sin^2\eta_0+3\sin^2\eta_1)$$

(b) Partial wave method

$$\frac{\sigma}{\pi a_0{}^2}=\frac{4}{(ka)^2}\left(\frac{a}{a_0}\right)^2(\sin^2\eta_0+9\sin^2\eta_1)$$

(c) Born approximation neglecting spin effect

$$\frac{\sigma}{\pi a_0{}^2}=\frac{2\pi}{(ka)^2}\left(\frac{a}{a_0}\right)^4\int_0^{2ka}\frac{(x-\sin x)^2}{x^5}dx$$

where a_0 is Bohr radius and $a/a_0=5.87$ in our case, η_0 and η_1 are respectively the phase shifts of s- and p-waves.

plasma cut-off wave vector. The calculation of cross section is given in Appendix I. The curves (c) and (a), shown in Fig. 3, represent respectively the total cross sections obtained by the Born approximation and by the partial wave method computing the phase shifts of s- and p-wave, where the spin effect is not considered. We find the Born approximation gives the larger cross section than that of the partial wave method. The curve (b) is the total cross section considering the spin direction (see Appendix I).

ii) *The effective coupling parameter of the electron-phonon interaction*

The Coulomb interactions between electrons contribute directly to the electrical resistance by their binary collisions, as mentioned above. In addition it has the effect of shielding the ionic field by the effective self field induced by coupling with the lattice vibrations. This was first investigated by J. Bardeen[6], who evaluated the probability for the electron to be scattered by the phonon, taking account of the Hartree's field; and Toya[7] furthermore considered the exchange interactions of the electrons in the simplified Hartree-Fock's approximation[8] and pointed out that this correlation between the parallel spins diminished the shielding effect given by J. Bardeen. One[9] of us also took into consideration the correlation between the anti-parallel spins in the same way as Toya did. Recently J. Bardeen and D. Pines discussed the problem of coupling between electrons and phonons by introducing the plasma mode and indicated that since the long range correlations between the electrons are included in the plasma mode, the coupling constant of electron-phonon interaction scarcely affected by the correlation effect of electrons when the wave vector of the phonon is smaller than k_c, and thus the effective matrix elements were in agreement with those obtained by J. Bardeen.

However, if the phonon wave length becomes comparable with or shorter than $2\pi/k_c$, the correlation between electrons through the screened Coulomb potential would have the appreciable influence on the electron-phonon interactions. In other words, the degree of shielding effect decreases when the correlation between electrons are considered, and hence the probability of electron-phonon collisions increases. Pines showed that this correlation of individual electrons was so large that it might contribute to the cohesive energy. Therefore, as to the formula of the matrix elements of electron-phonon interaction we use the following results. When the wave vector of phonon q is smaller than k_c, the result obtained by Bardeen is applicable. When q becomes larger than k_c, we calculate the correlation effect by using the simplified Hartree Fock's method, rewriting the correlation energy which depends only on the electron density into the form of the potential energy. The results are plotted in Fig. 4.

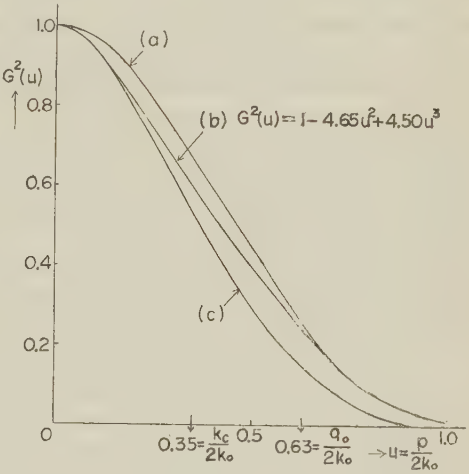

Fig. 4. (a) is the curve which was obtained by taking account of the correlation effect, which was calculated by using the simplified Hartree Fock's method, rewriting the correlation energy, which was evaluated by Pines(10) and depends only on the electron density, into the form of the potential energy. (b) is the curve which was obtained by interpolating the curves (a) and (c). (c) is the curve which was obtained by Bardeen(6).

According to the usual Bloch's theory, the probability that an electron emits or absorbs a phonon with wave vector $\boldsymbol{q}$ is given by

$$W(\boldsymbol{k}, \boldsymbol{k}', \boldsymbol{q}) = \left(\frac{2}{3} C\,|\boldsymbol{k}-\boldsymbol{k}'|\right)^2 \frac{\hbar}{2MN\omega_q} \delta_{\boldsymbol{k},\boldsymbol{k}'+\boldsymbol{q}+\boldsymbol{K}_n} \tag{2.8}$$

and the coupling parameter C is regarded as a constant of the same order as Fermi energy ζ and independent of the value of $|\boldsymbol{k}-\boldsymbol{k}'|$. However, as mentioned above, considering the shielding effect of electrons, C changes with $|\boldsymbol{k}-\boldsymbol{k}'|$. By using Bardeen's notation we write C as follows

$$C=\zeta G(u) \tag{2.9}$$

where

$$u=\frac{p}{2k_0}\,, \qquad \boldsymbol{p}=\boldsymbol{k}-\boldsymbol{k}'$$

and $G(u)$ is written by

$$G(u)=g(u)\,\frac{1+(V_0(r_s)-E_0)(3u^2/\beta\zeta)}{f(u)\{1-(3/2)(1-0.34)u^2\}+(2u^2/\beta)}\,. \tag{2.10}$$

This function differs from that of Bardeen only in a term $-(3/2)(1-0.34)u^2$ in the denominator. These terms $-(3/2)u^2$ and $(3/2)\times 0.34u^2$ come respectively from taking account of the correlation field of electrons with parallel and antiparallel spin. Fig. 4 shows that the quantity $|G(u)|^2$, which is proportional to the transition probability, becomes small markedly in the range where p is larger than k_c. We adopt in this paper the curve (b) which is obtained by the interpolation using both the curves (a) in the range of small value of p and the (c) in the range of large p.

In a range $u>(q_0/2k_0)\simeq 0.63$, U-process may occur, where q_0 is the magnitude of Debye's maximum wave vector.

In order to calculate $G(u)$ we require the matrix element of perturbing potential derived from electron clouds surrounding about a bare ion. Then we must evaluate the value of $(V_0(r_s)-E_0)$ in the numerator of Eq. (2.10), where $V_0(r_s)$ denotes the value of the undistorted potential on the surface of s-sphere and E_0 energy in the lowest state. As the value of $(V_0(r_s)-E_0)$, Bardeen[6)] took 0.2 e.v. and Toya[7)] 0.22 e.v., while Ziman[11)] used 1.3 e.v. reffering to Mott.

The equation to be solved by us is

$$-\frac{\hbar^2}{2m}\nabla^2\psi_0+(V_0(r)-E)\psi_0=0$$

$$V_0(r)=v+v_c+v_{\mathrm{cor}}$$

where v, v_c and v_{cor} denote respectively the potenial of bared ion, Coulomb potential by electron of uniform density and correlation potential, and ψ_0 the wave function of the ground state. Wigner and Seitz took the $-(\hbar/2m)\nabla^2+v$ as the unperturbed Hamiltonian and r_c as the perturbation. Mott's result correspond to the zeroth order, while Bardeen considered to the first order, namely

$$\bar{v}_c=4\pi\int_0^{r_s}\left(\frac{3}{2}\frac{e^2}{r_s}-\frac{e^2r^2}{2r_s^3}\right)r^2\,dr\bigg/\frac{4}{3}\pi r_s^3=1.2\,\frac{e^2}{r_s}$$

which was obtained with an approximation $u(r)\simeq 1$. In our case though v_{cor} also should be considered as a perturbation, we may consider that v_{cor} gives merely the constant energy of correlation independent of the position, because the Coulomb repulsion causes each electron to stay apart uniformly from point of view of the simplified Hartree Fock method, and also in sodium the wave function of the lowest state in nearly constant at the major portion of s-sphere. Therefore we adopted the Bardeen's result. It may be reasonable that we modify the Bardeen's result not by the alternation of the value of $(V_0(r_s)-E_0)$, but by taking account of the correlation field. However incidentally the interpolated curve, which is adopted by us, coincides fairly well with that which was used by Ziman[11)].

iii) *The energy spectrum*

The energy spectrum of electron deviates from that in the free electron approximation by the various factors. First, the crystalline field will be the most important cause. In alkali metals such as sodium, the wave function of electron may be expected to be nearly flat in the whole space except the points very near the ions, and hence a free electron model may be a good approximation. Second, the introduction of the plasma mode from the standpoint of Bohm and Pines brings the important effects. The effective mass of electron may be increased by the electron-plasma interaction and may be decreased by the restriction of the electronic states by the subsidiary conditions. The former has been estimated by D. Bohm and D. Pines, but the latter is the complicated problem. However, these effects may be not so important in Na because the freedom of phasma mode is not so large and they have the effects to cancel out each other. As for the rest of factors, one can consider the effects of the exchange energy through the screened short-range electron-electron interaction. In this case, we may expect not only the change of the effective mass of electron, but also the complicated change of the energy spectrum near the Fermi level (as well known, the state density near Fermi surface becomes abnormally small when we use the non-screened Coulomb potenial). F. J. Blatt and R. Barrie[12)] and Tuji[13)] have discussed the influences of exchange interactions through the screened Coulomb potentials on the level density and the relaxation time to determine the conductivities. If we consider this interaction between the electrons, then we also must take account of the effect of the electron-phonon interaction on the energy spectrum. However, the phenomena on which the structure of energy spectrum is supposed to affect delicately, particularly the thermoelectric phenomena at low temperature, will be reserved for another occasion, and in this paper we assume that the energy spectrum of electronic state is represented by the free electron model.

§ 3. Fundamental Transport Equation

To calculate the steady flow of the system under the external force or strain from the standpoint of the gas kinetic theory, we must obtain the velocity distribution function of one body in the steady state by solving the well known Boltzmann-Bloch equation. As is well known, there are two main mechanisms for the resistances with respect to the electron transport in metals, that is, the scattering of electrons by the thermal oscillation of the lattice (phonon) and by the static imperfection of the lattice. The latter mechanism is important at low temperature and in some substances causes a peculiar phenomenon of so called resistance minimum. In this paper we do not treat this mechanism but confine ourselves to the resistance by phonon scattering. In usual treatment to calculate ideal electrical conductivity one assume that the phonon distribution is in the thermal equilibrium. But since Peierls, there have been various comments for this problem and recently many authors have discussed the influences of the deviation of the phonon distribuion function from the equilibrium value on the transport properties in metals and semi-conductors, particularly on the thermo-electric phenomena. However, the treatments of this problem are compelled to be qualitative, because it is difficult to treat the relaxation processes of phonon system quantitatively. And as are pointed out by Sondheimer[14] and us[15], some incomplete points are involved in a few papers[16] of theirs. The detailed discussions about this problem will be given in another paper, and in this paper we assume that the phonon distribution is in thermal equilibrium. However, so far as the thermal conductivity is concerned, the results obtained in this paper may be applied without essential modification, even if the effect of so-called "phonon drag" is taken into account.

Provided that the deviation from the equilibrium distribution function of electron f_0 is small and the system is homogeneous, the electron distribution function $f(\boldsymbol{k})$ may be represented by

$$f(\boldsymbol{k})=f_0(\mathcal{E})-k_x\cdot c(\mathcal{E})\frac{\partial f_0(\mathcal{E})}{\partial \mathcal{E}} \tag{3.1}$$

where

$$f_0(\mathcal{E})=(e^{\mathcal{E}}+1)^{-1}\,, \qquad \mathcal{E}=(E-\zeta)/\kappa T\,. \tag{3.2}$$

To solve Bloch's integral equation with respect to $c(\mathcal{E})$, Sondheimer applied the variation method, in which the trial function $c(\mathcal{E})$ is expanded by the power series of $\mathcal{E}$. Now taking until the second term, it is

$$c(\mathcal{E})=c_1+c_2\cdot\mathcal{E}\,. \tag{3.3}$$

These terms mean respectively the uniform displacement of the Fermi sphere as a whole and the change of distribution in the neighborhood of the Fermi surface. For the electrical conductivity, we need only the first constant term, and if we regard the coupling parameter of the electron-phonon collision as a constant, then we have the Grüneisen formula for its ideal part. On the other hand, the thermal conductivity under the condition $\boldsymbol{j}=0$ is determined by the second term, the odd function of $\mathcal{E}$. However, it was pointed out by Kasuya[9] and Klemens[17] that this function $c_2\cdot\mathcal{E}$ could not be a good solution at the low temperature and furthermore the exact solution had to be a odd function of $\mathcal{E}$ which approaches to a constant value as $\mathcal{E}$ increases. Therefore, as a function with such a property we assume the following simple form

$$c(\mathcal{E})=c_1+c_2'\tanh\frac{\mathcal{E}}{2}\,. \tag{3.4}$$

In our case, though we must consider the distribution function under electron binary collisions as well as electron-phonon collisions, it will be allowed to assume that in the first approximation the electron distribution may be determined by electron-phonon collisions and given by Eq. (3.3) or (3.4).

In order to solve the equation of $c(\mathcal{E})$, we use the following method which is substantially equivalent to the variation method. Let us multiply on the both side of Bloch equation by $e\boldsymbol{v}(\boldsymbol{k})$, where $\boldsymbol{v}(\boldsymbol{k})$ is the electron belocity and e electronic charge, and sum over $\boldsymbol{k}$.

Then this equation represents that the changes of the electrical current density $\boldsymbol{j}$ per unit time by the external field and by the collision processes keep balance in a steady state. Similarly, if $\kappa T\mathcal{E}v(\boldsymbol{k})$ is multiplied, where $\mathcal{E}$ is given by Eq. (3.2), the equation means the balance of change of the thermal current density $\boldsymbol{Q}$ per unit time. Hereafter let us suppose that the directions of external fields are parallel to the x-axis for brevity and consider only these components of currents. Then the following two equations representing the total balance of the electrical and thermal flow are sufficient to determine two unknown constants c_1 and c_2 (or c_2').

$$\left(\frac{dj}{dt}\right)_{\text{drift}}+\left(\frac{dj}{dt}\right)_{\text{coll}}=0 \tag{3.5}$$

$$\left(\frac{dQ}{dt}\right)_{\text{drift}}+\left(\frac{dQ}{dt}\right)_{\text{coll}}=0\,. \tag{3.6}$$

Here the drift terms are

$$\left(\frac{dj}{dt}\right)_{\text{drift}}=-e\sum_{\boldsymbol{k}}v_x(\boldsymbol{k})\left\{\frac{e}{\hbar}F\frac{\partial f(\boldsymbol{k})}{\partial k_x}+v_x(\boldsymbol{k})\frac{\partial f(\boldsymbol{k})}{\partial x}\right\}, \tag{3.7}$$

$$\left(\frac{dQ}{dt}\right)_{\text{drift}}=-\kappa T\sum_{\boldsymbol{k}}\mathcal{E}(\boldsymbol{k})v_x(\boldsymbol{k})\left\{\frac{e}{\hbar}F\frac{\partial f(\boldsymbol{k})}{\partial k_x}+v_x(\boldsymbol{k})\frac{\partial f(\boldsymbol{k})}{\partial x}\right\}. \tag{3.8}$$

If we confine ourselves to the treatment linear concerning the fields, we may substitute $f_0(\mathcal{E})$ for $f(k)$ in the drift term and then can easily perform the summation by replacing with the integration over $\boldsymbol{k}$ as usual. Next the collision terms owing to the electron-phonon and electron-electron collisions are given by

$$\begin{aligned}-\left(\frac{dj}{dt}\right)_{\text{coll}}&=\frac{e2\pi}{\hbar}\sum_{\boldsymbol{k}}\sum_{\boldsymbol{k}'}\sum_{\boldsymbol{q}}W(\boldsymbol{k},\boldsymbol{k}',\boldsymbol{q})\{f_{\boldsymbol{k}}(1-f_{\boldsymbol{k}'})(N_q+1)-f_{\boldsymbol{k}'}(1-f_{\boldsymbol{k}})N_q\}(v_{\boldsymbol{k}'}-v_{\boldsymbol{k}})_x\delta(E_{\boldsymbol{k}'}-E_{\boldsymbol{k}}-\hbar\omega_q)\\&\quad+\frac{e2\pi}{\hbar}\sum\sum_{(\boldsymbol{k}_1\boldsymbol{k}_2)}\sum\sum_{(\boldsymbol{k}_3\boldsymbol{k}_4)}w(\boldsymbol{k}_1\boldsymbol{k}_2\boldsymbol{k}_3\boldsymbol{k}_4)f_{\boldsymbol{k}_1}f_{\boldsymbol{k}_2}(1-f_{\boldsymbol{k}_3})(1-f_{\boldsymbol{k}_4})(v_{\boldsymbol{k}_3}+v_{\boldsymbol{k}_4}-v_{\boldsymbol{k}_1}-v_{\boldsymbol{k}_2})_x\delta(E_{\boldsymbol{k}_1}+E_{\boldsymbol{k}_2}-E_{\boldsymbol{k}_3}-E_{\boldsymbol{k}_4})\,,\end{aligned} \tag{3.9}$$

$$\begin{aligned}-\left(\frac{dQ}{dt}\right)_{\text{coll}}&=\frac{2\pi\kappa T}{\hbar}\sum_{\boldsymbol{k}}\sum_{\boldsymbol{k}'}\sum_{\boldsymbol{q}}W(\boldsymbol{k},\boldsymbol{k}',\boldsymbol{q})\{f_{\boldsymbol{k}}(1-f_{\boldsymbol{k}'})(N_q+1)-f_{\boldsymbol{k}'}(1-f_{\boldsymbol{k}})N_q\}\\&\qquad\times(\mathcal{E}_{\boldsymbol{k}'}v_{\boldsymbol{k}'}-\mathcal{E}_{\boldsymbol{k}}v_{\boldsymbol{k}})_x\delta(E_{\boldsymbol{k}'}-E_{\boldsymbol{k}}-\hbar\omega_q)\\&\quad+\frac{2\pi\kappa T}{\hbar}\sum\sum_{(\boldsymbol{k}_1\boldsymbol{k}_2)}\sum\sum_{(\boldsymbol{k}_3\boldsymbol{k}_4)}w(\boldsymbol{k}_1\boldsymbol{k}_2\boldsymbol{k}_3\boldsymbol{k}_4)f_{\boldsymbol{k}_1}f_{\boldsymbol{k}_2}(1-f_{\boldsymbol{k}_3})(1-f_{\boldsymbol{k}_4})(\mathcal{E}_{\boldsymbol{k}_3}v_{\boldsymbol{k}_3}+\mathcal{E}_{\boldsymbol{k}_4}v_{\boldsymbol{k}_4}-\mathcal{E}_{\boldsymbol{k}_1}v_{\boldsymbol{k}_1}-\mathcal{E}_{\boldsymbol{k}_2}v_{\boldsymbol{k}_2})_x\\&\qquad\times\delta(E_{\boldsymbol{k}_1}+E_{\boldsymbol{k}_2}-E_{\boldsymbol{k}_3}-E_{\boldsymbol{k}_4})\end{aligned} \tag{3.10}$$

where $W(\boldsymbol{k},\boldsymbol{k}',\boldsymbol{q})$ is the square of the transition matrix element of electronphonon interaction and given by Eq. (2.8), while $w(\boldsymbol{k}_1\boldsymbol{k}_2\boldsymbol{k}_3\boldsymbol{k}_4)$ that of electron binary collision. As mentioned above, we assume that the phonon distribution is given by

$$N_q=N_0(x)=(e^x-1)^{-1}\,,\qquad x=\hbar\omega_q/\kappa T \tag{3.11}$$

where $N_0(x)$ is the thermal equilibrium distribution of phonon, and the electron energy spectrum is written by

$$E_k=\frac{\hbar^2}{2m}|\boldsymbol{k}|^2\,,\qquad v_k=\frac{\hbar k}{m} \tag{3.12}$$

where m means the effective mass of electron. In the following, we shall treat separately the electrical and thermal conductivity.

The electrical conductivity σ—For the electrical current, the odd part of $c(\mathcal{E})$ can be neglected since it gives only the higher orders of $\kappa T/\zeta$, while in the drift term $\partial T/\partial x$ is zero and thus we obtain

$$j=e\sum_k v_x(k)f(k)=\frac{en}{\hbar}\kappa Tc_1\,, \tag{3.13}$$

$$\left(\frac{dj}{dt}\right)_{\text{drift}} = -\left(\frac{e\hbar}{m}\right)^2 F \sum_{k} k_x^2 \frac{\partial f_0}{\partial E} = \frac{ne^2}{m} F . \tag{3.14}$$

Here it is convenient to introduce the average relaxation time τ_σ which is determined by the equation

$$\left(\frac{dj}{dt}\right)_{\text{coll}} = -\frac{j}{\tau_\sigma} . \tag{3,15}$$

Then it follows that using Eq. (3.13) to (3.15) and Eq. (3.5),

$$\sigma = j/F = \frac{ne^2}{m}\tau_\sigma . \tag{3.16}$$

Provided that two collision processes are independent of each other, we have

$$\frac{1}{\tau_\sigma} = \frac{1}{\tau_\sigma{}^p} + \frac{1}{\tau_\sigma{}^e} \tag{3.17}$$

where $\tau_\sigma{}^p$ and $\tau_\sigma{}^e$ denote respectively the average relaxation times of the electrical current by electron-phonon and electron binary collision processes. These calculations are performed in Appendix II.

The thermal conductivity κ—If we express the second term in Eq. (3.3) or (3.4) as $c_0(\mathcal{E})$, which indicates the odd function of $\mathcal{E}$, $c(\mathcal{E})$ is written by

$$c(\mathcal{E}) = c_1 + c_0(\mathcal{E}) \tag{3.18}$$

where

$$c_0(\mathcal{E}) = c_2 \cdot \mathcal{E} \qquad \text{or} \qquad c_2' \cdot \tanh\frac{\mathcal{E}}{2} . \tag{3.19}$$

Using Eqs. (3.1) and (3.18), j and Q are given by

$$j = e\sum_{k} v_x(\boldsymbol{k}) f(\boldsymbol{k}) = \frac{ne}{\hbar}\kappa T\left\{ c_1\left(1+\frac{\pi^2}{8}\gamma^2\right) - \frac{3}{2}\gamma\int_{-\infty}^{\infty} \mathcal{E} c_0(\mathcal{E}) \frac{\partial f_0}{\partial \mathcal{E}} d\mathcal{E}\right\} , \tag{3.20}$$

$$Q = \kappa T \sum_{k} \mathcal{E}_k v_x(\boldsymbol{k}) f(\boldsymbol{k}) = \frac{n\zeta}{\hbar}\kappa T\left\{ c_1\frac{\pi^2}{2}\gamma^2 - \gamma\int_{-\infty}^{\infty} \kappa c_0(\mathcal{E}) \frac{\partial f_0}{\partial \mathcal{E}} d\mathcal{E}\right\} , \tag{3.21}$$

in the approximation to take until the order of $(\kappa T/\zeta)^2 \equiv \gamma^2$.

Now we consider the thermal current density Q_0 under the condition $j=0$. By Eq. (3.20), this condition is equivalent to the relation

$$c_1 = \frac{3}{2}\gamma\left(1-\frac{\pi^2}{8}\gamma^2\right)\int_{-\infty}^{\infty} \mathcal{E}\cdot c_0(\mathcal{E}) \frac{\partial f_0}{\partial \mathcal{E}} d\mathcal{E} . \tag{3.22}$$

Substituting this relation into Eq. (3.21), we can easily see that the first term is negligibly smaller than the second. Therefore, in our approximation we may define Q_0 by

$$Q_0 = -\frac{n}{\hbar}(\kappa T)^2 \int_{-\infty}^{\infty} \mathcal{E} c_0(\mathcal{E}) \frac{\partial f_0}{\partial \mathcal{E}} d\mathcal{E} = \frac{n}{\hbar}(\kappa T)^2 c , \qquad c = \frac{\pi^2}{3}c_2 \quad \text{or} \quad \frac{1}{2}c_2' . \tag{3.23}$$

By the same consideration as the above, the drift term depends only on $\partial T/\partial x$ and the term proportional to $(eF+\partial\zeta/\partial x)$ becomes higher order with respect to γ and is negligible in our approximation, that is,

$$\left(\frac{dQ_0}{dt}\right)_{\text{drift}} = -\frac{\pi^2 n\kappa T}{3m}\frac{dT}{dx} . \tag{3.24}$$

If we introduce the average relaxation time τ_κ of the thermal flow by

$$\left(\frac{dQ_0}{dt}\right)_{\text{coll}}=-\frac{Q_0}{\tau_\kappa}, \tag{3.25}$$

the thermal conductivity κ becomes

$$\kappa=-Q_0\Big/\frac{dT}{dx}=\frac{\pi^2 n k^2 T}{3m}\tau_\kappa . \tag{3.26}$$

Corresponding to the case of electrical resistance, τ_κ is written by $\tau_\kappa{}^p$ and $\tau_\kappa{}^e$ by

$$\frac{1}{\tau_\kappa}=\frac{1}{\tau_\kappa{}^p}+\frac{1}{\tau_\kappa{}^e}. \tag{3.27}$$

Their evaluations are shown in Appendix II.

§ 4. Comparison with Experimental Results

In the first place we shall consider the thermal and electrical conductivities κ^p and σ^p which are attributed to the electron-phonon collisions and then compare them with the experimental results.

We obtain the full expressions for κ^p and σ^p by inserting $\tau_\kappa{}^p$, A(2.7) and $\tau_\sigma{}^p$, A(1.9) into the Eqs. (3.26) and (3.16). To compare with the experimental results at high and low temperatures, we have give the limiting formulas of the above expressions. Concerning κ^p, we use the expression of A(2.9) at low temperature. At high temperature, the both expressions of A(2.8) and A(2.8′) are equal.

$$\frac{1}{\kappa^p}=\begin{cases}\dfrac{3\pi}{4}\dfrac{\hbar^3 k_0}{M\kappa^3}\left\{72.7\dfrac{T^2}{\Theta^4}+\dfrac{0.18}{T^2}\left(1+\dfrac{\Theta'}{T}\right)\exp\left(-\dfrac{\Theta'}{T}\right)\right\}, & \dfrac{\Theta}{T},\ \dfrac{\Theta'}{T}\gg 1 \qquad (4.1)\\[2ex] \dfrac{3\pi}{4}\dfrac{\hbar^3 k_0}{M\kappa^3}\left\{\dfrac{0.41}{\Theta^2}+\dfrac{0.54}{\Theta'^2}\right\}, & \dfrac{\Theta}{T},\ \dfrac{\Theta'}{T}\ll 1 \qquad (4.2)\end{cases}$$

$$\frac{1}{\sigma^p}=\begin{cases}\dfrac{\pi^3}{4e^2}\dfrac{\hbar^3 k_0}{M\kappa}\left\{498\dfrac{T^5}{\Theta^6}+\dfrac{0.54}{T}\exp\left(-\dfrac{\Theta'}{T}\right)\right\}, & \dfrac{\Theta}{T},\ \dfrac{\Theta'}{T}\gg 1 \qquad (4.3)\\[2ex] \dfrac{\pi^3}{4e^2}\dfrac{\hbar^3 k_0}{M\kappa}\left\{\dfrac{0.41}{\Theta^2}T+\dfrac{0.54}{\Theta'^2}T\right\}, & \dfrac{\Theta}{T},\ \dfrac{\Theta'}{T}\ll 1 \qquad (4.4)\end{cases}$$

The experimental data of Na are listed in Table I.

Table I.

low temp.	high temp.
$\frac{T}{\kappa}=\begin{cases}0.42 \\ 0.06\end{cases}+3.8\times10^{-4}T^3$ (B.M.[18]) $3.5\times10^{-4}T^3$ (M.W.W.[19]) Watt$^{-1}\cdot$cm$\cdot$deg	$\kappa=1.38$ Watt$\cdot$cm$^{-1}\cdot$deg^{-1}
$\rho=\begin{cases}9.05\times10^{-9} \\ 1.52\times10^{-9}\end{cases}+5.37\times10^{-15}T^5$ (B.M.) $\Omega\cdot$cm 1.38×10^{-9} $8.4\times10^{-15}T^5$ (8∼15°K) (M.W.W.) $+8.6\times10^{-16}T^6$ (4∼9°K) (W.[20])	$\rho_{300°\mathrm{K}}=4.945\times10^{-6}$ $\rho_{196°\mathrm{K}}=2.916\times10^{-6}$ $\Omega\cdot$cm (B.P.[21])

As discussed at the beginning of § 3, the effects of the deviation of the phonon distribution function from the equilibrium value have not been considered in our treatment. This contributes to the thermal conductivity only in the higher order, but it may be expected that this has some contribution to the electrical conductivity though it depends on the relaxation process of phonon system. Therefore, first we shall fit Θ and Θ' by comparing with experimental results of thermal conductivity. However, it should be noticed that Θ^n in Eqs. (4.1)~(4.4) must be interpreted as a mean value over the variation of sound velocity, since the sound velocity which is one of factors determining Θ or Θ' is fairly anisotropic.

i) For κ^p at low temperature we can see that the contribution from U-processes is negligibly small. Thus by comparing the first term in Eq. (4.1) with experimental value, we obtain

$$\Theta \simeq 263^\circ\mathrm{K} \ (\mathrm{B.M.}) , \qquad (4.5)$$

$$\Theta \simeq 268^\circ\mathrm{K} \ (\mathrm{M.W.W.}) . \qquad (4.6)$$

The value of Θ depends on the from of the function $c_0(\mathcal{E})$ and the above result is obtained by using the c_2' term in Eq. (3.19) which is not the exact solution of Bloch equation at low temperature. According the Klemens[17], who solved the Bloch equation numerically in a limiting form at the low temperature, the numerical factor of the normal part in Eq. (4.1) is not 72.7 but 64.0. Hence, if we take account of this fact, Θ decreases about 9°K.

ii) For κ^p at high temperature we fit Θ' of Umklapp part to the experimental value by using Eq. (4.5) or (4.6) as Θ of N-part (i.e. first term) in Eq. (4.2). The value of Θ defined at low temperature is the mean value of Θ^{-4}. At higher temperature, however, the mean value of Θ^{-2} is aquired. These differences are, however, very small and we use the Eq. (4.5) or (4.6) for Θ. And it should be noticed that in the U-process both the longitudinal and transversal phonons contribute with nearly the same weight. For simplicity we here assume that both the modes participate in this process at the ratio 1:2. Then we have, using the Eq. (4.5)

$$\Theta \simeq 153^\circ\mathrm{K} . \qquad (4.7)$$

Even if we take Eq. (4.6) instead of Eq. (4.5), the above value scarcely changes. If we use Eq. (4.7) for the left hand side of A(3.3), we can estimate q' which is a parameter introduced in Appendix II and approximately evaluated as a mean wave vector of phonon concerning to U-process.

$$q'/q_0 \simeq 0.75 .$$

This value may be reasonable. In Fig. (5) the thermal resistance $(\kappa^p)^{-1}$ are plotted by using Eq. (4.5) as Θ and Eq. (4.7) as Θ'. (In our case, unknown parameters are reduced to two Debye temperatures Θ and Θ'.) As has been pointed out by many authors, the conductivity calculated by considering only a normal process has a fairly conspicuous minimum near $T/\Theta \simeq 0.2$ and the temperature dependence is in disagreement with experiment. Our normal part curve (a) has also same tendency. But Fig. (5) shows that this minimum is cancelled almost completely by the Umklapp part (b) and the coincidence with the experimental results is fairly good.

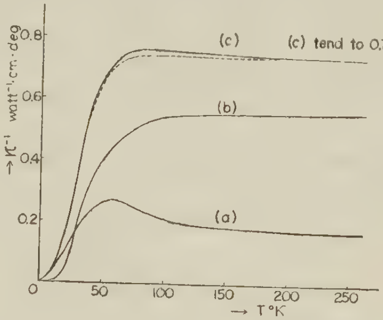

Fig. 5.

(a) Normal part which was fitted to experimental value at low temperature. (Θ=263°K)

(b) Umklapp part which was fitted to experimental value at high temperature. (Θ'=153°K)

(c) (a)+(b)

Dotted curve shows the experimental result. (B.M.[18])

iii) It is evident from Eqs. (4.2) and (4.4) that Wiedeman-Franz' law $\kappa/\sigma T = (\pi\kappa/e)^2/3$ is valid in the limits of high temperature. Therefore, σ^p at high temperature is in a good agreement with the experiment by using Θ and Θ' which are chosen to fit to κ^p for high temperature. However, experimentally this law is invalid near a melting point, for example in sodium it is near 370°K and the resistance is not proportional to T.* It seems to us that this increase of resistance is due to the self-diffusion of ions or the production of lattice-vacancy. Actually Gutowsky reported the motional narrowing of line width in nuclear magnetic resonance of sodium.

iv) Next, let us consider the electrical conductivity in low temperature. If we ignore the Umklapp part and consider only the normal part with Θ in **i**), the theoretical values of electrical conductivity becomes too large. As stated previously, the effect of non-equilibrium of the phonon distribution might be important in the electrical resistivity at low temperature. However, this effect has the tendency to decrease the electrical resistivity and thus no contribution to remove this discrepancy. Here we shall estimate roughly to what extent it can be adjusted by taking account of Umklapp process. Since the sound wave has fairly large anisotropy, we shall make use of the averaged one. (See Appendix III). Then, at low temperature, Umklapp part of $(\sigma^p)^{-1}$ results

---

* See Bradshaw and Pearson[21] for the resistivity of Na.

$$\overline{U}=\frac{1}{3}(\overline{U}_l+2\overline{U}_t)$$
$$=\frac{1}{3}\cdot\frac{0.54}{T}\left(0.54\frac{T}{\Theta_{l0}'}\exp\left(-\frac{\Theta_{l0}'}{T}\right)\right.$$
$$\left.+1.1\frac{T}{\Theta_{t0}'}\exp\left(-\frac{\Theta_{t0}'}{T}\right)\right)$$

by using Eqs. A(3.5) and A(3.6). From the comparison with the experimental value at $T=10$°K, we obtain

$$\Theta_{l0}'\simeq\Theta_{t0}'\simeq 85°\text{K} ,$$

if we substitute Θ of normal part for the value in Eq. (4.5). And we find that Umklapp part is about four times normal part. But the above evaluation is very rough and also the temperature dependence is not necessarily in agreement with experiment at low temperature, in which the electrical resistance is proportional to T^5 or T^6. However, since this temperature dependence is only valid in a very narrow range of temperature, our results seem to be not so unreasonable.

Lastly it remains to consider the contributions from the electron binary collisions σ^e and κ^e. Using $\tau_\sigma{}^e$ and $\tau_\kappa{}^e$ given by respectively A(1.23) and A(2.20), we obtain for Na

$$\frac{1}{\sigma^e}=0.01\frac{\hbar k_0}{e^2}\sigma_{t0t}\left(\frac{\kappa T}{\zeta}\right)^2$$
$$\simeq 1.1\times10^{-15}T^2\ (\Omega\cdot\text{cm}) , \tag{4.9}$$
$$\frac{1}{\kappa^e}=\frac{5.0}{\pi^2}\frac{\hbar k_0}{\kappa\zeta}\sigma_{t0t}\frac{\kappa T}{\zeta}$$
$$\simeq 6.0\times10^{-5}T\ (\text{watt}^{-1}\cdot\text{cm}\cdot\text{deg}) . \tag{4.10}$$

If we compare these results with the ideal part (i.e. that which the residural resistance is deducted from the experimental value), we find that both at 5°K and 300°K the thermal resistance (4.10) is smaller than ideal part by a factor of the order 10^{-2} and the electrical resistance (4.9) is smaller than the experimental value at low temperature by a factor of the order 10^{-3}, at high temperature by a factor of the order 10^{-4}. Hence, we may say that in monovalent metals the electron binary collisions may scarcely contribute to the resistances. In multivalent metals, however, the value of $A(K_0)$ becomes nearly unity in interband transitions. If we take $A(K_0)$ as unity, the electrical resistance by electron binary collisions becomes the same order of magnitude as that of electron-phonon collision in very low temperatures. The transport theory of multivalent metals has, however, many difficult problems and is not treated in detail in this paper.

Appendix I. Calculation of the Cross Section by the Partial Wave Method

The Schrödinger equation can be exactly solved for the potential given by Eq. (2.7). When the wave function is expanded into the partial waves, for $r<a$ its radial part $R_l(r)$ is so-called Coulomb function;

$$R_l(r)\propto F_l(Kr)/Kr ,$$

where

$$F_l(Kr)=(Kr)^{l+1}e^{iKr}f(l+1+in|2l+2|-2iKr)$$
$$K^2=k^2+(a_0a)^{-1} ,\qquad nK=(2a_0)^{-1} ,$$
$$a_0:\ \text{Bohr radius}$$
$$2k=k_1-k_2 ,\qquad 0<|k|<k_0$$

and f is the confluent hypergeometric function that is regular at the origin. For $r>a$,

$$R_l(r)\propto\cos\eta_l j_l(kr)-\sin\eta_l n_l(kr) ,$$

where j_l and n_l are respectively "spherical Bessel and Neumann" functions. The required phase shift η_l ($l=0, 1. 2, \cdots$) is computed by the boundary condition that the logarithmic derivative of $R_l(r)$ for $r\gtrless a$ be continuous at $r=a$, and then it follows

$$\tan\eta_l=\frac{\alpha_l j_l(ka)-j_l'(ka)}{\alpha_l n_l(ka)-n_l'(ka)} ,$$

where

$$\alpha_l=\left\{\left(\frac{r}{F_l}\frac{dF_l}{dr}\right)_{r=a}-1\right\}\Big/ka .$$

The values of $(r/F_l)(dF/dr)_{r=a}$ are tabulated on the reference (5) (Bloch, et al.) (in our case Ka falls in the range 2.4~3.8). η_l was calculated from $l=0$ to $l=2$. However, η_2 is very small and hereafter neglected. Thus the total cross section is given by

$$\sigma=\frac{4\pi}{k^2}(\sin^2\eta_0+3\sin^2\eta_1) . \tag{a}$$

As we consider the collisions of two identical particles with spin ½, we must take into account that collisions described by the symmetric and antisymmetric wave functions in the spacial part occur at the ratio 1:3, and so the differential cross section becomes

$$\sigma(\theta)=\frac{1}{4}(\sigma_s(\theta)+3\sigma_a(\theta))$$

where $\sigma_s(\theta)$ and $\sigma_a(\theta)$ are respectively symmetric and antisymmetric differential cross sections and are given by using the scattering amplitude $f(\theta)$ as follows

$$\sigma_s(\theta)=|f(\theta)+f(\pi-\theta)|^2=\frac{4}{k^2}\sin^2\eta_0$$

$$\sigma_a(\theta)=|f(\theta)-f(\pi-\theta)|^2=\frac{36}{k^2}\sin^2\eta_1\cos^2\theta$$

and so the total cross section becomes

$$\sigma_{tot}=\frac{4\pi}{k^2}(\sin^2\eta_0+9\sin^2\eta_1)\ . \tag{b}$$

In the range of larger ka, the contribution of p-wave becomes comparable order of that of s-wave. Abraham[22)] computed only the η_0 by the potential of type shown in Fig. 2 (d). In our case σ_{tot} depends scarcely on k as shown in Fig. 3 (b) and the constant value is about

$$\sigma_{tot}\simeq 19.0\pi a_0^2\ . \tag{b$'$}$$

Using the scattering amplitude

$$f(\theta)=-\frac{me^2}{\hbar^2K}\int_0^a\left(\frac{1}{r}-\frac{1}{a}\right)r\sin Kr\,dr$$

$$=-\frac{a^2}{a_0}\frac{1}{x^2}\left(1-\frac{\sin x}{x}\right),\quad x=Ka=2ka\sin\frac{\theta}{2},$$

and thus the cross section in the Born's approximation through the potential given by Eq. (2.7) is given by

$$\sigma=2\pi\int_0^\pi|f(\theta)|^2\sin\theta\,d\theta$$

$$=\frac{2\pi}{k^2}\left(\frac{a}{a_0}\right)^2\int_0^{2ka}\frac{(x-\sin x)^2}{x^5}dx\ . \tag{c}$$

This result was plotted in Fig. 3 in order to compare with the result (b) in which the spin quantum number is not taken into account.

Appendix II. Calculation of τ

1) *Electrical conductivity*

Calculation of $\tau_\sigma{}^p$—Using Eqs. (3.9), (3.13), (3.15) and (3.17), $\tau_\sigma{}^p$ becomes

$$\frac{1}{\tau_\sigma{}^p}=\frac{2\pi\hbar}{mn\kappa T}\sum_{\boldsymbol{k}}\sum_{\boldsymbol{k}'}\sum_{\boldsymbol{q}}W(\boldsymbol{k},\boldsymbol{k}',\boldsymbol{q})f_0(\mathcal{E}_{\boldsymbol{k}})f_0(\mathcal{E}_{\boldsymbol{k}'})N_0(x)\,e^{\mathcal{E}}{}_{\boldsymbol{k}'}(k_x-k_x)^2\,(E_{\boldsymbol{k}'}-E_{\boldsymbol{k}}-\hbar\omega_{\boldsymbol{q}})\ . \tag{A(1.1)}$$

Introducing the new variables by

$$\boldsymbol{k}'-\boldsymbol{k}=\boldsymbol{p}\ ,\qquad \mathcal{E}_{\boldsymbol{k}'}-\mathcal{E}_{\boldsymbol{k}}=\frac{\hbar\omega_{\boldsymbol{q}}}{\kappa T}=x \tag{A(1.2)}$$

A(1.1) may be rewritten as follows

$$\frac{1}{\tau_\sigma{}^p}=\frac{2\pi\hbar}{mn\kappa T}\sum_{\boldsymbol{k}}\sum_{\boldsymbol{P}(\boldsymbol{q})}W(|\boldsymbol{p}|,\boldsymbol{q})f_0(\mathcal{E})f_0(\mathcal{E}+x)\,e^{\mathcal{E}+x}N_0(x)\,p_x^2\,\delta(E'-E-\hbar\omega_{\boldsymbol{q}})$$

where for brevity we rewrite $\mathcal{E}_{\boldsymbol{k}'}$, $\mathcal{E}_{\boldsymbol{k}}$ and $E_{\boldsymbol{k}'}$, $E_{\boldsymbol{k}}$ by $\mathcal{E}'$, $\mathcal{E}$ and E', E and $\sum_{\boldsymbol{P}(\boldsymbol{q})}$ means the summation respect to Normal and Umklapp processes, as will be illustrated later. As usual these summations may be replaced by the integral over $\boldsymbol{k}$ and $\boldsymbol{p}$, furthermore the polar coordinates (k,θ_1,φ_1) with the polar axis in the direction $\boldsymbol{p}$ is used for the integration over $\boldsymbol{k}$ and (p,θ_2,φ_2) with the polar axis in the direction $\boldsymbol{x}$ (direction of field) is used for the integration by $\boldsymbol{p}$. Performing the integral over θ_1, θ_1 is determined by the property of δ-function such as

$$E'-E-\hbar\omega_{\boldsymbol{q}}=\frac{\hbar^2}{2m}(2pk\cos\theta_1-p^2)-\hbar\omega_{\boldsymbol{q}}=0\ , \tag{A(1.3)}$$

and for another slowely varying quantity of θ_1, θ_1 is substituted by

$$\cos\theta_1=\frac{m\omega_{\boldsymbol{q}}}{\hbar^2pk}-\frac{p}{2k}\ . \tag{A(1.4)}$$

Then one can readily perform other integrals apart from the integral over p and obtains

$$\frac{1}{\tau_\sigma{}^p}=\frac{m}{6\pi^3\hbar^3 n}\int_0^{2k_0}dp\,\frac{xp^3W(|\boldsymbol{p}|,\boldsymbol{q})}{(e^x-1)(1-e^{-x})}=\frac{m\zeta^2}{27\pi^3 MNn\hbar\kappa T}\int_0^{2k_0}dp\,\frac{p^5G^2(p/2k_0)}{(e^x-1)(1-e^{-x})} \qquad \text{A(1.5)}$$

where n and N are respectively the densities of electron and ion. We carry out the integration over p by separating the integral range into two parts as follows

$$0<p<q_0 \qquad \text{or} \qquad 0<u<\frac{q_0}{2k_0}=0{,}63 \qquad \text{A(1.6)}$$

$$q_0<p<2k_0 \qquad \text{or} \qquad 0.63<u<1 \qquad \text{A(1.6')}$$

where k_0 and q_0 denote respectively the magnitude of the Fermi maximum and Debye cut off wave vectors. In the range A(1.6) the Normal (or N-) process occurs, where the variable p may be replaced by the magnitude of phonon wave vector q, and $G^2(u)$ in A(1.5) is given by the approximate formula

$$\begin{aligned}G^2(u)&=1-4.65u^2+4.50u^3\\&=1-\frac{4.65}{4}\left(\frac{\delta}{t}\right)^2x^2+\frac{4.50}{8}\left(\frac{\delta}{t}\right)^3x^3\,, \qquad t=\frac{\Theta}{T}\,, \qquad \delta=\frac{q_0}{k_0}\end{aligned} \qquad \text{A(1.7)}$$

as shown in Fig. 3(b). On the other hand, in the range A(1.6′) the so-called Umklapp (or U-) process occurs, where $|\boldsymbol{p}|=p$ is determined by the relation $\boldsymbol{p}=\boldsymbol{q}+\boldsymbol{K}_0$ ($\boldsymbol{K}_0$ is a principal vector of the reciprocal lattice), depending on both the magnitude of $\boldsymbol{q}$ and angle $\widehat{\boldsymbol{q}\cdot\boldsymbol{K}_0}$. However, it is very difficult to perform the integration A(1.5) over this range rigorously by taking into account of this relation with $\boldsymbol{q}$. By using the approximation that q and x is constant, the integration over p is performable numerically such as

$$\int_{q_0}^{2k_0}dp\,p^5G^2\left(\frac{p}{2k_0}\right)=(2k_0)^6\int_{0.63}^{1}du\,u^5G^2(u)\simeq 0.0084(2k_0)^6 \qquad \text{A(1.8)}$$

which was obtained by using the curve for $u>0.63$ in Fig. 4. It is easily seen that the wave vector q of the phonons contributing to the U-process have the values close its maximum value and in contrast to the Normal process not only the longitudinal but also the transversal phonons play a equally important role. However when q becomes large, we shall be no able to distinguish these polarization modes and it will be also not a good approximation to use the relation $\omega_q=c_0q$, where c_0 represents the sound velocity (even if we allow this relation, practically c_0 depends on temperature and exhibits an anisotropy as mentioned in § 4). According to the facts stated above, we shall introduce a parameter Θ' defined by the relation $\hbar c_0q'=\kappa\Theta'$, in which q' means an averaged wave number of phonons contributing to Umklapp process, apart from Θ corresponding to q_0. Thus $\tau_\sigma{}^p$ is written with the two parameters, say $\Theta/T\equiv t$ and $\Theta'/T\equiv t'$, such as

$$\begin{aligned}\frac{1}{\tau_\sigma{}^p}&=\frac{m\zeta^2}{27\pi^3MNn\hbar\kappa T}\left[\left(\frac{q_0}{t}\right)^6\int_0^t dx\,\frac{x^5\left\{1-\frac{4.65}{4}\left(\frac{\delta}{t}\right)^2x^2+\frac{4.53}{8}\left(\frac{\delta}{t}\right)^3x^3\right\}}{(e^x-1)(1-e^{-x})}\right.\\&\qquad\qquad\left.+\frac{(2k_0)^6}{(e^{t'}-1)(1-e^{-t'})}\int_{0.63}^{1}du\,u^5G^2(u)\right]\\&=\frac{\pi m\zeta^2}{3M\hbar\kappa}\left[\frac{1}{\Theta}\frac{4}{t^5}\left\{\phi_5(t)-1.85\frac{\phi_7(t)}{t^2}+1.13\frac{\phi_8(t)}{t^3}\right\}+\frac{1}{\Theta'}\frac{0.54t'}{(e^{t'}-1)(1-e^{-t'})}\right].\end{aligned} \qquad \text{A(1.9)}$$

To obtain the last expression we used A(1.8) and relations

$$n=\frac{k_0{}^3}{3\pi^2}\,, \qquad N=\frac{q_0{}^3}{6\pi^2}\,, \qquad \delta^3=\left(\frac{q_0}{k_0}\right)^3=2 \quad \text{(for monovalent metal)} \qquad \text{A(1.10)}$$

and $\phi_n(t)$ is given by

$$\phi_n(t)=\int_0^t dx\frac{x^n}{(e^x-1)(1-e^{-x})} . \qquad \text{A(1.11)}$$

In A(1.9), if we ignore the Umklapp part and keep only the term $\phi_5(t)$ and replace ζ with the coupling constant C, we obtain the well known Grüneisen's formula.

Calculation of τ_σ^e—In order to compute the τ_σ^e defined by Eqs. (3.15) and (3.17) analytically we assume that the transition probability $w(\boldsymbol{k}_1\boldsymbol{k}_2\boldsymbol{k}_3\boldsymbol{k}_4)$ in Eq. (3.9) is not dependent on the wave number $\boldsymbol{k}$, but constant w. From Eqs. (2.4), (3.1) and Eq. (3.9), and taking account of the number of pairs 4 for the spin direction, we obtain

$$\frac{1}{\tau_\sigma^e}=\frac{\pi\hbar}{mn\kappa T}\sum_{\boldsymbol{k}_1}\sum_{\boldsymbol{k}_2}\sum_{\boldsymbol{k}_3} w f_0(\mathcal{E}_1)f_0(\mathcal{E}_2)f_0(-\mathcal{E}_3)f_0(-\mathcal{E}_4)\, K_{0x}{}^2\,\delta(E_1+E_2-E_3-E_4) \qquad \text{A(1.12)}$$

where since we allowed that the suffixes of this summation run over independently each other, we multiplied a factor $\frac{1}{4}$, and for simplicity denoted $\mathcal{E}_{\boldsymbol{k}_1}$ and $E_{\boldsymbol{k}_1}$ as $\mathcal{E}_1$ and E_1. Now we put

$$\boldsymbol{k}_1+\boldsymbol{k}_2=\boldsymbol{s}\ , \qquad \boldsymbol{k}_3+\boldsymbol{k}_4=\boldsymbol{r} \qquad \text{A(1.13)}$$

and use the approximation that for the calculation of summation in A(1.12) we consider only the processes of electron collisions in which both vectors $\boldsymbol{s}$ and $\boldsymbol{r}$ have the same directions as $\boldsymbol{K}_0$. This corresponds to the assumption that the system is homogeneous. Introducing the polar coordinates $(k_3, \theta_3, \varphi_3)$, polar axis being in the direction $\boldsymbol{r}$, $(k_2, \theta_2, \varphi_2)$, one being in $\boldsymbol{k}_1$ and $(k_1, \theta_1, \varphi_1)$, one being in $\boldsymbol{x}$, and then replacing the summation by the integration as follows

$$\left.\begin{aligned}&\sum_{\boldsymbol{k}_1}\sum_{\boldsymbol{k}_2}\sum_{\boldsymbol{k}_3}\rightarrow\left(\frac{1}{8\pi^3}\right)^3\int k_1{}^2\,dk_2\,d\Omega_1\int k_2{}^2\,dk_2\,d\Omega_2\int k_3{}^2\,dk_3\,d\Omega_3\ ,\\ &d\Omega_i=d(\cos\theta_i)\,d\varphi_i\ , \qquad i=1, 2, 3\end{aligned}\right\} \qquad \text{A(1.14)}$$

we can perform these integrations, using the following relations

$$|\boldsymbol{k}_1|\simeq|\boldsymbol{k}_2|\simeq|\boldsymbol{k}_3|\simeq|\boldsymbol{k}_4|\simeq k_0\ ,$$

$$E_4=\frac{\hbar^2}{2m}\cdot k_4{}^2=\frac{\hbar^2}{2m}(r^2+k_3{}^2+2rk_3\cos\theta_3)\ ,$$

$$\begin{aligned}E_1+E_2-E_3-E_4&=\frac{\hbar^2}{2m}(k_1{}^2+k_2{}^2-2k_3{}^2-r^2-2k_3r\cos\theta_3)\\ &\simeq-\frac{\hbar^2}{2m}(r^2+2k_0r\cos\theta_3)\ ,\end{aligned} \qquad \text{A(1.15)}$$

$$K_{0x}{}^2=\frac{K_0{}^2}{s^2}k_0{}^2(\cos\theta_1+\cos\alpha)^2\ , \qquad \text{A(1.16)}$$

$$s^2=2k_0{}^2(1+\cos\theta_2)\ , \qquad \text{A(1.17)}$$

$$\cos\alpha=\cos\theta_1\cos\theta_2+\sin\theta_1\sin\theta_2\cos\varphi_2\ . \qquad \text{A(1.18)}$$

Then as to the integration over θ_3, we notice only the δ-function and θ_3 is given by the relation A(1.15)=0. From the restriction $|\text{coo}\ \theta_3|<1$, the following relation

$$\left|\frac{r}{2k_0}\right|\leq 1 \qquad \text{or} \qquad s\geq K_0-2k_0\ ,$$

exists or in view of A(1.17) it becomes the restriction respect to $\cos\theta_2$; i.e.

$$\cos\theta_2\geq 2(b-1)^2-1\ , \qquad b=\frac{K_0}{2k_0}\ . \qquad \text{A(1.19)}$$

Then the integrations over solid angle Ω_i is performable using A(1.15)~(1.18) and becomes

$$\begin{aligned}
&\int K_{0x}^2\, \delta(E_1+E_2-E_3-E_4)\, d\Omega_1\, d\Omega_2\, d\Omega_3 \\
&= -\frac{2\pi m}{\hbar^2 k_0}\int \frac{K_{0x}^2}{K_0-s}\, d\Omega_1\, d\Omega_2 \\
&= -\frac{(2\pi)^3 m K_0^2}{2\hbar^2 k_0}\int_{2(b-1)^2-1}^{1} d(\cos\theta_2)\int_0^1 d(\cos\theta_1)\, \frac{\cos^2\theta_1(1+\cos\theta_2)^2+\frac{1}{2}\sin^2\theta_1\cdot\sin^2\theta_2}{(1+\cos\theta_2)(K_0-k_0\sqrt{2(1+\cos\theta)}\,)} \\
&= \frac{(2\pi)^3 32m}{3\hbar^2}\, b^2\left[1-\frac{b}{2}\{1+\log(b-1)\}\right]. \qquad \text{A(1.20)}
\end{aligned}$$

In the remaining integrals over k (k_1, k_2, k_3) we make use of $\mathcal{E}_i$ instead of k_i. Then we find that these integrations are transformed into a form of A(1.11) in which t is taken as infinity. Thus τ_σ^e becomes

$$\frac{1}{\tau_\sigma^e} = \frac{3}{8\pi}\frac{mk_0}{\hbar^3}n\left(\frac{\kappa T}{\zeta}\right)^2 \phi_2(\infty) w b^2\left[1-\frac{b}{2}\{1+\log(b-1)\}\right]. \qquad \text{A(1.21)}$$

For the transition probability w in above expression we may substitute $|2MA(K_0)|^2$ given in Eq. (2.4) when Born approximation is applicable. When Born approximation is not applicable, we assume that M can be replaced by the total cross section calculated in the case of the thermal conduction (see Appendix I and A(2.19)). As a result,

$$w \simeq \frac{4\pi\hbar^4}{m^2}\sigma_{tot}|A(K_0)|^2 . \qquad \text{A(1.22)}$$

Here $A(K_0)$, given in Eq. (2.5), were numerically calculated from Wigner-Seitz's result for sodium (using the wave function $u_0(r)$ at the ground state and $r_s=3.96$ Bohr unit) that is

$$A(K_0) \simeq 4.7\times 10^{-2} .$$

Substituting A(1.22) with this result, $\phi_2(\infty)\simeq 3.3$ and $b=(K_0/2k_0)\simeq 1.14$ (for sodium) for A(1.21), we obtain the final result

$$\frac{1}{\tau_\sigma^e} = 0.044\frac{\hbar k_0}{m} n\, \sigma_{tot}\left(\frac{\kappa T}{\zeta}\right)^2 . \qquad \text{A(1.23)}$$

Or if we define the mean free path by $l^e=\tau^e v_0=\hbar k_0\tau^e/m$,

$$l_\sigma^e = 0.044 n\, \sigma_{tot}\left(\frac{\kappa T}{\zeta}\right)^2 . \qquad \text{A(1.24)}$$

2) *Thermal conduction*

Calculation of τ_κ^p—From Eqs. (3.23), (3.28), (3.29) and (3.31), τ_κ^p is rewritten by the same way as that of τ_σ^p

$$\begin{aligned}
\frac{1}{\tau_\kappa^p} = \frac{2\pi\hbar}{mn\kappa Tc}\sum_{\boldsymbol{k}}\sum_{\boldsymbol{k}'}\sum_{\boldsymbol{q}} & W(\boldsymbol{k}, \boldsymbol{k}', \boldsymbol{q}) f_0(\mathcal{E}_k) f_0(\mathcal{E}_{k'}) e^{\mathcal{E}_{k'}} N_0(x)\{k_x' c_0(\mathcal{E}_{k'})-k_x c_0(\mathcal{E}_k)\} \\
& \times(\mathcal{E}_{k'}k_x'-\mathcal{E}_k k_x)\, \delta(E_{k'}-E_k-\hbar\omega_q) . \qquad \text{A(2.1)}
\end{aligned}$$

After the integration by solid angular variables, A(2.1) becomes

$$\frac{1}{\tau_\kappa^p} = \frac{m}{6\pi^3\hbar^3 nc}\int_0^{2k_0} dp\int_{-\infty}^{\infty} d\mathcal{E}\, W(|\boldsymbol{p}|, \boldsymbol{q})\, p N_0(x) f_0(\mathcal{E}_k) f_0(\mathcal{E}+x)\, e^{\mathcal{E}+x} K(\mathcal{E}, p) , \qquad \text{A(2.2)}$$

where

$$K(\mathcal{E},p)=xk^2\{c_0(\mathcal{E}+x)-c_0(\mathcal{E})\}+\frac{p^2}{2}\{\mathcal{E}c_0(\mathcal{E}+x)+(\mathcal{E}+x)c_0(\mathcal{E})\}+\frac{m\omega_q}{\hbar}\{(2x+\mathcal{E})c_0(\mathcal{E}+x)-(\mathcal{E}+x)c_0(\mathcal{E})\}\,. \tag{A(2.3)}$$

If we transform $c_0(\mathcal{E}+x)$ into $c_0(\mathcal{E})$ by means of the following relations for the odd-function $c_0(\mathcal{E})$ of $\mathcal{E}$,

$$\int_{-\infty}^{\infty}d\mathcal{E}\frac{c_0(\mathcal{E}\pm x)+c_0(\mathcal{E})}{(e^{-\varepsilon}+1)(e^{\varepsilon\pm x}+1)}=0\,,\qquad \int_{-\infty}^{\infty}d\mathcal{E}\frac{\mathcal{E}c_0(\mathcal{E}\pm x)-(\mathcal{E}\pm x)c_0(\mathcal{E})}{(e^{-\varepsilon}+1)(e^{\varepsilon\pm x}+1)}=0 \tag{A(2.4)}$$

and substitute Eq. (3.19) for $c_0(\mathcal{E})$ and then integrate over $\mathcal{E}$, A(2.2) and A(2.3) are reduced to

$$\frac{1}{\tau_\kappa{}^p}=\frac{m}{6\pi^3\hbar^3nc}\int_0^{2k_0}\frac{xpW(|\boldsymbol{p}|,\boldsymbol{q})}{(e^x-1)(1-e^{-x})}K'(p)\,, \tag{A(2.5)}$$

$$K'(p)=\begin{cases} c_2\left\{k_0{}^2x^2+p^2\left(\dfrac{\pi^2}{3}-\dfrac{x^2}{6}\right)\right\} & \text{(for high temp.)}\\[2ex] c_2'\left[k_0{}^2\left(\dfrac{x}{e^x-1}+\dfrac{x}{1-e^{-x}}-2\right)+p^2\left\{1-\dfrac{x}{4}\left(\dfrac{1}{e^x-1}+\dfrac{1}{1-e^{-x}}\right)\right\}\right] & \text{(for low temp.)}\end{cases} \tag{A(2.6)}$$

where c in A(2.5), being defined by Eq. (3.23), means c_2 or c_2' in accordance with that in $K'(p)$.

Now if one takes Eq. (2.8) for W and the term involving c_2 for $K'(p)$ and neglect the Umklapp process, one obtains the well-known expression for the thermal conductivity (Wilson[23]). In our treatment, Eq. (2.8) combined with Eq. (2.9) is substituted for W, then A(2.5) becomes

$$\frac{1}{\tau_\kappa{}^p}=\frac{m\zeta^2}{27\pi^3MNn\hbar\kappa Tc}\int_0^{2k_0}dp\,\frac{p^3G^2(p/2k_0)}{(e^x-1)(1-e^{-x})}K'(p)\,,$$

The integration over p can be performed by separating integral range into the regions defined by A(1.6) and A(1.6′) in the same way for $\tau_\sigma{}^p$. In the latter range we use the relation A(1.8) and

$$\int_{q_0}^{2k_0}dp\,p^3G^2\left(\frac{p}{2k_0}\right)=(2k_0)^4\int_{0.63}^{1}du\,u^3G^2(u)\simeq 0.014(2k_0)^4$$

to calculate the U-process.

As a result we have

$$\frac{1}{\tau_\kappa{}^p}=\frac{\pi mn\zeta^2}{3MN\hbar\kappa T}\begin{cases} g(t,t') & \text{(for high temp.)}\\ g'(t,t') & \text{(for low temp.)}\end{cases} \tag{A(2.7)}$$

where

$$g(t,t')=\frac{4}{t^6}\left\{(1+0.19t^2)\left(\phi_5(t)+\frac{1.13}{t^3}\phi_8(t)\right)-\left(0.40+\frac{1.85}{t^2}\right)\phi_7(t)+\frac{0.93}{t^2}\phi_9(t)-\frac{0.57}{t^3}\phi_{10}(t)\right\}$$
$$+\frac{0.54}{(e^{t'}-1)(1-e^{-t'})}(1+0.76t'^2)\,,$$

$$g'(t,t')=\frac{4}{t^6}\left\{2.52t^2\phi_3(t)-10.3\phi_5(t)+\frac{7.09}{t}\phi_6(t)+\frac{3.70}{t^2}\phi_7(t)-\frac{2.81}{t^3}\phi_8(t)-\frac{0.213t^6}{(e^t-1)(1-e^{-t})}\right\}$$
$$+\frac{0.180}{(e^{t'}-1)(1-e^{-t'})}\left\{1+\frac{t'(e^{t'}-e^{-t'})}{(e^{t'}-1)(1-e^{-t'})}\right\}.$$

These limiting expressions for the high and low temperatures are given by

$$g(t,t')=\begin{cases}\dfrac{0.413}{t^2}+\dfrac{0.540}{t'^2} & t,t'\ll 1 \qquad \text{A(2.8)}\\[2ex] \dfrac{95.2}{t^4}+0.540(1+0.76t'^2)\,e^{-t'} & t,t'\gg 1 \qquad \text{A(2.9)}\end{cases}$$

$$g'(t,t')=\begin{cases}\dfrac{0.413}{t^2}+\dfrac{0.540}{t'^2} & t,t'\ll 1 \qquad \text{A(2.8')}\\[2ex] \dfrac{72.7}{t^4}+0.180(1+t')\,e^{-t'} & t,t'\gg 1 \qquad \text{A(2.9')}\end{cases}$$

where we used $\phi_3(\infty)=7.212$ to obtain the first term in A(2.9′). The first terms of these equations indicate the contribution from Normal process and the second terms from Umklapp process. It is found from A(2.8) and A(2.8′) that in the limit at the high temperature they may attain to the same result whether c_2 is adopted for $c_0(\mathcal{E})$ in Eq. (3.19) or c_2', but for the Normal part at low temperature A(2.9′) become smaller than A(2.9).

Calculation of τ_κ^e—From the definition of τ_κ^e, Eqs. (3.25), (3.27), and (3.1) (3.23), τ_κ^e is calculated in the same way for τ_σ^e as follows:

$$\frac{1}{\tau_\kappa^e}=\frac{\pi\hbar}{mn\kappa Tc}\sum_{\boldsymbol{k}_1}\sum_{\boldsymbol{k}_2}\sum_{\boldsymbol{k}_3}\sum_{\boldsymbol{k}_4} w(\boldsymbol{k}_1\boldsymbol{k}_2\boldsymbol{k}_3\boldsymbol{k}_4)f_0(\mathcal{E}_1)f_0(\mathcal{E}_2)f_0(-\mathcal{E}_3)f_0(-\mathcal{E}_4)$$
$$\times\{k_{3x}c_0(\mathcal{E}_3)+k_{4x}c_0(\mathcal{E}_4)-k_{1x}c_0(\mathcal{E}_1)-k_{2x}c_0(\mathcal{E}_2)\}(k_{3x}\mathcal{E}_3+k_{4x}\mathcal{E}_4-k_{1x}\mathcal{E}_1-k_{2x}\mathcal{E}_2)\,\delta(E_1+E_2-E_3-E_4) \qquad \text{A(2.10)}$$

where for simplicity $\mathcal{E}_1$ and $\mathcal{E}_2$ denote $\mathcal{E}_{k_1}$ and $\mathcal{E}_{k_2}$. Here we consider only the process which conserves the total wave vector; i.e.

$$\boldsymbol{k}_1+\boldsymbol{k}_2-\boldsymbol{k}_3-\boldsymbol{k}_4=0 \qquad \text{A(2.11)}$$

and use for w the total cross section which was obtained by the partial wave method in Appendix I. Now if we put

$$\boldsymbol{k}_3-\boldsymbol{k}_1=\boldsymbol{k}_2-\boldsymbol{k}_4=\boldsymbol{l}\,, \qquad \text{A(2.12)}$$

four sums over $\boldsymbol{k}$'s are reduced to those over $\boldsymbol{k}_1$, $\boldsymbol{k}_2$ and $\boldsymbol{l}$. Then introducing three polar coordinates (k_1,θ_1,φ_1), (l,θ_2,φ_2) and (k_2,θ_3,φ_3), their poles being respectively the directions of $\boldsymbol{l}$, $\boldsymbol{k}_2$ and $\boldsymbol{x}$ (the direction of temperature gradient), and representing the angles that $\boldsymbol{x}$ makes with $\boldsymbol{k}_1$ and $\boldsymbol{l}$ respectively by α and β, we can make the following replacement,

$$\sum_{\boldsymbol{k}_1}\sum_{\boldsymbol{k}_2}\sum_{\boldsymbol{l}}\to\left(\frac{1}{8\pi^3}\right)^3\int l^2\,dl\,d\Omega_2\int k_2^2\,dk_2\,d\Omega_3\int k_1^2\,dk_1\,d\Omega_1\,,$$

$$d\Omega_i=d(\cos\theta_i)\,d\varphi_i\,;\qquad i=1,2,3\,,$$

$$k_{1x}=k_1\cos\alpha\,,\qquad k_{2x}=k_2\cos\theta_3\,,\qquad l_x=l\cos\beta\,,$$

$$\cos\alpha=\cos\theta_1\cos\beta+\sin\theta_1\sin\beta\cos\varphi_1\,,$$

$$\cos\beta=\cos\theta_2\cos\theta_3+\sin\theta_2\sin\theta_3\cos\varphi_2$$

and for the energy,

$$E_3+E_4-E_1-E_2=\frac{\hbar^2 l}{m}(k_1\cos\theta_1-k_2\cos\theta_2+l)\,, \qquad \text{A(2.13)}$$

$$\mathcal{E}_3-\mathcal{E}_1=\mathcal{E}_2-\mathcal{E}_4=z\,, \qquad \text{A(2.14)}$$

where

$$z=Al(2k_1\cos\theta_1+l)=Al(2k_2\cos\theta_2-l)\,, \qquad \text{A(2.15)}$$

$$A=\hbar^2/2m\kappa T\,. \tag{A(2.16)}$$

Furthermore transforming the variables θ_2 and k into z and $\mathcal{E}$ as follows,

$$d(\cos\theta_2)=\frac{dz}{2Alk_2}\,,\qquad k\,dk=\frac{d\mathcal{E}}{2A}\,,$$

it is easy to carry out the integration respect to the angles except θ_1, for which we need to notice only the variable $\cos\theta_1$ involved in the δ-function and to replace θ_1 in another slowly varying part with

$$\cos\theta_1=(k_2\cos\theta_2-l)/k_1\,,$$

which is derived from the condition of energy conservation, say A(2.13)=0. From A(2.15) and $|\cos\theta_1|\leq 1$, the range of z is restricted by

$$Al^2(1-2k_1/l)<z<Al^2(1+2k_1/l)\,. \tag{A(2.17)}$$

Since the range of l is in $0<l<2k_0$ from A(2.12) and hence the value of Al^2 falls into the range $0<Al^2<4\zeta/\kappa T$, we may be possible to approximate as follows

$$-\infty<z<+\infty\,,$$

instead of A(2.17). Thus after the integration of the angles except θ_2 we have

$$\frac{1}{\tau_\kappa^e}=(192\pi^5 n\hbar\kappa TA^3c)^{-1}w\int_0^{2k_0}dl\int_{-\infty}^{\infty}dz\int_{-\infty}^{\infty}d\mathcal{E}_1\int_{-\infty}^{\infty}d\mathcal{E}_2\,f_0(\mathcal{E}_1)f_0(\mathcal{E}_2)f_0(\mathcal{E}_1+z)f_0(\mathcal{E}_2-z)$$
$$\times e^{\mathcal{E}_1+\mathcal{E}_2}K(\mathcal{E}_1,\mathcal{E}_2,l,z)\,, \tag{A(2.18)}$$

where

$$K(\mathcal{E}_1,\mathcal{E}_2,l,z)=-\frac{z^2}{2A}\{c_0(\mathcal{E}_1)+c_0(\mathcal{E}_2)\}+\left(zl^2-2k_0^2z+\frac{z^3}{2A^2l^2}\right)\{c_0(\mathcal{E}_1)-c_0(\mathcal{E}_2)\}$$
$$+l^2\{\mathcal{E}_1c_0(\mathcal{E}_1)+\mathcal{E}_2c_0(\mathcal{E}_2)\}-\frac{z}{A}\{\mathcal{E}_1c_0(\mathcal{E}_2)-\mathcal{E}_2c_0(\mathcal{E}_1)\}\,, \tag{A(2.19)}$$

where to obtain A(2.18), A(2.19) we used A(2.4). We find that when we integrate over $\mathcal{E}_1$ and $\mathcal{E}_2$, the first and fourth term in A(2.19) vanish, if we remember that $c_0(\mathcal{E})$ is the odd-function of $\mathcal{E}$ and the Fermi function f_0 has form given by Eq. (3.2). Therefore it remains that we substitute the concrete form of $c_0(\mathcal{E})$, Eq. (3.19), for the second and third term (now since our attention lie in low temperature we take c_2' term) and integrate respect to the remaining variables. The final result is

$$\frac{1}{\tau_\kappa^e}=\frac{nmk_0}{\pi\hbar^3}\phi_2(\infty)w\left(\frac{\kappa T}{\zeta}\right)^2. \tag{A(2.20)}$$

Here as mentioned previously, replacing w with the total cross section σ_{tot} by

$$w=\frac{\pi\hbar^4}{m^2}\sigma_{tot} \tag{A(2.21)}$$

and using $\phi_2(\infty)\simeq 3.29$, we have

$$\frac{1}{\tau_\kappa^e}=6.6n\sigma_{tot}\frac{\hbar k_0}{m}\left(\frac{\kappa T}{\zeta}\right)^2 \tag{A(2.22)}$$

or writing by the mean free path

$$l_\kappa^e=6.6n\sigma_{tot}\left(\frac{\kappa T}{\zeta}\right)^2. \tag{A(2.23)}$$

Appendix III. Anisotropy of the Sound Velocity

The sound velocity of sodium was measured by Quimby-Siegel[24] and Bender[25]. Both results are fairly different, and Blackman[26] estimated $\overline{\Theta^n}$ by using the latter result. We here adopt the former. According to this result, the sound velocities of longitudinal and transversal waves c_l, c_t can be expressed approximately by the following experimental formulas;

$$c_l=\{1.4+4.0\sin^2\theta(\cos^2\theta+\tfrac{1}{4}\sin^2\theta\sin^2 2\varphi)\}\times 10^5\ \text{cm/sec}\ , \tag{A(3.1)}$$

$$c_t=\{2.4-4.7\sin^2\theta(\cos^2\theta+\tfrac{1}{4}\sin^2\theta\sin^2 2\varphi)\}\times 10^5\ \text{cm/sec}\ . \tag{A(3.2)}$$

It may be thought that only the longitudinal wave contributes to the Normal process, and hence all Θ^n in Eqs. (4.1)$\sim$(4.4) are to be understood as $(\hbar q_0/\kappa)\overline{c_l{}^n}$. To the Umklapp process we must consider the contribution from the phonons with two polarizations. Now if the both types of sound wave are mixed together at the ratio 1:2, those which we require are the following. First in high temperature,

$$\overline{\frac{1}{\Theta'^2}}=\frac{1}{3}\left(\frac{q_0}{q'}\right)^2\left(\frac{\kappa}{\hbar q_0}\right)^2\left\{\overline{\frac{1}{c_l{}^2}}+2\overline{\frac{1}{c_t{}^2}}\right\}, \tag{A(3.3)}$$

where q' is defined by the relation $\kappa\Theta'=\hbar cq'$ (see § 4 (ii)). Estimating roughly the mean values of $c_l{}^{-2}$ and $c_t{}^{-2}$ from the above experimental formulas these values are nearly equal; i.e.

$$\overline{c_t{}^{-2}}\simeq\overline{c_l{}^{-2}}\simeq 0.24\times 10^{-10}\,(\text{cm}\cdot\text{sec}^{-1})^{-2}\ . \tag{A(3.4)}$$

Next in low temperature, we need the mean value of the following quantity

$$\exp\left(-\frac{\Theta'}{T}\right)=\frac{1}{3}\left\{\exp\left(-\frac{\hbar q' c_l}{\kappa T}\right)+2\exp\left(-\frac{\hbar q' c_t}{\kappa T}\right)\right\}.$$

In order to evaluate the above quantity approximately, we shall expand c around its minimum point since we consider the case $\Theta'\gg T$. c_l has the minimum values in the six directions, that is, $\theta=0$, π and $\theta=\pi/2$; $\varphi=n\pi/2$ ($n=0, 1, 2, 3$). As each direction is equivalent, expanding around z-axis, we have

$$c_l\simeq(1.4+4\theta^2)\times 10^5\ \text{cm}\cdot\text{sec}^{-1}\ .$$

On the other hand, c_t has the minimum values in the eight directions, that is, $\cos\theta=\pm 3^{-1/2}$; $\varphi=\pi/4+n\pi/2$ ($n=0, 1, 2, 3$), and hence we must the original coordinate system into the new coordinate system with z'-axis, being in the direction $\cos\theta=3^{-1/2}$; $\varphi=\pi/4$, then the transformation matrix is given by

$$\sin\theta\cos\varphi=\frac{1}{\sqrt{2}}\sin\theta'\cos\varphi'+\frac{1}{\sqrt{6}}\sin\theta'\sin\varphi'+\frac{1}{\sqrt{3}}\cos\theta'\ ,$$

$$\sin\theta\sin\varphi=-\frac{1}{\sqrt{2}}\sin\theta'\cos\varphi'+\frac{1}{\sqrt{6}}\sin\theta'\sin\varphi'+\frac{1}{\sqrt{3}}\cos\theta'\ ,$$

$$\cos\theta=\qquad -\sqrt{\frac{2}{3}}\sin\theta'\sin\varphi'+\frac{1}{\sqrt{3}}\cos\theta'\ .$$

Hence we have

$$\sin^2\theta(\cos^2\theta+\sin^2\theta\cos^2\varphi\sin^2\varphi)\simeq\tfrac{1}{3}(1-2\theta'^2)$$

and using this result, c_t becomes

$$c_t\simeq(0.84+3.1\theta'^2)\times 10^5\ \text{cm}\cdot\text{sec}^{-1}\ .$$

Thus as the mean value of Umklapp part of electrical resistance at low temperature over the sound velocity we obtain

$$\begin{aligned}\overline{U_l}&=\frac{1}{4\pi}\frac{0{\cdot}54}{T}\int_{-1}^{1}dt\int_{0}^{2\pi}d\varphi\,\exp\left(-\frac{\hbar q'\,c_l(t,\varphi)}{\kappa T}\right)\\&\simeq\frac{0.54}{T}\cdot\frac{4.3}{8.0}\frac{T}{\Theta_{l0}'}\exp\left(-\frac{\Theta_{l0}'}{T}\right),\end{aligned}\tag{A(3.5)}$$

where

$$\kappa\Theta_{l0}'=\hbar q'\times1.4\times10^5$$

and

$$\overline{U_t}\simeq\frac{0.54}{T}\frac{3.4}{6.2}\frac{T}{\Theta_{t0}'}\exp\left(-\frac{\Theta_{t0}'}{T}\right),\tag{A(3.6)}$$

where

$$\kappa\Theta_{t0}'=\hbar q'\times0.84\times10^5\ .$$

On the Superstructure of the Ordered Alloy Cu_3Pd.
III. High Temperature Electron Diffraction Study

By Denjiro WATANABE

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai, Japan

(Received October 9, 1958)

Using a high temperature electron diffraction camera, Cu_3Pd alloys have been investigated in thin oriented, evaporated films at temperatures below and above the critical point of order-disorder. The present work has elucidated that, in alloys of α''-phase, the line-up number of anti-phase domains and the degree of order inside domains decrease with increasing temperature in the range of 20∼40°C below the critical point, and an abrupt decrease of the line-up number of domains occurs at the critical point. In the range of 100∼150°C above the critical point, short chains of one-dimensional anti-phase domains with the same period of out-of-steps as in the ordered state remain randomly in an equilibrium state. On the other hand, anti-phase domains are absent in the alloys of α'-phase below as well as above the critical point.

§ 1. Introduction

In Part I of the present study[1)], the structure of ordered copper-palladium alloys has been investigated by electron diffraction in the composition range from 10 to 28 per cent Pd*, using thin single-crystalline films prepared by evaporation. It was shown that the alloys with compositions of 18 to 28 per cent Pd (α''-phase alloys) have a two-dimensional anti-phase domain structure in a fully ordered state, a fundamental cell of which is face-centred tetragonal with an atomic arrangement of the ordered Cu_3Au type. Alloys with palladium less than 18 per cent (α'-phase alloys) have the ordered Cu_3Au type structure with cubic symmetry, being consistent with the results obtained by Jones and Sykes[2)]. The two-dimensional anti-phase domain structure has been satisfactorily confirmed in bulk specimens in Part II[3)] and by Schubert, Kiefer, Wilkens and Haufler[4)], both using X-rays.

In Part I, weak diffuse maxima with peculiar splitting have been reported to remain at superlattice reflection positions, having more distinct contrast than those obtained from a quenched disordered CuAu alloy[5)], as shown in Fig. 6 of Part I, after quenching of the alloy films from temperatures above the critical point of order-disorder (T_c). As a relaxation time for ordering is considerably long in the present alloys[2)], the above splitting of superlattice reflections after quenching will reveal the actual state of the alloys above T_c and suggest the presence of anti-phase domains with nearly definite size. In order to obtain a distinct conclusion, however, it is necessary to observe diffraction patterns directly at high temperatures. According to Jones and Sykes[2)], there is a well-marked tail on the specific heat versus temperature curve of the alloy containing 24.9 per cent Pd above T_c (465°C), and in this respect, this alloy resembles Cu_3Au. On the electrical resistivity versus temperature curves of the present alloys, a peculiar anomaly has been found above T_c by Borelius, Johansson and Linde[6)] and by Kaya[7)]. These anomalous effects also seem to be attributed to the presence of some local order. Thus, the present work has been undertaken to elucidate the high temperature state of Cu_3Pd alloys up to 700°C, using a high temperature electron diffraction camera.

Until now, several high temperature diffraction studies on the alloys Cu_3Au and CuAu have been carried out by various authors, using X-rays[8)] as well as electrons[9)]. Raether's work of single-crystalline films of Cu_3Au gave an important information on the existence of anti-phase domains with various sizes at temperatures above T_c, 388°C, and is intimately connected with the present work. In the present paper, it will be shown that out-of-steps, classified into "the first kind"[1], with nearly definite period remain even at temperatures above T_c in the equilibrium state of α''-phase alloys, while such out-of-steps are absent in α'-phase alloys. The mode of line-up of anti-phase domains was studied also in the range of 20~40°C below T_c.

---

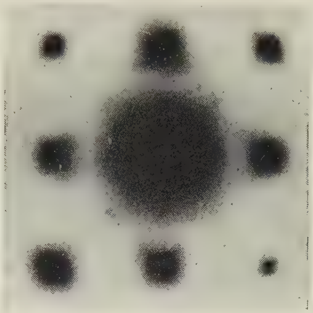

Fig. 1. Diffraction pattern obtained at 500°C from α'-phase film containing 13 per cent Pd.

§ 2. Experimental Method

Four kinds of single-crystalline films of copper-palladium alloys containing 13, 18, 25 and 28 per cent Pd respectively were prepared in the same way as described in Part I. These films were annealed for about 300 hours in the temperature range between critical points and 250°C and were cooled down to room temperature. This treatment was sufficient to complete the ordered state. Then, they were heated in the electron diffraction camera provided with a small high temperature furnace with heating velocity of 1~0.3°C/min. The diffraction patterns were observed on a fluorescent screen during heating and suitably recorded on dry plates.

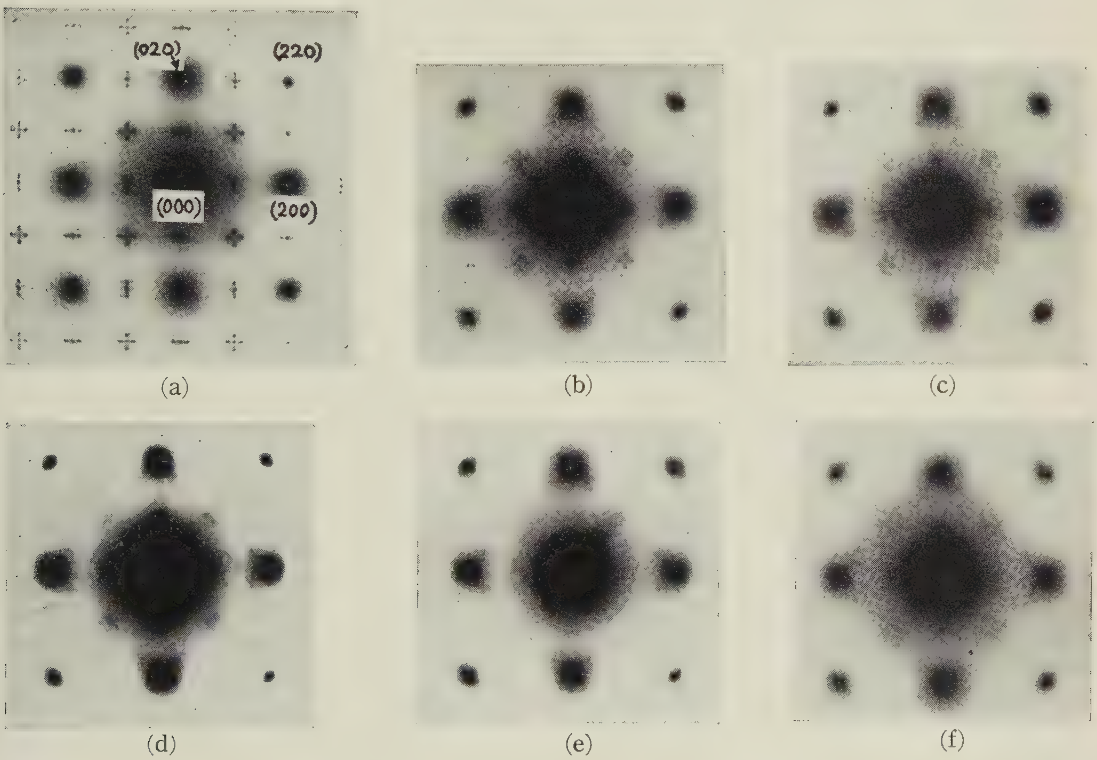

Fig. 2. Diffraction patterns obtained at various temperatures from α''-phase film containing 25 per cent Pd. (a) room temperature (fully ordered state), (b) 442°C, (c) 451°C, (d) 453°C, (e) 685°C, (f) 476°C (cooling case). Indices assigned to normal reflections are referred to the disordered cubic lattice.

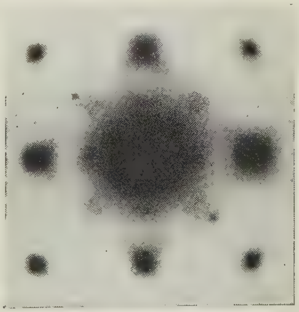

Fig. 3. Diffraction pattern obtained at 413°C from α''-phase film containing 28 per cent Pd.

The diffraction camera used was the same as described in Part I. The high temperature furnace was of a similar type to that used by Germer, Haworth and Lander10) in its construction and size, but was made of stainless steel instead of copper in order to avoid specimen contamination due to evaporation of copper at high temperatures. The heat loss by radiation was depressed by a shield made of stainless steel located around the furnace, and the conduction loss was estimated to be fairly low because both the furnace and the shield were connected with a supporting metal block only through a disk of steatite. A maximum temperature attained by a specimen film was about 750°C at 30 watt. The temperature was measured by means of a Pt-Pt·Rh thermocouple of 0.1 mm in diameter and a high resistance millivoltmeter. The temperature scale indicated on the latter was compared with critical points of order-disorder of the films of Cu_3Au and Cu_3Pd of known atomic compositions, and the apparent temperature was found to be about 10°C lower than the true temperature of a specimen film in the range between 380 and 500°C. In the present paper, temperatures indicated by the millivoltmeter are used for convenience' sake.

§ 3. Experimental Results

(1) *α′-phase alloy (13 per cent Pd)*

The sharpness and the intensity of diffraction spots did not change up to about 440°C (see Fig. 5 in Part I). Above 450°C, however, superlattice reflections gradually weakened with increasing temperature, their sharpness remaining scarcely changed. These reflections became diffuse abruptly and still fainter at 494°C, as shown in Fig. 1, but remained visible even at 600°C. The ordered structure known from the pattern is analogous to that of Cu_3Au, and the shape of the superlattice reflections shows that any kind of anti-phase domains is absent in this alloy below as well as above T_c.

(2) *α′′-phase alloys*

The ordered alloys of this phase have a two-dimensional anti-phase domain structure characterized by the two kinds of out-of-steps, as reported in Part I. According to the present high temperature study, the anti-phase domain characterized by the second kind of out-of-steps gradually faded away as the temperature approached T_c, while the other kind of anti-phase domain was preserved up to T_c throughout α′′-phase. It is remarkable that fairly well defined out-of-steps still persisted above T_c. Details of these aspects will be described about the sample of 25 per cent Pd as follows (see Fig. 2): While such a

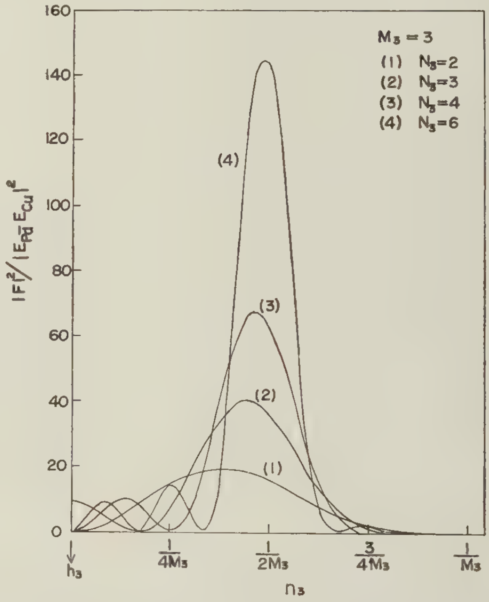

Fig. 4. The profile of split maximum along $[00h_3]$ in reciprocal space, given by numerical calculation.

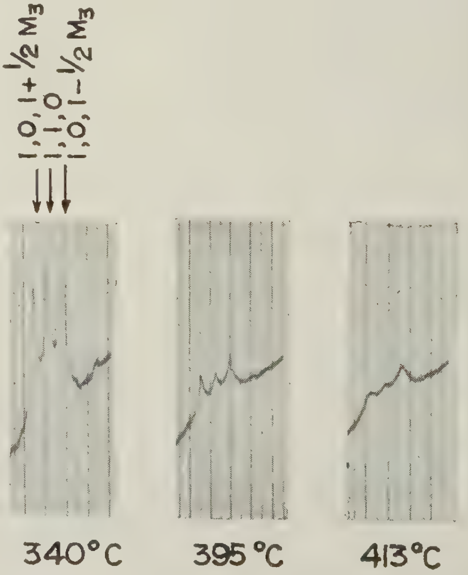

Fig. 5. Microphotometer curves of split superlattice reflections of the alloy containing 28 per cent Pd, at various temperatures.

pattern as shown in Fig. 2 (a) almost persisted up to about 420°C, the superlattice reflections exhibiting complex splits were gradually weakened with increasing temperature in the range between about 430 and 452°C, and, especially, the splits due to the second kind of out-of-steps almost faded away, as shown in Fig. 2 (b) and (c). The intensities of the splits due to the first kind of out-of-steps became far weaker immediately below 452°C than those of the splits in the fully ordered state, the sharpness being scarcely changed visually. At 452°C, these reflections became diffuse abruptly and fainter slightly, as the case of 13 per cent Pd, but diffuse maxima with peculiar splitting still remained, having far more distinct contrast than those in disordered CuAu alloy[5,11]. They were weakened gradually with increasing temperature and became very weak at about 490°C, but were visible even at about 600°C. Fig. 2 (d) shows the diffraction pattern at 453°C. At about 700°C, shapes of the faint diffuse maxima could no more be distinguished (Fig. 2 (e)). When the specimen was slowly cooled from 700°C with cooling rate of 1°C/min., the pattern changed almost reversibly (Fig. 2 (f)).

For 28 per cent Pd, the split sharp superlattice reflections were gradually weakened at temperatures above about 380°C and became very weak at 398°C. At 400°C, they became diffuse suddenly and fainter slightly, but separations of split maxima were scarcely changed though the splittings characterized by the second kind of out-of-steps disappeared. On further heating, the diffuse split maxima behaved themselves almost similarly to those of 25 per cent Pd (Fig. 3). For 18 per cent Pd, the behavior of superlattice reflections with rising temperature was essentially the same, except that the second kind of out-of-steps was not observed from the beginning.

The fact that the superlattice reflections in the alloy film of Cu_3Au decrease their intensities and become diffuse suddenly at T_c, 388°C, as reported by Raether[9], enables us to estimate the true temperature using this alloy film, which was found to be about 10°C higher than the apparent temperature as already described in § 2. Taking into account both this measurement and values of T_c for Cu_3Pd alloys determined by several investigators[2,12], we are able to regard the temperatures, at which the superlattice reflections become diffuse abruptly, as critical points of the present alloy films.

§ 4. Interpretations and Discussions for the Results

The following conclusions may be given from the above results about the mode of line-up of anti-phase domains in α''-phase alloys below and above T_c. The fact that the split superlattice reflections continue to be considerably sharp up to T_c seems to mean the keeping of a large line-up number of anti-phase domains, and the intensity decrease immediately below T_c may be mainly caused by the decreasing degree of order within each domain. Above T_c, diffraction maxima at superlattice reflection positions consist of diffuse split maxima with tolerable contrast, and the separations of their splits are much the same as in the ordered state, as shown in Table I. Therefore, we may have to consider that there remain anti-phase domains, characterized by the first kind of out-of-steps with nearly definite period, in a crystal where long range order vanishes. It seems that the model for such a state should be what is definitely distinguished from that below T_c in the line-up number of domains as well as in the degree of order within each domain, because the "disordered state" is treated.

Next, we shall examine the observed results in detail, considering the diffraction effect caused by the anti-phase domain structure on the basis of the one-dimensional structure characterized by the first kind of out-of-steps. If the line-up number of anti-phase domains along the z direction is N_3 and the period of out-of-steps, i. e., the size of anti-phase domain, measured in atomic distance, is M_3, the absolute value of the structure amplitude, $|F|$, is given for such a crystal by the following two equations, corresponding to even and odd values of N_3 respectively, at positions, h_1, h_2, $h_3 \pm n_3$, in reciprocal space*:

$$|F| = |E_{Pd} - E_{Cu}| \cdot \left| \frac{\sin M_3 n_3 \pi}{\sin n_3 \pi} \right| \cdot \left| \frac{\sin N_3 M_3 n_3 \pi}{\cos M_3 n_3 \pi} \right| \tag{1–1}$$

for N_3=even, and

---

* Here, h_1, h_2 and h_3 represent reciprocal lattice points, as usual.

$$|F|=|E_{Pd}-E_{Cu}|\cdot\left|\frac{\sin M_3n_3\pi}{\sin n_3\pi}\right|\cdot\left|\frac{\cos N_3M_3n_3\pi}{\cos M_3n_3\pi}\right| \tag{1-2}$$

for N_3=odd, where h_1 and h_2 are mixed, n_3 is continuous variable, and E_{Pd} and E_{Cu} are the atomic scattering factors for electron of palladium and copper respectively. If N_3 is of the same order of magnitude as M_3, the positions of maxima of $|F|^2$ are determined both by $|\sin N_3M_3n_3\pi/\cos M_3n_3\pi|^2$ or $|\cos N_3M_3n_3\pi/\cos M_3n_3\pi|^2$ and by $|\sin M_3n_3\pi/\sin n_3\pi|^2$, contrary to the case where N_3 predominates. Fig. 4 shows $|F|^2/|E_{Pd}-E_{Cu}|^2$ along the h_3 direction for small N_3 values, 2, 3, 4 and 6, M_3 being assumed to be 3. It can easily be seen from this figure that the peak of a split maximum shifts from the position, $h_3\pm(1/2M_3)$, toward the original superlattice reflection position, h_3, and its half value breadth increases as N_3 becomes small. On the other hand, it is located in the position, $h_3\pm(1/2M_3)$, when N_3 is larger than 6. The same holds for other M_3 values. If the collapse of order inside each domain occurs, the peak intensities of split spots decrease, since the scattering intensities of superlattice reflections are proportional to S^2, where S is the long range order parameter, but the sharpness will be unaffected.

Now, we can estimate N_3 values for various temperatures from the half value breadths of split maxima in the intensity curves obtained from microphotometer traces (Fig. 5). The results are given in Table II with mean sizes of chains of domains corresponding to them. From this measurement, it was found that N_3 is about 10 or more in the fully ordered state of 25~28 per cent Pd films and it gradually decreases with increasing temperature in the neighbourhood of T_c, reaching about 5~6

Table I. The separation of the split maxima in reciprocal space, m, and the period of out-of-steps, M_3.

18% Pd ($T_c\approx$483°C)			25% Pd ($T_c\approx$452°C)			28% Pd ($T_c\approx$400°C)		
Temperature (°C)	m	M_3	Temperature (°C)	m	M_3	Temperature (°C)	m	M_3
			fully ordered state	$\frac{2a_3^*}{7.2}$	3.6	fully ordered state	$\frac{2a_3^*}{6.1}$	3.0
440	$\frac{2a_3^*}{18.8}$	9.4	442	$\frac{2a_3^*}{7.6}$	3.8	395	$\frac{2a_3^*}{6.3}$	3.2
470	$\frac{2a_3^*}{21.5}$	10.8	451	$\frac{2a_3^*}{7.4}$	3.7	413	$\frac{2a_3^*}{6.2}$	3.1 (2.8)
			453	$\frac{2a_3^*}{7.7}$	3.9 (3.5)			
			462	$\frac{2a_3^*}{8.0}$	4.0 (3.6)			

In this table, m corresponds to the separation in superlattice reflections split along the h_3 direction in Fig. 11 of Part I, and a_3^* is the reciprocal lattice constant. M_3 has been calculated from the following relation: $m/2a_3^*=1/2M_3$. Parenthesized values have been estimated, assuming N_3 to be 3. In general measured values of M_3 are not integer, as in the fully ordered state[13].

Table II. N_3 values estimated from the half value breadths of split maxima and mean sizes of chains of domains corresponding to them.

25% Pd			28% Pd		
Temperature (°C)	N_3	Mean size (Å)	Temperature (°C)	N_3	Mean size (Å)
340	>9	>140	340	>10	>120
442	8~7	~100	395	7	~ 80
451	6~5	~ 70	398	6~5	~ 60
455	~3	~ 40	413	~3	~ 30

immediately below T_c. This decrease of N_3 causes peak intensities of split spots to be reduced approximately to one fourth. But the visually estimated intensities immediately below T_c are surely smaller than this expected value, as readily seen from Fig. 2. Therefore, some of the intensity decrease should be ascribed to a fall of the degree of order inside each domain. From the abrupt decrease of N_3 to about 3 immediately above T_c, it is suggested that a chain of anti-phase domains is cut to pieces by disordered regions appearing at T_c. In this case, however, an enormous change of intensity is not observed, as can be seen in Fig. 2. In order to explain the above-mentioned fact, the following model may be considered for the line-up of anti-phase domain structure in α''-phase alloys: The line-up number of domains, N_3, decreases almost to half with increasing temperature in the range of 40~20°C below T_c, and at the same time the degree of order inside each domain decreases rapidly, reaching the state with low ordering of atoms at T_c. Immediately above T_c, N_3 is diminished to about 3 which definitely distinguishes the state of the alloy from that below T_c, but a strong collapse of the degree of order seems not to occur within each domain. As the split maxima are visible even in the range of 100~150°C over T_c, it is certain that there is a sporadic random distribution of short chains of anti-phase domains in this temperature range. Inside a domain the degree of order is considerably lowered, but between domains the anti-phase relation yet remains.

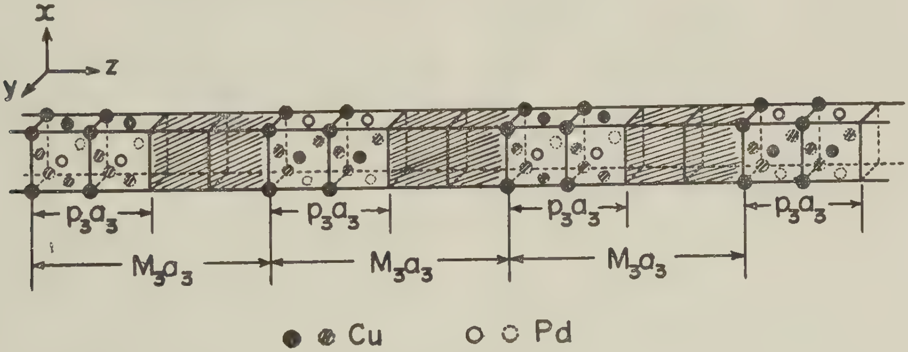

Fig. 6. Anti-phase domain structure including a disordered region at each domain boundary. The shaded regions indicate the disordered lattices.

A model shown in Fig. 6 is tentatively proposed for the anti-phase domain structure above T_c. It is a structure with a considerable size of a completely disordered region between comparatively ordered domains. The domain size and the period of out-of-steps are expressed by P_3a_3 and M_3a_3 respectively*. In the expression of the structure amplitude of superlattice reflections for such a lattice, the disordered region has nothing to do, and therefore the following expression is readily obtained for $|F|$ of superlattice reflections:

$$|E| = |E_{Pd} - E_{Cu}| \cdot \left| \frac{\sin P_3 n_3 \pi}{\sin n_3 \pi} \right| \cdot \left| \frac{\sin N_3 M_3 n_3 \pi}{\cos M_3 n_3 \pi} \right| \qquad (2)$$

for N_3=even, where N_3 and n_3 have the same significance as in equation (1). This equation leads to a similar result to that obtained from equation (1). That is to say, positions of split maxima are determined by $1/2M_3$ for N_3 larger than P_3, and a profile of splitting is similar to Fig. 4 for N_3 as small as P_3. But the peak intensity is much lowered in proportion to $|\sin P_3 n_3 \pi / \sin n_3 \pi|^2 / |\sin M_3 n_3 \pi / \sin n_3 \pi|^2$. It is chiefly the period of out-of-steps that determines the separation of split, while the intensity decreases with decreasing domain size. The present model seems to explain qualitatively the behavior of superlattice reflections at temperatures not too higher than T_c. For the intensity decrease of split maxima with further temperature rise, the decrease of P_3, N_3 and S inside domains will be responsible. Above 150°C over T_c, the peculiar shapes of diffuse maxima become indistinguishable, indicating the vanishing of domains, and faint superlattice reflections caused by the pure short range order are left.

---

* a_3 is the lattice constant along the z axis in terms of the fundamental cell.

An opinion might be given that the survival of anti-phase domain above T_c is not in equilibrium. However, the fact that when a film of 25 per cent Pd was cooled down from about 700°C the pattern reversibly changed denies this opinion. Because, if observed domains at rising temperature did not exist in an equilibrium state, the film cooled down should not have given peculiar forms of superlattice reflections. Thus, anti-phase domains characterized by the first kind are definitely present in an equilibrium state even above T_c in α''-phase alloys. The formation of anti-phase domains has been found in a Cu_3Au alloy[9] above T_c, but the split maxima were so diffuse that these were not regarded as separated. It is remarkable that diffuse split maxima in the present α''-phase alloys above T_c are sufficiently separated to enable us to recognize that the period of occurring out-of-steps is the same as that in the ordered state. The short chains of anti-phase domains formed above T_c are reasonably considered to be nuclei of anti-phase domains in the ordered state. Thus, the nucleation of ordering begins to occur in the range of 100∼150°C over T_c. In the X-ray study of CuAu alloy, Roberts[8] observed the outward shift of the (100) and (300) diffuse peaks above T_c, and suggested the existence of micro-regions of layered material similar to the ordered state. In the present alloy, however, the shift of split maxima corresponding to the tetragonality was not observed above T_c, as the axial ratio almost attains unity immediately below T_c.

In the following, some discussions will be given of the present result, in connection with the physical properties of Cu_3Pd alloy. Jones and Owen[14] concluded from the temperature dependence of the tetragonality that the long range order of the ordered alloy Cu_3Pd decreases with increasing temperature slowly at first but more rapidly above about 420°C, vanishing at 460°C. The change of anti-phase domain structure with increasing temperature below T_c revealed by the present work coincides fairly well with their conclusion. Moreover, the fact that the second kind of out-of-steps vanished in the temperature range of about 20°C below T_c in the heating case of the 25 per cent Pd alloy supports the suggestion given by Hirabayashi and Ogawa[3] that a well-marked maximum at about 400°C in the specific heat versus temperature curve obtained by Jones and Sykes[2] probably means the transition from the two-dimensional to the one-dimensional anti-phase domain structure. As is commonly known, a large change has been found to occur at T_c in physical properties of Cu_3Pd such as specific heat, electrical resistivity, etc[2],[6],[7]. According to the present experiment, on the other hand, the remarkable, crystallographical change at T_c in α''-phase alloys is the change of the line-up number of anti-phase domains rather than that of the degree of order inside domain. It should be remarked that such a structural change at T_c has not been found as yet on any alloy other than Cu_3Pd. According to Borelius, Johansson and Linde[6] and Kaya[7], the electrical resistivity of Cu_3Pd somewhat decreases with increasing temperature between 470 and 600°C, and normally increases above 600°C. They attributed this effect to the presence of a short range order and its collapse in connection with the corresponding anomaly on the specific heat versus temperature curve, but did not confirm these by X-rays. The short chains of anti-phase domains 30∼40Å long found by the present work in the temperature range of 100∼150°C above T_c may be responsible for the anomaly in electrical resistivity as well as in specific heat.

§ 5. Conclusion

According to the present high temperature electron diffraction work using thin single-crystalline films, the crystallographical states below and above the critical point of order in the Cu_3Pd alloys have been elucidated, concerning particularly the behavior of anti-phase domains. In α''-phase alloys, the line-up number of anti-phase domains decreases gradually with increasing temperature, reaching about 5∼6 immediately below the critical point, and the degree of order inside each domain decreases also. At the critical point, the abrupt decrease of the line-up number of domains takes place rather than that of the degree of order within domains. Diffuse scattering with peculiar splitting remains at superlattice reflection positions in the range of 100~150°C over the critical point. This means that in this temperature range the short chains of anti-phase domains, corresponding to the out-of-steps characterized by the first kind and with the same period as in the fully ordered state, are present, being scattered in the disordered state, in equilibrium. The above results seem to be consistent with the changes of physical properties accompanying the order-disorder transformation so far observed. In α'-phase alloy any kind of anti-phase domains is absent below as well as above the critical point.

Acknowledgement

The present author wishes to express his sincere thanks to Professor S. Ogawa for his kind guidance and encouragement. His thanks are also due to Mr. M. Hirabayashi whose discussion was very useful.

The present investigation has been supported partly by the fund of the Ministry of Education in Aid of Scientific Researches.

(Received November 19, 1958)

The KCl single crystal which was grown from the melt, thermally quenched, and additively coloured with potassium metal were observed electronmicroscopically using replica technique. Growth of crystallites was seen both on the outer surfaces and in the interior of the crystal when it was thermally quenched or it was coloured additively. The crystallites grew more markedly in the latter case than in the former. The mechanism by which F centres are formed were considered.

§ 1. Introduction

Since Hedges and Mitchell[1)] succeeded in decorating the dislocations in AgBr crystal with printed out silver particles, many similar experiments have been carried out on the alkali-halide crystals[2)], divalent ionic crystals[3)] and silicon[4)]. These experiments have a characteristic feature that the dislocation patterns inside the crystal can be seen by an opitical microscope. This promotes the study about the possible arrangements of dislocations, the interaction between them, the movements of dislocations under various circumstances and the interaction between stoichiometric excess metal or segregated metal and dislocations.

One of the present authors has given attentions to the correlations between crystal growth and colouration of crystals, and carried out electronmicroscopic observations, using replica technique, for the alkali halide crystal coloured with X-ray[5)]. This experiment indicated that the crystallites appeared not only on the X-rayed (001) surface and side faces of the crystal, but also in the inner parts of this crystal as the irradiation of the crystal with X-ray proceeded, and that the grown crystallites disappeared in the reverse course of growth when the X-rayed crystal was bleached thermally and photochemically. These phenomena were also confirmed with the successive observations on the definite portion of the (001) plane of the same KCl crystal irradiated with X-ray and subsequently bleached photochemically, using the two-stage replica technique[6)]. This confirmation led to the conclusion that these phenomena could hardly be ascribed to the mere surface phenomena.

This article reports electronmicroscopic observations of the KCl single crystal which was coloured additively with excess potassium metal, here the observations were made with one-stage replica technique. Our main interests were directed upon the changes induced on the outer surfaces and in the inner parts of the crystal when it was coloured additively.

§ 2. Experimental Methods

Prior to the study of the crystal coloured with excess potassium metal, electronmicroscopic observations were made on the pure KCl single crystal which was heated and subsequently quenched to room temperature in vacuum. In this section, therefore, descriptions are given about the thermal treatment of KCl crystal in vacuum, the additive colouration of KCl crystal with potassium metal, and the preparation of replica.

2.1 *The heat treatment*

The KCl single crystal of about $1\times1\times2\,cm$ in the evacuated ($10^{-4}\,mmHg$) and sealed-off pyrex glass tube was heated in an electric furnace at the temperature of 520° to 580°C for 4 hours and then cooled very rapidly to room temperature. These conditions are the same as those of colouring the crystal additively except for one point, the lacking of potassium metal.

---

* The present Address: *Department of Physics, The Faculty of Science, Tohoku University, Sendai, Japan.*

2.2 *Additive colouration of crystal with potassium metal*

The KCl single crystal containing only *F* centres was obtained as usual by heating the crystal in the atmosphere of potassium vapour at the temperature of 520° to 580°C for 4 hours and then by cooling it very rapidly. Although the colouring agent, potassium metal, was more carefully distilled in vacuum than the case of usual optical study, it was difficult to avoid for the surface of distilled metal to be whitened slightly.

As is well known, when the amount of sealed potassium metal is too much, the surfaces of coloured crystal are covered with the residual metal. This metal film or drops of residual metal, together with the dark brown film usually enclosing the coloured crystal, disturbed the electronmicroscopic observation, because the replica was destroyed when it was removed from the surface of crystal in water (cf. Part **2.3** in this section) or because the replica became too thick to allow an electron-beam of an electron microscope to pass through it. After several trials, it was found that the appropriate amount of potassium metal to avoid these disturbances was obtainable, in the range of temperature employed, by distilling the metal the amount of which was that required to form *F* centres of density of about $10^{18}\ cm^{-3}$.

It was also confirmed that the coloured crystal showed only the *F* absorption band in the wavelength region of 2,300A to 10,000A.

2.3 *Preparation of replica*

Electronmicroscopic observations on the crystal surface were made using the one-stage replica technique. The methods for preparating replicas consist of two processes: (i) The crystal surface to be examined is obliquely

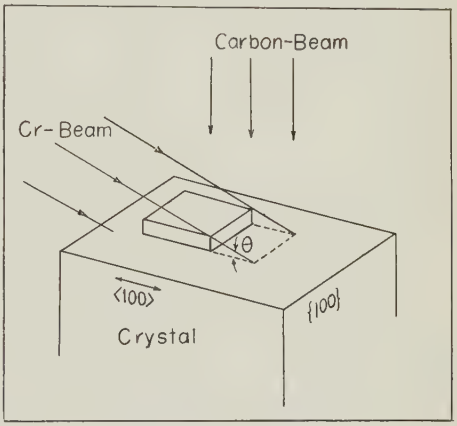

Fig. 1. The schematic diagram for the preparation of replicas.

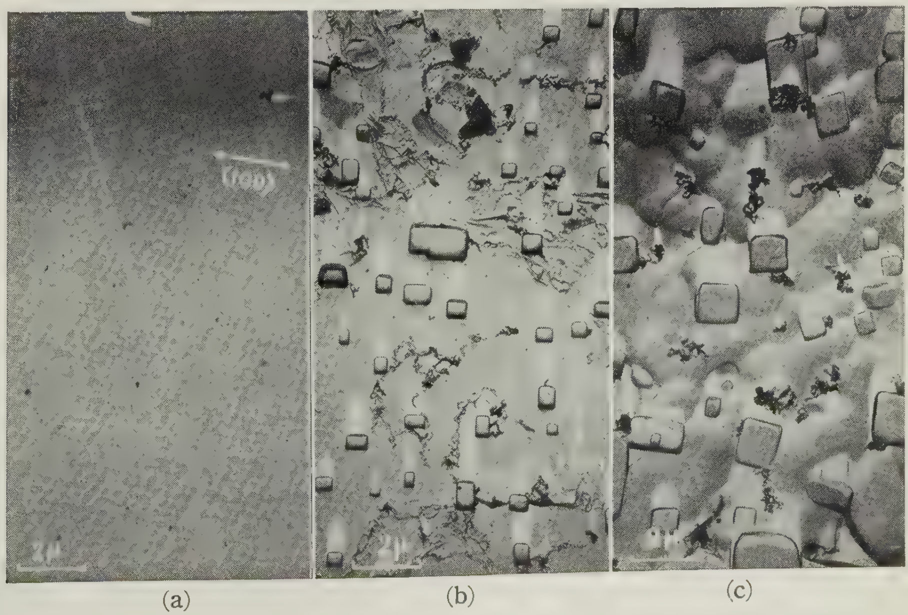

(a) (b) (c)

Fig. 2. (a): A fresh {100} cleavage plane of the KCl crystal grown from the melt. (b) and (c): {100} outer surfaces of the KCl crystal which was heated at 580°C for 4 hours and was quenched subsequently to the room temperature.

deposited with evaporated chromium in high vacuum. The direction of chromium-beam was chosen to be parallel to one of the ⟨100⟩ direction of the crystal and the angle between chromium-beam and the crystal surface θ was $\tan\theta = 1/3$. This chromium film was subsequently reinforced with carbon film. The schematic diagram of the apparatus for making a replica is shown in Fig. 1. (ii) The film was then removed from the replicated crystal surface by disolving the salt in water.

In order to observe the inner parts of the crystal, the replica was prepared on the fresh {100} cleavage surface of the crystal according to the procedures just described.

§ 3. Experimental Results

The descriptions are conveniently classified as follows:

3.1 The growth of crystallites on the surface of the KCl crystal which was quenched from high temperature in vacuum, and those on the surface of the KCl crystal which was coloured additively with excess potassium metal.

(a) The {100} cleavage surface of the KCl crystal cleaved from the block crystal.

(b) The {100} outer surface of the KCl crystal quenched thermally.

(c) The {100} outer surface of the KCl crystal coloured additively.

3.2 The inner part, *i.e.* the fresh {100} cleavage planes of the KCl crystal which was quenched from high temperature in vacuum and those of which was coloured additively with excess potassium metal.

(a) The fresh {100} cleavage planes of the KCl crystal quenched thermally.

(b) The fresh {100} cleavage planes of the KCl crystal coloured additively.

3.1 *The growth of crystallites on the surface of the KCl crystal which was quenched from high temperature in vacuum, and those on the surface of the KCl crystal which was coloured additively*

(a) *The {100} cleavage surface of the KCl*

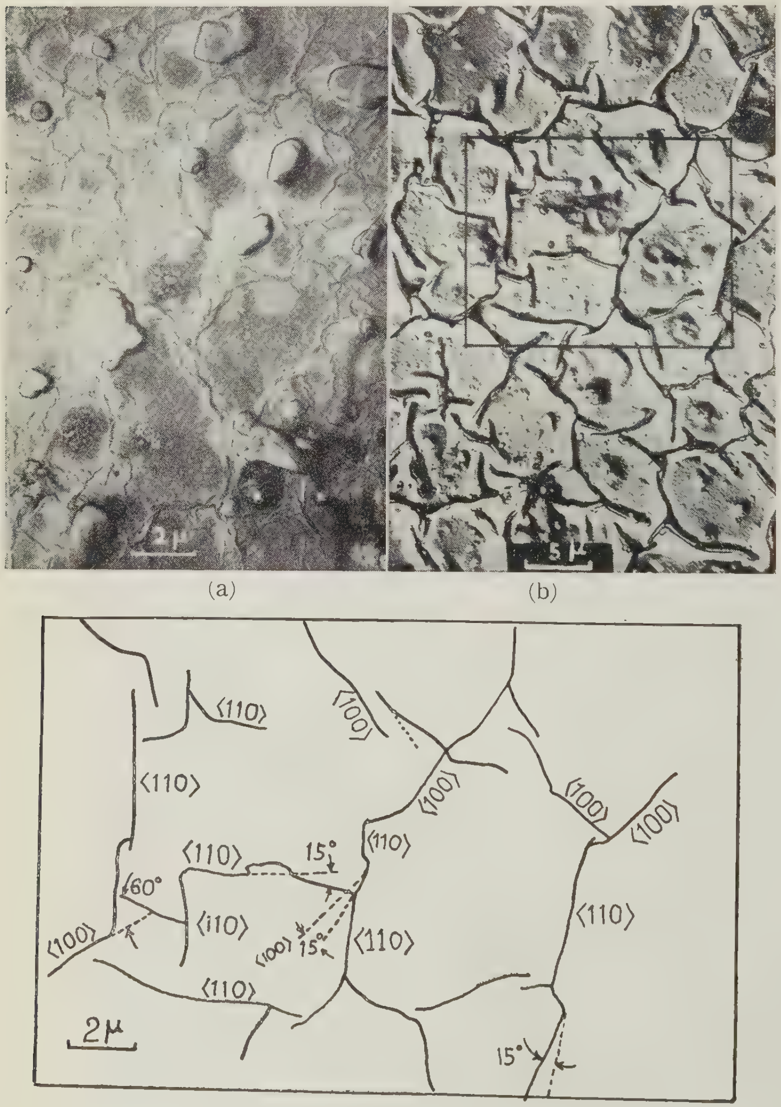

Fig. 3. (a) and (b): {100} outer surface of the KCl crystal which was coloured additively at 580°C for 4 hours. (c): The analysis of the crystallographic directions which appeared on the surface region enclosed by black lines in the figure 3 (b).

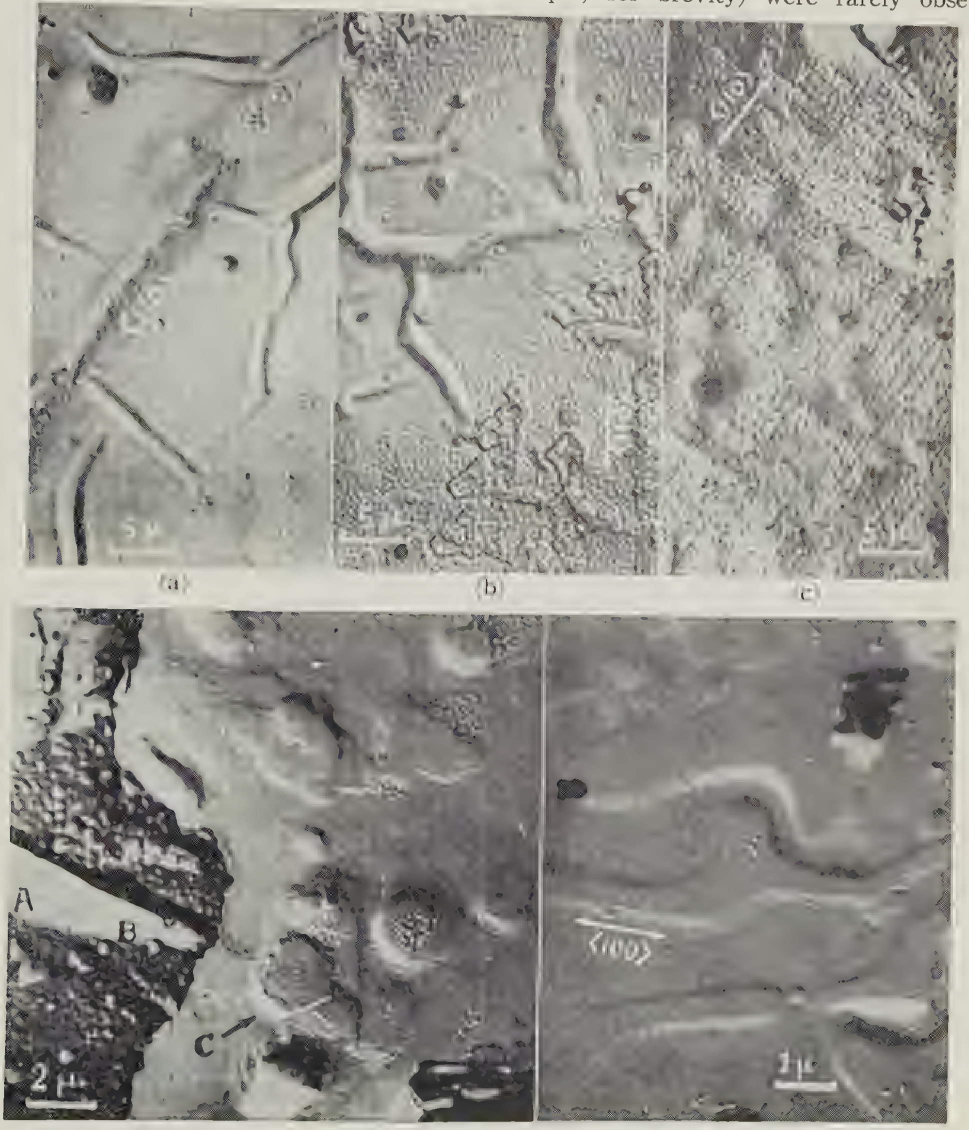
single crystal cleaved from the block crystal

Fig. 2 (a) shows one of the typical electron images of the freshly cleaved {100} surfaces of the KCl single crystal grown from the melt. In this figure, two linear cleavage steps can be seen on the flat and smooth surface. The step marked with white line makes an angle of 60° with the ⟨100⟩ direction of the KCl crystal (*i.e.* an angle of 15° with the ⟨110⟩) and the other step (dark line in the figure) makes an angle of 30° with the ⟨100⟩ direction of the crystal (*i.e.* an angle of 15° with the ⟨110⟩).

In general, the observed steps were straight and parallel to the crystallographic ⟨100⟩, ⟨100⟩±15°, ⟨110⟩ and ⟨110⟩±15° directions of the basal plane, though the steps composed of steps segments each of which is directed to one of the crystallographic directions just above (we term such a step as "composite step", for brevity) were rarely observable.



(a) (b) (c)

(d) (e)

Fig. 4. (a), (b) and (c): Three representative structures on the {100} outer surfaces of the KCl crystal which was coloured additively at 570°C±10°C. The surface area shown was covered with thin brownish film. (d) and (e): The outer surfaces of the KCl crystal coloured additively at 570°±10°C for 4 hours. The surface area shown corresponds to the real surface of the crystal not having the thin film.

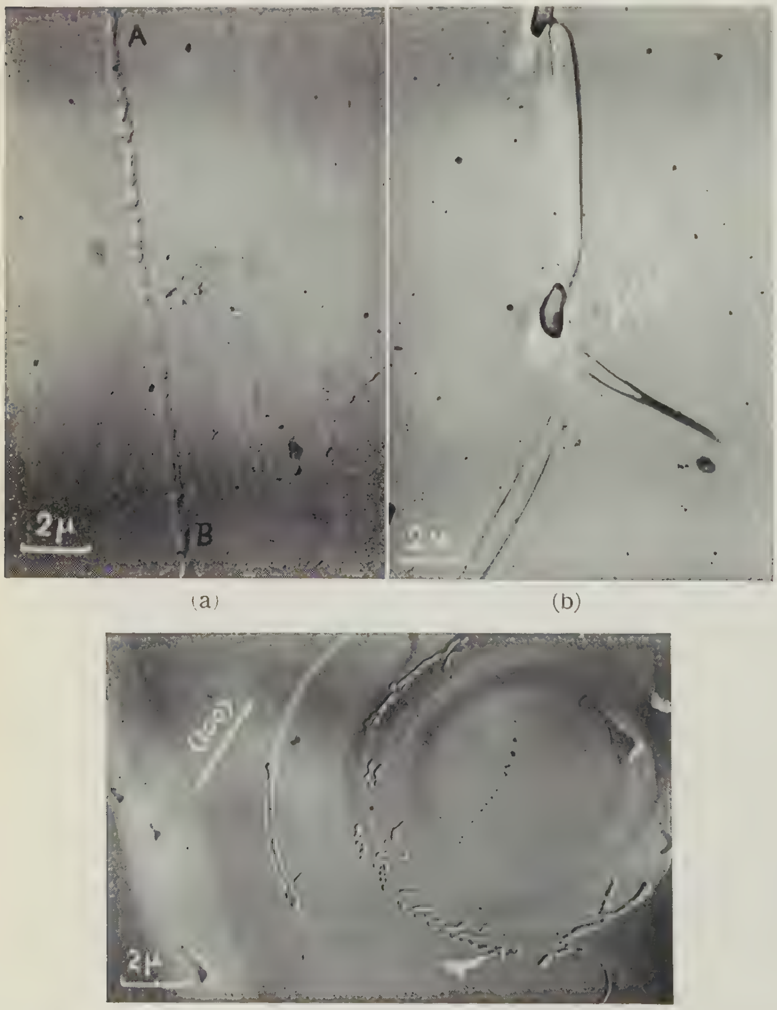
The freshly cleaved {100} faces of KCl crystal were electronmicroscopically flat and smooth except for the cleavage steps. These characteristic features were used as a reference state in deciding whether the surface of crystal changed or not under the applied treatments.

(b) *The {100} outer surface of the KCl crystal quenched thermally*

When the KCl single crystal in the evacuated and sealed-off pyrex glass tube was quenched rapidly from 580°C to room temperature, the crystal surface became white visually.

Fig. 2 (b) is the photograph of the surface of this crystal. Many parallelopiped crystallites, the surface density of which was estimated as $10^7\ cm^{-2}$, can be seen on the flat {100} basal plane and they are about 0.4∼0.5 *microns* or less in heights. Their side planes are parallel to the ⟨100⟩ directions of the base crystal. In the case when the basal plane turns into a humpy state as shown in Fig. 2 (c), it can be seen that parallelopiped crystallites appear in the various crystallographic orientations. These humpy structures of the basal {100} plane are resulted from the network of the V-type grooves, which may be possibly corresponded to the *mosaic* structures (and the network of dislocations).

From Figs. 2 (b) and (c), it is sure that the parallelopiped crystallites came out on the {100} surface as the result of the thermal treatment, though their crystallographic orientations seem to depend closely on the microgeometry on the surface of the KCl crystal.



(a) (b)

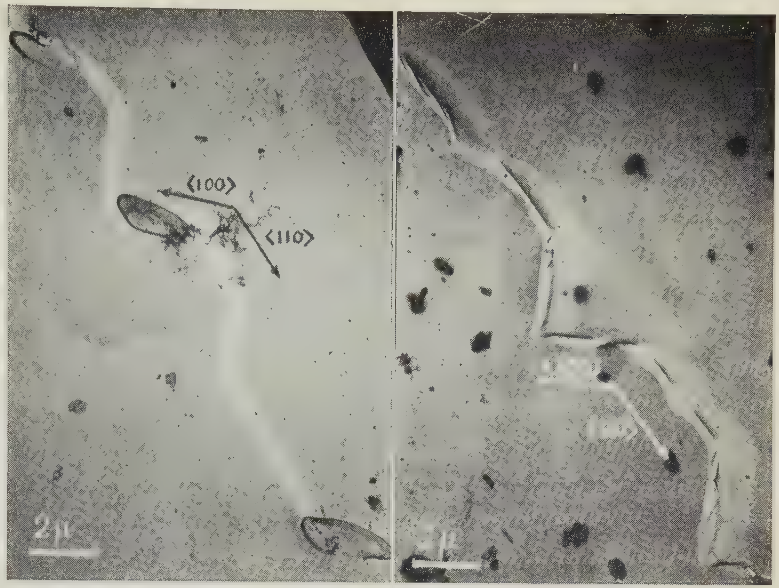
(c)

Fig. 5. (a), (b) and (c): The fresh {100} cleavage surfaces of the KCl crystal which was heated in vacuum at 580°C for 4 hours and was then quenched to the room temperature.

(c) *The {100} outer surface of the KCl crystal coloured additively*

Fig. 3 (a), which was taken in the early stage of this experiment, shows the {100} surface of the KCl single crystal which was coloured additively by heating it in potassium vapour at the temperature of 580°C for 4 hours. Network patterns and many crystallites can be seen. As to the network patterns, we considered them to have appeared as a result of either (i) the wrinkles of the replica or (ii) the decorations of the netwerk imperfections with KCl molecules, *i.e.*, network structure of KCl layer newly built up preferentially along the imperfections on the surface.

Continuing observations to decide experimentally



(a) (b)

Fig. 6. (a) and (b): The fresh {100} cleavage planes of the KCl crystal which was coloured additively at 580°C for 4 hours.

which of these two occurs are shown in the next series of photographs. The network patterns appeared on the KCl {100} surface are, as shown in Fig. 3 (b), composed of the mountain ranges whose directions are mostly directed to the ⟨100⟩, ⟨100⟩±15°, ⟨110⟩ and ⟨110⟩±15° of the basal {100} plane. The results of these analyses were also shown in Fig. 3 (c). Thus, it is hard to consider that the replica wrinkles in conformity to the crystallographic directions of the crystal, and so it is more natural to consider these patterns correspond directly to the changes on the surface of the crystal itself. Furthermore, these patterns vary from places to places depending on the microgeometries of the {100} surfaces of a crystal plate. They are roughly classified into the next three types:

(***I***) *The type of well-defined network patterns*

The network pattern of this type is shown in Fig. 4 (a). These network patterns are also composed of the protruding mountain-ranges whose directions are parallel to the ⟨100⟩, ⟨100⟩±15°, ⟨110⟩ and ⟨110⟩±15° of the base crystal. In this figure, the network patterns are larger in their size and more regularly arranged than those shown in Fig. 3 (b). The surface of the basal crystal is covered with many small grains.

On the surface region of the crystal having the features of this type, the parallelopiped crystallites, side planes of which were parallel to the ⟨100⟩ of the basal plane, could be occasionally observed. They grow usually at the kink sites of the protruding mountain ranges, or at the end points of the isolated segments of mountain ranges.

(***II***) *The type having the dendritic patterns and the network patterns*

The characteristic feature of this type is shown in Fig. 4 (b). The dendritic patterns can be seen on the right lower part and the network patterns grow on the left upper part of this figure. In general, it has been deduced from observations that these two patterns do not appear on the same portion of the surface of the crystal simultaneously and that the directions of the preferential growth of the dendrites are parallel to the ⟨110⟩ of the basal plane.

(***III***) *The type having a regular alignment of grains along the ⟨110⟩*

The characteristic feature of this type is shown in Fig. 4 (c). The grains of about 0.2 *microns* in size arrange regularly along the ⟨110⟩ directions of the basal plane and the network patterns do not develop markedly.

As was stated in § 2, the surfaces of KCl crystal coloured additively with excess potassium are usually covered with the dark brown thin film, even with the careful determination of the quantity of metal to be used. Figs. 3 and 4 are electron images showing the surface area covered with such film. But we have no needs to alter the preceding results and the analyses that the crystallites appear in the form of the network patterns or the isolated protuberances as shown in Fig. 3 (a) after the colouration of the KCl crystal. Fig. 4 (d) and Fig. 4 (e) will serve as these evidences. Fig. 4 (d) is the electron image of the surface area which was covered with the thin film (left side) and was not (right side). On the latter part of the surface, crystallites of about 2 *microns* in size grow and their shapes are very similar to those shown in Figs. 3 (a) and 4 (c). The lamellar structures can also be observed. Especially, the crystallites in a cross shape (marked as ***C*** in the figure) are continuously connected to the patterns of mountain range (***AB*** in the figure) on the surface area covered with the film. The surface structure ***AB*** is certainly the same type as the network pattern described above. The protuberances in the shape of mountain range in Fig. 4 (e) where the real surface of KCl crystal is shown are also corresponded to the network pattern and their directions can easily be assigned to the crystallographic directions such as the ⟨100⟩, ⟨110⟩ etc. of the basal plane. It is also observable in Fig. 4 (d) that the granular structures on the thin film, which have been already shown in Figs. 4 (a)—(c), disappear discontinously on the surface area not having the thin film. On the basis of these observations, we can safely conclude that the KCl crystallites grow either in the shape of the mountain range whose directions can be assigned to the crystallographic ⟨100⟩, ⟨110⟩ etc. directions of the basal plane or in the form of the isolated protuberances and the lamella structures, when the KCl crystal was coloured additively with excess potassium metal. We can also state that the granular structures are not related to the growth of KCl crystal. The dendrites and grains aligned along the ⟨110⟩ will probably be composed of potassium metal.

3.2 *The inner part, i.e., the fresh* {100} *cleavage planes of the KCl crystal which was quenched from high temperature in vacuum and those of which was coloured additively with excess potassium metal*

(a) *The fresh* {100} *cleavage planes of the KCl crystal quenched thermally*

The typical features of the fresh cleavage {100} planes normal to those shown in Figs. 2 (b) and (c) are represented in Fig. 5. The thermal conditions were already described in § **2.1.** The cleavage steps in Fig. 5 (a) are straight, but they have either the lamellar structures (perhaps it will be impossible to discern them in the reproduction) or the protuberances in the form of mountain range (step ***AB*** in the figure). In Fig. 5 (b), the step is not linear, but is composed of the step setments having

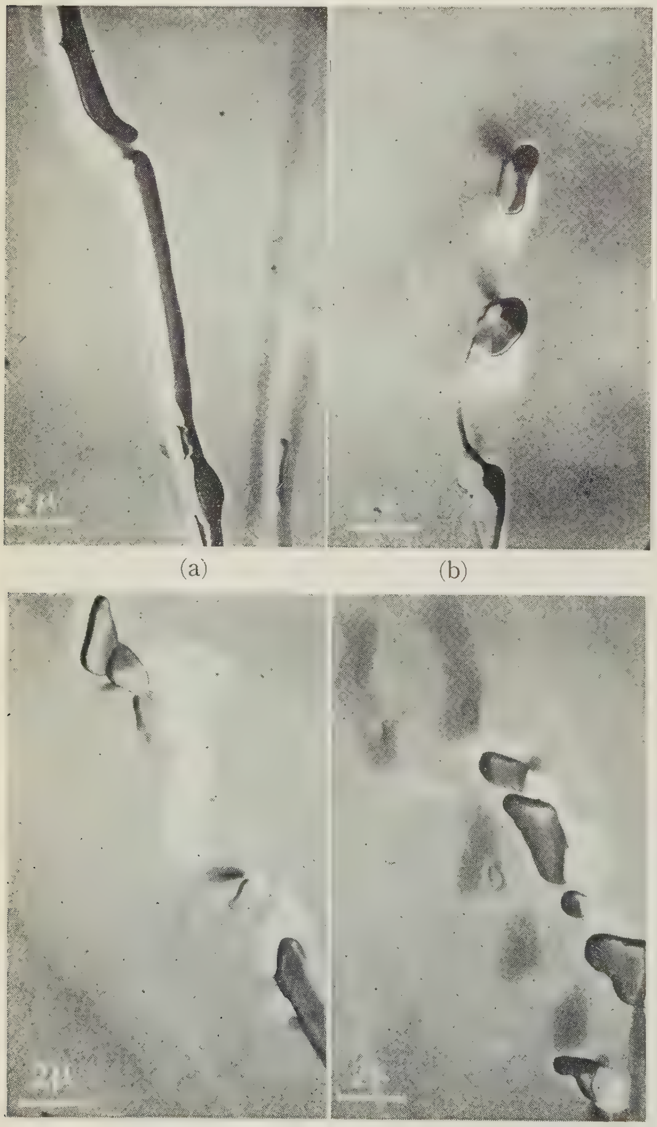


Fig. 7. (a), (b), (c) and (d): The fresh cleavage planes of the KCl crystal which was coloured additively with excess potassium metal. The colouration of the crystal becomes deeper in the alphabetic order.

the crystallographic ⟨100⟩ and ⟨110⟩±15° directions. At the kink sites of this step, a crystallite grows. The elliptical hills, as shown in Fig. 5 (c), were occasionally observed on the fresh {100} cleavage planes of the KCl crystal thermally quenched. The closed confocal elliptic steps forming this structure are decorated with many small elongated crystallites and are quite independent of the cleavage steps, for the latters are usually normal to the propagation front of the cleavage crack. It is deduced from observations that the mean value of the ratio of the major axis to the minor axis of these ellipses is about 1.3, and the lengths of the major axes vary from 0.5 to 0.7 *microns*.

(b) *The fresh* {100} *cleavage planes of the KCl crystal coloured additively*

Figs. 6 (a) and (b) show the fresh cleavage planes of the crystal coloured additively at the temperature of 580°C for 4 hours, and the {100} outer surfaces of this crystal were already shown in Fig. 3 (a). The steps are not linear, but are composed of the segments of step directed either to the ⟨110⟩ or to the ⟨100⟩. The crystallites can be seen at the kink sites of the step in Fig. 6 (a), and they are nearly parallel to the step directed to the ⟨100⟩ direction. These phenomena are quite analogous to those found in the crystal which was treated thermally (cf. Fig. 5 (b)), but it is clear that they appear in a larger scale than in Fig. 5 (b).

Since these changes of the inner parts of the crystal are decidedly caused by the colouration (or heat treatment), it is necessary to give attentions to the correlation between the changes of the inner parts of the coloured crystal and the degree of its colouration. When the comparisons were made, in achieving this experiment, betweeen the fresh cleavage planes of the crystals each of which had a different concentration of F centres and was coloured uniformly in itself, the results were too divergent to extract the correlation. This is probably due to the differences of the distribution of lattice imperfections inside each crystal, even when they were cleaved off from the same block of the crystal grown from the melt. We coloured, therefore, a single block of the KCl specimen in such a way as to produce inhomogeneity of colour inside the crystal. In this experiment, the colour was deeper in the central part of the crystal. Fig. 7 are the electron images of the fresh {100} cleavage surface of this crystal. The surface area corresponding to the inner part which is nearest to the outer surface of the block of the coloured crystal is represented by Fig. 7 (a) and the surface area corresponding to the central part of the coloured crystal is shown by Fig. 7 (d). Two intermediate parts, one of which is nearer to the region shown by Fig. 7 (a) and the other is nearer to the region shown by Fig. 7 (d), are represented by Fig. 7 (b) and (c), respectively. On the basis of the observations of these electron images, the followings can be summarized: As the degree of the colouration of the crystal proceeds, the zigzag steps and the crystallites appearing at the kink sites of steps become more numerous. These correlation between the degree of colouring of the crystal and the changes induced inside this crystal were quite identical with those found earlier in the NaCl and KBr crystals irradiated with X-ray⁵⁾. It is also remarkable that groups of wavy micro-steps, in addition to the zigzag steps, appear on the cleavage plane where the colouring was deeper and the zigzag steps with crystallites appear remarkably (see Figs. 7 (c) and (d), for example).

It must be mentioded that, although the crystallites coming out at the zigzag steps were observed frequently, the reverse structures of the fresh cleavage planes, *i.e.*, the hollow structures in which the crystallites are to be fitted to form the continuous crystal lattice were not observed. Furthermore, the shadows of the crystallites indicate that each crystallite is connected to the cleavage plane only at the kink sites of the step and the remainder sticks out upon the cleavage surface (see Fig. 7 (c), for example). Judging from these phenomena, the zigzag steps will probably be a kind of internal surfaces surrounded by the clusters of vacancy or cavities into which the crystallites come out (a kind or "crystal growth" inside the crystal).

From the observations of the fresh cleavage planes of KCl crystal which was thermally treated and which was coloured additively, it is concluded that these processes cause the changes inside the crystal, and that the effects are enhanced by the colouration.

§ 4. Interpretation of Experimental Results

In this paragraph, descriptions are given on the next three: 4.1, the fresh (100) cleavage planes of the KCl crystal grown from the melt; 4.2, the crystal growth of the KCl crystal which was thermally quenched and 4.3, the crystal growth of the KCl crystal coloured additively and the mechanism of additive colouration.

4.1 *The fresh* {100} *cleavage planes of the KCl crystal grown from the melt*

Many authors[7)-11)] have been interested in the cleavage surfaces of the crystals and have carried out the extensive experiments mainly with an optical microscope. Their main purposes were directed either to the propagation process of the cleavage crack or to the correlation between the patterns of the cleavage steps and the crystal imperfections. Confining these experiments to the ionic crystal, these works will be summarized as follows: The cleavage steps are usually perpendicular to the front of the cleavage crack and are the rough indication of the propagation direction of the crack. When a crack is propagating with velocity larger than a critical value ($\sim 6.10^3$ *cm/sec* in LiF crystal, for example[9)]), the cleavage steps appear relatively linear, and if the velocity of the propagation of the crack front is less than this, a crak proceeds unstably or stops sealing the loops of the dislocation into the crystal. In this case, the cleavage steps kink and new cleavage steps are formed at places where the dislocation loops were sealed in. Forty termed these places as "deformation zone"[10)]. On the other hand, when a cleavage crack meets a twist boundary, the same phenomena appear, and new cleavage steps are formed at screw dislocations. These observations with an optical microscope are not sufficient to interpret our results, because the detailed lineage of steps was not resolved optically.

According to the electronmicroscopic observations on the cleavage planes of the KCl single crystal grown from the melt (cf. **3.1** (a)), the cleavage steps were parallel to the crystallographic ⟨100⟩, ⟨110⟩, ⟨100⟩±15° and ⟨110⟩±15° directions and were straight, while the cleavage steps on the "deformation zone" became rather complicated. Taking account of the ambiguities of the *Cr*-shadow directions, ⟨100⟩±15° and ⟨110⟩±15° can reasonably be assigned to the ⟨120⟩, ⟨230⟩ and ⟨130⟩ directions of the basal crystal. Thus, we can conclude that the fresh cleavage {100} plane of the KCl crystal grown from the melt is flat and has steps having the directions of the ⟨100⟩, ⟨110⟩, ⟨120⟩, ⟨230⟩ and ⟨130⟩, provided that the crystal is perfect. This conclusion does not contradict to the observations that the cleavage steps run radially from the point at which the cleavage crack has been introduced, because they are considered to be composed of steps having the directions mentioned above.

4.2 *The crystal growth of the KCl crystal grown from the melt*

In the case of thermally treated KCl crystal in the evacuated and sealed off glass tube, many parallelopiped crystallites and the networks of V-type groove appeared on the outer surface of the specimen, while on the fresh cleavage plane of such a crystal composite steps and elliptic steps can be seen.

In genaral, when the KCl crystal in the evacuated, sealed off glass tube was heated, it is considerable that the KCl molecules evaporate from the surface of a sealed KCl crystal, thus the vapour pressures of solid phase and gas phase become equal at the prolonged heating at a given temperature. In this equilibrium state, the number of KCl molecules escaping from the surface and arriving at the surface must be equal. On the other hand, the KCl crystal kept at a higher temperature will acquire more vacancies than the crystal at room temperature. These vacancies can be supplied both from the outer surfaces and from the internal surfaces by diffusion process or from the dislocations by their climbing[16)].

Taking these situations into account, the present results can partly be explained. Concerning the growth of the parallelopiped crystallites on the outer surface of the specimen, three possible mechanisms may exist:

(i) The parallelopiped crystallites may have been resulted from the preferential flow of the matter from the interior, because if the vacancies diffuse uniformly from the outer surface into the crystal, outer surface must acquire a new layer of crystal. This preferential flow of matters may occur through dislocations or a kind of internal cracks.

(ii) The climb of composite dislocations sealed in beneath the surface during the cleaving process may also lead to the growth of crystallites, if the circumstances are available[16].

(iii) When the crystal in a pyrex glass tube was quenched to room temperature, the superfluous KCl molecules in gas phase may condense to form parallelopiped crystallites epitaxially grown on the outer surface of the specimen.

On the other hand, networks of V-type groove may result from the preferential thermal evaporation of KCl molecules from the subboundaries.

According to Figs. 5 (b) and (c), it is conceivable that internal surfaces and dislocations may serve as vacancy sources. We are inclined to consider that the composite step, or zigzag step such as shown in Fig. 5 (b) and Fig. 7, may correspond to such a kind of internal surfaces, because the crystallites at the kink sites grow sticking out on the fresh cleavage plane. Therefore, a zigzag step and a crystallite along it must be resulted from a crystal growth occurred on the internal surface, which associated with the flow of vacancies into the inner lattice sites. Especially, elliptic steps are quite independent of cleavage steps, and they are in a closed form. This is the reason why we consider an elliptic hill to correspond to the lattice misorientations which are quite independent of the cleaving process. One of the possible explanations for this structure may be the following: When an edge dislocation climbs delivering the vacancies into the interior to form dislocation rings, each rings will be pushed forwards by mutual repulsion, supposing that the edge dislocation is fixed at both ends. Then, if the cleavage crack happens to pass across this region, dislocation loops will come out on the fresh cleavage plane taking a shape of an elliptic hill because of easy cleave caused by the localized concentration of stress field arround the dislocation loops. Usually, these steps are decorated with crystallites as shown in Fig. 5 (b). The detailed explanation including these effects is impossible at present.

4.3 *The crystal growth of the KCl crystal coloured additively—the mechanism of additive colouration*

Colour centres in the alkali halide crystals have been an outstanding interest for many decades, and have been studied both from the theoretical and the experimental points of view[12)13)]. However, the electronmicroscopic studies have never been carried out on the additively coloured crystal (and also the thermally quenched crystal[14)]).

It is clear from the present observations that various kinds of changes appeared both on the outer surface and in the inner part of the KCl crystal which was quenched thermally and coloured additively, and that these changes occurred more markedly in the latter case: In the case of the KCl crystal coloured additively, crystallites grew on the outer surface of a coloured crystal block either in a form of mountain range or in a form of isolated protuberances; on the other hand, in the interior of the coloured crystal, the zigzag steps having crystallites at their kink site appeared more remarkably as the colouring of the crystal became deeper.

Now, the conditions of the additive colouration differ only one point from those of the thermal quenching in our experiment; the crystal was heated in the atmosphere of potassium vapour instead of KCl vapour.

Mott and Gurney[12)] discussed the mechanism by which F centres are formed additively: An atom of potassium metal is adsorbed on the surface, for example, at a point such as a kink site of the surface[17)]. Then an electron of the adsorbed atom is released into the conduction band; the positive ion left on the surface draws a negative ion beneath to form new layer of the crystal; the vacant lattice point then migrates to the interior and eventually traps the electron to form an F centre. In this case, the crystal is assumed to be ideal except for the surface.

In practice, however, an *ideal* crystal can hardly be obtainable, because the lattice imperfections can be sealed in the crystal in various modes both during crystal growth and during the process of cleavage. We consider that the growth of crystal having a lamella structure, such as shown in Fig. 4 (d), may corresprnd to the Mott and Gurney's case, approximately. Since the network patterns (cf. Figs. 4 (a) and (b)) grow preferentially on the outer surface of a coloured crystal, it is necessary to take these phenomena into account. In an alkali-halide crystal, slip takes place usually on the {110} along the ⟨110⟩, so the array of the screw dislocation appears along the ⟨110⟩ on the {100}, while the array of the edge dislocation lies along the ⟨100⟩ on the {100}. According to the analyses of the present observations, the directions of the above pattern were parallel to the ⟨100⟩, ⟨110⟩ and to the directions deviated 15° from them, as shown in Figs. 3 (c), 4 (a) and 4 (b). Therefore, the network patterns having a shape of mountain range correspond to the KCl layer preferentially built up along the array of dislocation emergences on the {100} outer surface. This fact indicates that ions can diffuse more freely through dislocations than through the perfect crystal lattice. In the *real* crystal, therefore, F centres can also be formed by potassium atoms which diffused into the interior of the KCl crystal through the internal surfaces or dislocations, in addition to the processes discussed by Mott and Gurney: Potassium atom is adsorbed not only on the outer surface, but also on the inner surface at a kink site or jogs of dislocations; electrons may be released from the potassium atoms to the conduction band, then, the positive ions are left at adsorbed places and draw the negative ions to form the KCl crystal lattice. This leads to either the crystal growth on the outer surface or the changes inside the crystal, i.e., the crystal growth interior of the crystal or changes of the shape of internal surface. The vacant lattice points migrate to the interior and trap eventually the released electrons to form F centres. The crystallites sticking out on the fresh cleavage planes and zigzag steps may probably be built up by the mechanism described above. These interpretations do not appear to contradict to the facts that the changes induced inside the crystal are enhanced in the coloured crystal relative to the thermally treated one.

Now, this crystal growth inside the crystal becomes more markedly as the colouration proceeds (cf. Fig. 7). If this can be served as a measure of a degree of colouration of the crystal, it would be reasonable to consider that F centres are formed preferentially in the region where imperfections exist: In the additive colouration of the KCl crystal by heating in the atmosphere of potassim vapour, F centres are produced uniformly at most in the localized region of the specimen.

§ 5. Summaries

Electronmicroscopic observations were made on the KCl single crystal either cleaved from the block, or quenched from high temperature to room temperature in the evacuated, sealed off glass tube or coloured additively with excess potassium metal, by means of replica technique. The important results obtained from these observations are summarized as follows:

(1) The cleavage steps on the fresh {100} cleavage plane of the KCl single crystal cleaved from the block are straight and parallel to the ⟨100⟩, ⟨110⟩, ⟨120⟩, ⟨130⟩ and ⟨230⟩ of the basal plane, if the crystal is perfect.

(2) When the KCl crystal in the evacuated, sealed off glass tube was heated, followed by the rapid quenching, the changes are induced not only on the outer surfaces, but also in the interior of the crystal. These phenomena are considered to be resulted from the formation of vacancies inside the crystal.

(3) In the case of the coloured crystal, the crystallites grew on the outer surface either in a form of mountain ranges or in a form of isolated protuberances, and the crystal growth occurred more markedly inside the crystal than the thermally treated one. The mechanism by which F centers are formed was considered.

Acknowledgements

It is a great pleasure to express the author's thanks to Prof. M. Ueta who gave us the detailed informations about the colouring procedure and checked the coloured crystal spectrophotometrically, and to Dr. T. Suzuki who read the manuscript and discussed with us with valuable suggestions. One of the authors (T. Tomiki) would like to express his thanks to Prof. S. Ogawa who provided him an opportunity to achieve this experiment at Research Institute for Scientific Measurements, Tohoku University.

Successive Electronmicroscopic Observation of Coloured and Bleached KCl Crystal

By Tadatosi HIBI and Keiji YADA

Research Institute for Scientific Measurements,
Tōhoku University, Sendai, Japan

(Received December 1, 1958)

The surface changes in a given part of the same KCl crystal during colouration by X-rays and in the process of bleaching by natural light have been successively observed by using two-stage replica. A slightly modified Bradley's method was used for making two-stage replica. By this method, the surface change at the definite position of the same KCl crystal was observed successively. According to the present results, it has been clearly confirmed that crystallites grown on the KCl crystal during X-ray colouration disappear during bleaching through the process quite reverse to the crystal growth in colouration and that the behaviour of the crystal growth and its disappearance are not simple, but very peculiar. Results obtained have been briefly discussed.

§ 1. Introduction

From electronmicroscopic observation of coloured NaCl and KBr crystals by X-ray irradiation and also of bleached crystals by natural light, one of the authors[1] observed the growth of crystallites on the front face, on the side face and on the new cleavage face of crystals with the progress in colouration. It was also observed that crystallites grown during colouration disappeared in bleaching by natural light through the process quite reverse to the crystal growth in colouration. A peculiar growth of crystallites was also observed on the front face with the progress in colouration. All these results were obtained by using ordinary one-stage replica. After making the deposited fims on the surfaces of many specimens irradiated by X-rays for different periods of time, alkali-halide crystals were dissolved in water and then deposited films were used as one-stage replica. However, crystallites appeared on the front face are not uniform in form and the behaviour of the crystal growth is not simple. Accordingly, after an exhaustive observation of several specimens obtained under the same experimental conditions, the ordinary method in which some characteristic properties are statistically determined was adopted. The result obtained by such a method should have some obscurities. Therefore, successive electronmicroscopic observations of the change in a given part of the same crystal are highly desired. In this experiment, the surface change in the given part of the same KCl crystal with colouration by X-rays and in the process of bleaching by natural light has been successively observed by using two-stage replica.

§ 2. Experimental Method

Direct electronmicroscopic observation of coloured and bleached alkali-halide crystal is impossible because of the change caused by electron bombardment in the course of its observation. So, replica method should be used and two-stage replica is also necessary for successive observation. However, it is difficult technically to locate the definite position of the same specimen always on the definite place of the definite hole of the fine mesh. A few methods[2] were hitherto presented for this purpose, and two electronmicrographs before and after a change in the specimen were shown by these methods. Only Bradley[3] reported on the possibility of successive observation of corrosion process of pearlitic steel, in which he succeeded in the illustration of the effect of etching time on a given field of a metallurgical specimen. Recently, Fourie[4] reported on the method for making successive replica based on Bradley's method to observe the successive change of slip lines appeared on the α-brass single crystal with plastic deformation. We first tried another method[5] to obtain a successive replica of the definite position of the specimen more accurately, though it was more difficult technically than Bradley's method. The defect of this method is in the difficulty of stripping one-stage replica from alkali-halide crystal. Therefore, in place of the above method a slightly modified Bradley's method was used in this experiment as described below.

The specimen was fixed on the glass plate by about 20% gelatin in water. After drying gelatin, some reference was marked on the surface of the specimen. A few scratched traces at right angle to each other along ⟨100⟩ direction were marked as reference by using fine tungsten wire 0.14 mm in diameter. The width of this scratch trace is several microns and it can be seen easily by optical microscope with 60 times magnification. After marking the reference on the crystal, a thin film of methylmethacrylate was cast on the surface from about 0.5% solution of benzene. As alkali-halide crystal is poisoned by chloroform which is solvent of Formvar, Formvar solution used by Bradley could not be used in this experiment.

Copper sheet mesh to 150 holes per inch having larger hole (0.15 mm in diameter) in the centre than other holes was used as the specimen grid. The position of this central hole can be found easily by the observation of intermediate image of electronmicroscope.

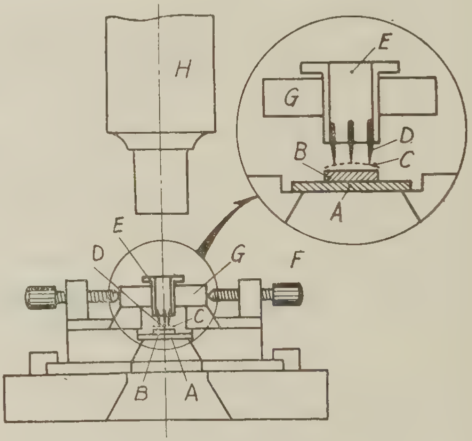

Fig. 1. The apparatus for obtaining successive two-stage replicas.

Fig. 1 illustrates the apparatus for the preparation of replicas as desired. In this figure A is glass plate, and B is the specimen. Sheet mesh C is attached to the tips of pins D which are soldered to holder E with a small amount of adhesive. Holder E is put in G which is movable in two directions horizontally by four screws F. To prevent the interest part of the specimen from being poisoned by mechanical contact when the mesh was displaced, the mesh was bent a little and only both ends touched to the thin film of methylmethacrylate. Observing by optical microscope H, reference mark of the specimen was brought into the marked opening of the

mesh by four screws F. Next, one or two drops of a few percent, methylmethacrylate solution in benzene were droped on the mesh by using an injector, and then it was dried in air stream from a fan. After perfectly drying methylmethacrylate the mesh was removed from the specimen. And then Cr oblique two-stage replica reinforced by C was made. The evaporation angle of the replica was about $\tan^{-1}(1/3)$ for the front face. Special care was taken to cast the shadow perpendicularly to the cube edge of the crystal in the replication of the front face. After replication, the mesh was placed on the brass net with large squares and then it was immersed in the mixture of equal amount of benzene and chloroform. The brass net with the mesh was picked up gently from the

solution after dissolution of methylmethacrylate. The mesh was ready for examination under electronmicroscope.

When methylmethacrylate was dissolved, deposited thin film remained fixed in its original position, as pointed out by Bradley, and so it was not so difficult to obtain replicas of the definite position of the same specimen. However, we met with many other technical difficulties. It was necessary to choose the suitable tickness of deposited film, because rents would often occur in the film if the film was too thin, and the resolution of electron image would be lowered when the film was too thick. Besides, as contamination would often appear at the position to be observed, successive observations by replicas would be impossible. There were many kinds of contamination, namely, those clearly attributed to the dust and those to the residues of the methylmethacrylate. In addition, contamination due to the substance removed from the specimen surface was also observed, as shown in Fig. 2. Pattern shown in Fig. 3 also appeared, though it was still unknown whether it was attributed to adsorbed gas or moisture on the surface or to the change of crystal itself. When such an effect gave a

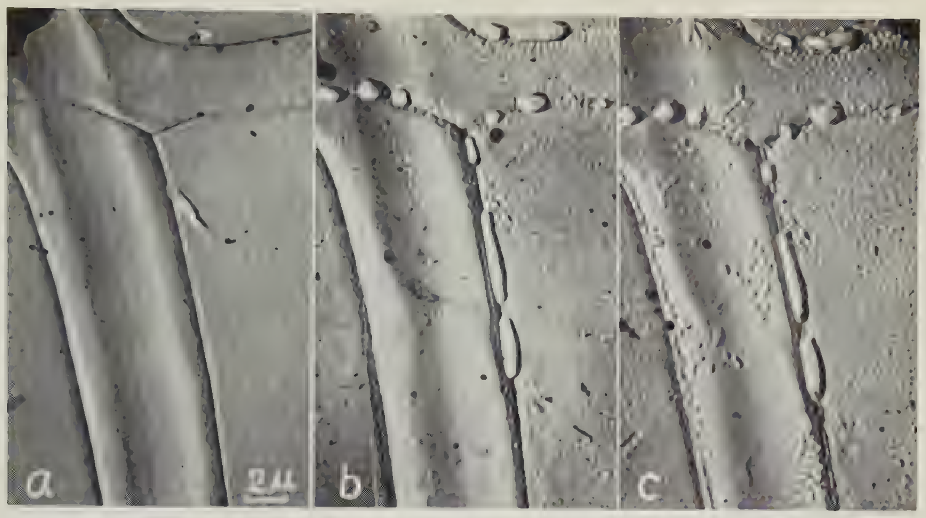

Fig. 8. The successive change caused by X-ray irradiation that appeared on the reference mark on the surface of KCl crystal: (a) the standard crystal, (b) the crystal coloured by X-ray irradiation for 4 hours and (c) the crystal coloured by X-ray irradiation for 3 hours in excess after (b).

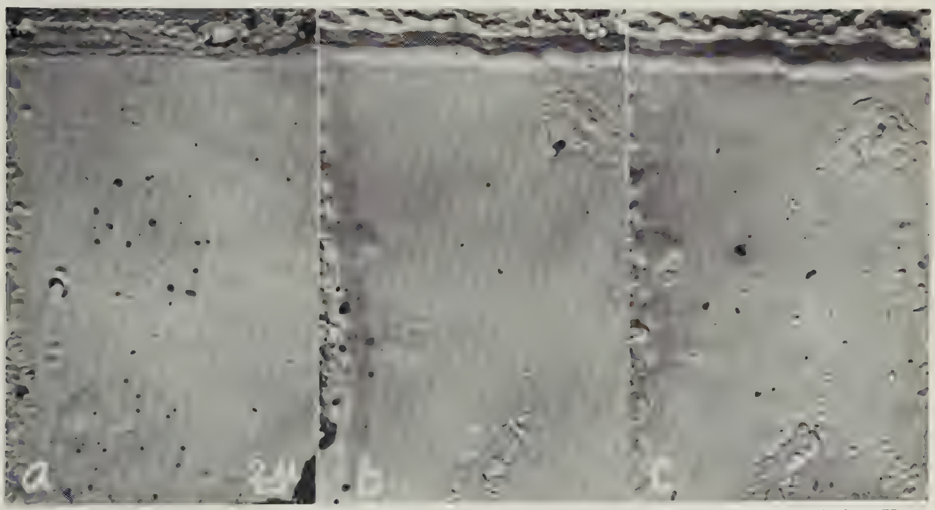

Fig. 9. The successive change on the smooth surface of KCl crystal coloured by X-ray irradiation: (a) the standard crystal, (b) and (c) the same crystal coloured by X-ray irradiation for 4 hours and for 10 hours after (a), respectively.

strong influence, successive observations became again impossible. However, these difficulties could be removed or minimized by technical training to the extent making successive observation possible. The largest technical difficulty was, however, the effect of humidity. When humidity was high, the contour of crystallites appeared on the surface became obscure, as shown in Fig. 4 (a), while clear crystal form shown in (b) could be obtained when observation was made as soon as possible after drying it in a desiccator. However, it was difficult to strip one-stage replica from the specimen when humidity was too low. It was found that the humidity of about 65% was the most suitable condition for replication.

In this experiment artificial KCl crystals were used as specimens, because they were comparatively insensitive to humidity and other conditions. The crystal was cloven in air into cubic pieces of about 4 mm × 5 mm × 0.5 mm and fixed on the slide glass by gelatin. The crystals were always used without pre-treatment such as water-polishing or annealing. They were also always irradiated by X-rays of 7 mA, 40 KV radiating from Fe target, and were kept in the dark during the X-ray irradiation. The distance between the specimen and the target was about 4 cm. Al foil of about 0.02 mm thickness was used as a window of X-ray tube. It took about 15 minutes to make the replication. In this experiment, therefore, coloured crystals were exposed to light only for this time interval.

§ 3. Experimental Results

To confirm whether the surface of KCl crystal will change or not by the casting of methylmethacrylate for making one-stage replica, some crystallite appeared on the surface of KCl crystal by scratch was selected as a standard to follow any change in the specimen. The result is shown in Fig. 5: (a), (b) and (c) are the electron images of the 1st, 2nd and 3rd replica. In this figure a little change is seen, but any essential change is hardly observable. Accordingly, it was confirmed that the specimen change due to casting of methylmethacrylate was very small. Whether the surface of KCl crystal will change or not by holding it in air for several days was also confirmed. Fig. 6 shows the electron image of some crystallites appeared on the surface of KCl crystal by scratch: (a) is the image of the standard specimen, (b) and (c) are the images of KCl crystal held in air for 4 days and for 7 days after (a), respectively. Fig. 7 also shows the electron images of the smooth surface of KCl crystal: (a) is the image of the standard specimen, (b) and (c) are the images of KCl crystal held in air for 4 days and for 7 days after (a), respectively. In these figure a little change is seen, but any essential change is hardly recognized. Therefore, it was also confirmed that the change on the surface of specimen due to humidity or contamination occured by holding it in air for several days was very small.

Fig. 8 shows the successive changes caused by X-ray irradiation that appeared on the reference mark on the surface of KCl crystal. (a) is the electron image of the standard KCl crystal, (b) that of the crystal coloured by X-ray irradiation for 4 hours, and (c) that of the crystal coloured by further X-ray irradiation for additional 3 hours after replication of (b). From this figure, it is clearly seen that in alkali-halide crystals coloured by X-ray ir-

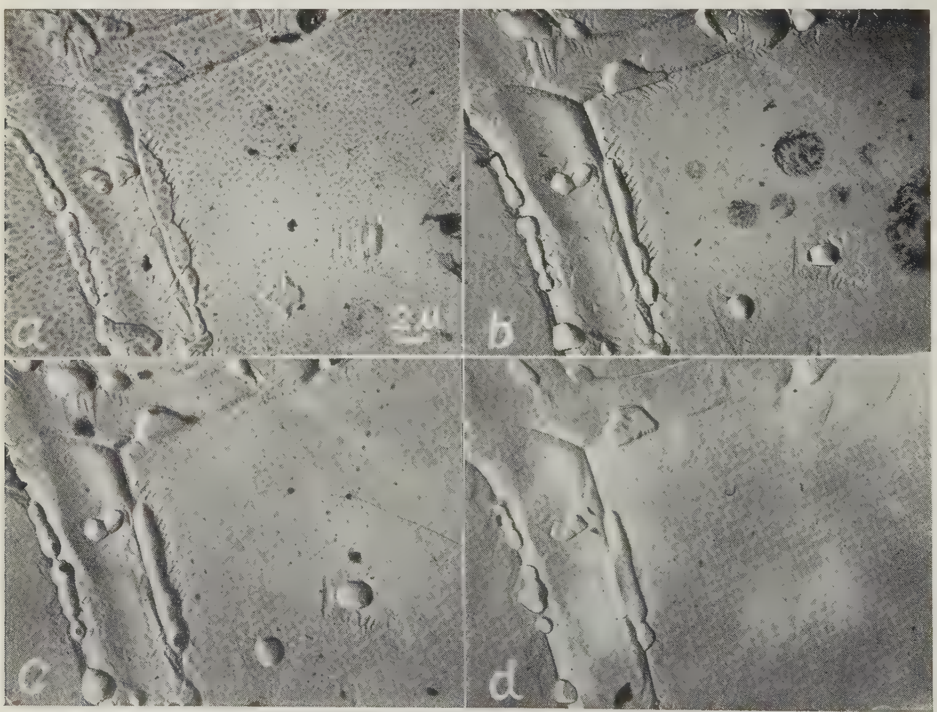

Fig. 10. The successive observation of the process of bleaching by natural light: (a) KCl crystal coloured by X-ray irradiation for 11 hours, (b), (c) and (d) the same crystal obtained 1 day, 2 days and 3 days after colouration, respectively.

radiation crystal growth appears on and along the reference mark. Fig. 9 shows the change on the smooth surface of KCl crystal coloured by X-ray irradition: (a) is the electron image of the standard specimen, (b) and (c) are the images of crystal coloured by X-ray

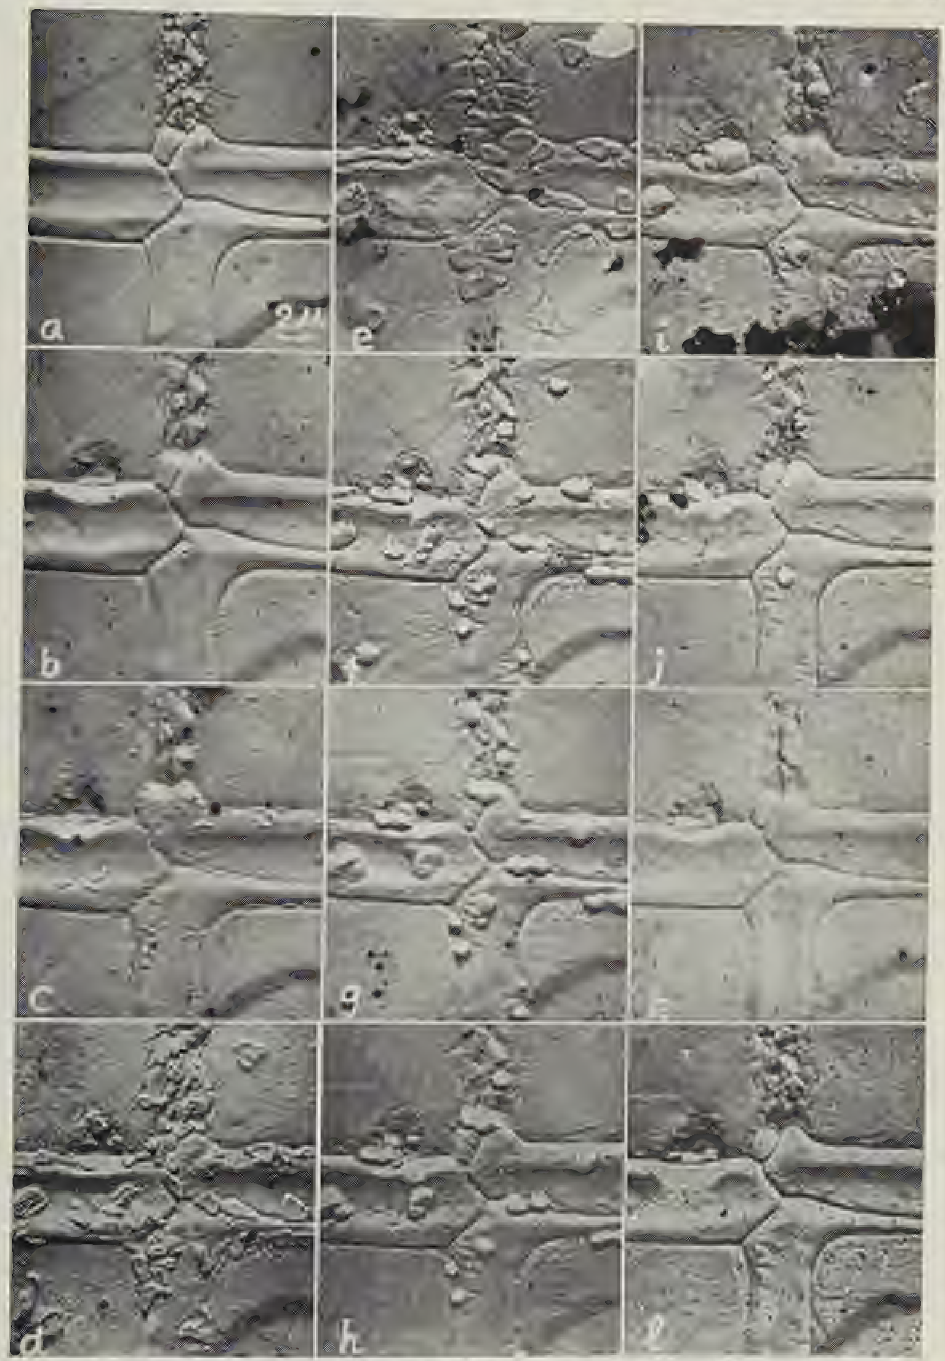

Fig. 11. The successive change of the definite position of the same KCl crystal coloured by X-ray irradiation and then bleached by natural light: (a) the standard crystal, and (b), (c) and (d) the crystal coloured by X-ray irradiation for 4, 7 and 11 hours respectively. From (e) to (l) shows the result of the process of bleaching by natural light after colouration by X-ray: (e) 30 minutes, (f) 1 day, (g) 2 days, (h) 3 days, (i) 23 days, (j) 24 days, (k) 29 days, and (1) 53 days, after (d) respectively.

irradiation for 4 hours and for 10 hours after (a), respectively. It was found in these images that crystal growth would also appear on the smooth surface by X-ray irradiation.

Fig. 10 shows the result of successive observations on the process of bleaching by natural light. (a) is the electron image of KCl crystal coloured by X-ray irradiation for 11 hours in which crystal growth is seen on both the reference mark and the smooth surface. (b), (c) and (d) are the images of the same specimen obtained 1 day, 2 days and 3 days after colouration, respectively. It is clearly seen from the results that the crystallites appeared either on the reference mark or on the smooth surface by X-ray irradiation disappear through the process of bleaching by natural light. It should be noted that the behaviour of disappearance of crystallites is not simple, but very peculiar

To obtain further confirmation of above-mentioned experimental results, the surface change of the definite position of the same KCl crystal coloured by X-ray irradiation and then bleached by natural light was observed successively. Fig. 11 shows the result: (a) is the electron image of standard specimen, and (b), (c) and (d) are the images of the same specimen coloured by X-ray irradiation for 4, 7 and 11 hours respectively. From these images it is clearly seen that a pronounced and peculiar crystal growth appears on the reference mark and also on the smooth surface. (e) to (l) illustrate the result of the process of bleaching by natural light after colouration by X-rays. (e), (f), (g), (h), (i), (j), (k) and (l) are the electron images of KCl crystal obtained 30 minutes, 1 day, 2 days, 3 days, 23 days, 24 days, 29 days and 53 days after (d), respectively. It is clearly seen from these that the crystallites grown during colouration disappear in a peculiar manner in bleaching by natural light and also that (k) and (l) obtained 29 days and 53 days after colouration are very similar to (b) coloured by X-ray irradiation for 4 hours. From this it was clearly confirmed that the crystallites grown during colouration disappeared in the course of bleaching through the reverse process to the crystal growth in colouration. These results agree with the previous experimental results[1).

§ 4. Consideration

From the above-mentioned results it was clearly confirmed that the crystallites grown on KCl crystal during colouration by X-rays disappeared during bleaching possibly by the process quite reverse to the crystal growth during colouration. It is difficult to explain this experimental fact as being the change of alkali-halide crystal only due to the surface evaporation or the surface migration. Accordingly, we must consider the mechanism of crystal growth due to ionic or atomic diffusion from the inner part of crystals for the explanation of the present phenomena and it will also be necessary to consider the reverse process for explaining the disapperance of crystallites during bleaching. In this experiment only surface observation was made. As seen in the previous experiment[1), it may naturally be anticipated that crystallites grow or disappear on mechanical imperfections (e. g., dislocations) in the crystals during colouring or bleaching process, respectively.

From this experiment it was found that the more pronounced crystal growth was seen on and along the artificial damage such as the scratched trace of the reference mark than that on the smooth surface. This fact is in agreement with the previous experimental result[1) that crystallites is easier to grow on the mechanical imperfections than on the smooth surface. It was also found in consistent with the previous experiment[1) that the behaviour of crystal growth and its disappearance were not simple, but very peculiar. The structure, similar to the one on the deposited thin film, that appeared in the cases of NaCl and KBr was not obtained from this experiment throughout the processes of colouring and bleaching. We did not also observe here such a special case as seen in previous experiment[1), in which the ⟨100⟩ direction of the crystallites was predominantly parallel either to the cube edge of the substrate or to the diagonal of the substrate. It seems that we missed observing such a stage in this experiment. Further successive observation is desirable to confirm clearly such phenomena and also to know finer changes in the crystals.

Influence of Order-Disorder on Creep of a Superlattice Alloy*

By Taira SUZUKI and Mikio YAMAMOTO

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai, Japan

(Received November 24, 1958)

A study has been made of the influence of order-disorder on the creep of a superlattice alloy Ni_3Fe. The results obtained strongly support the dislocation-climb mechanism. The activation energy for creep, independent of applied stress, slightly increases with the degree of order: 45.8 kcal/mol for disordered and 47.5 ± 2.0 kcal/mol for ordered phases. A discontinuity occurs at the critical temperature, *i.e.*, 505°C in the curves of creep rate *versus* the reciprocal of temperature. A remarkable acceleration of creep has been observed on the disordered alloys below T_C, which were obtained by quenching from 800°C, as compared with the rates expected from the values above T_C. A semi-quantitative theory has been proposed for such a configurational acceleration of creep in terms of order-disorder kinetics and dislocation processes in the superlattice alloy of AB_3 f.c.c. type.

In ordered alloys, the vacancy diffusion introducing the dislocation-climb is thought to be anisotropic with regard to the orientation of slip bands. This will result a significant difference in the stress dependence of creep rates in ordered phases from the one in disordered phases as observed here.

§ 1. Introduction

As the possible mechanisms for high temperature creep of close-packed metals the following are to be considered, (a) stress-induced diffusion of vacancies, (b) cross-slip, (c) intersection of other dislocations, (d) dislocation climb and (e) grain boundary flow. While (a) plays a predominant role in producing noncrystalline flow only near the melting point,[1] others are possible over a wide range of temperature, and all except (b) have more or less direct connections with the formation and the migration of the vacancy in those metals. The activation energy for creep, however, is thought to be different from each other in magnitude and in the dependence on applied stress. Mott has first discussed the importance of (d) and showed that the activation energy, independent of applied stress, should be close to that for the self-diffusion.[2] Many experimental works on high temperature creep of metals, *e.g.*, by Dorn *et al.*,[3] have since contributed to the promotion of theoretical surveys.

The most recent development of theories has been established by Weertman.[4] It has been understood that the steady-state creep occurs at a balanced state between hardening and recovery in metals concerned. The Weertman's model for the hardening and the recovery responsible for the creep is as follows: The slip dislocations are piled-up in front of barriers such as grain boundaries or the Lomer-Cottrell sessile dislocations, and introduce hardening. At high temperatures, where the equilibrium concentration of vacancies sets up near the lead dislocations, the vacancy flow along a concentration gradient between those dislocations will induce dislocation climb. The metals will thus recover from the hardened state and continue to flow. He obtained the creep rate at steady-state as

$$K=A\sigma^{m}\Psi/kT \quad \text{for } n\sigma b^{3}/kT<1\,, \quad (1)$$

where A is a constant, k is Boltzmann's constant, T is absolute temperature, σ is applied stress, b is the Burgers vector and n is the number of piled-up dislocations in one group. In this equation the exponent m is a factor to be determined by a detailed process of the dislocation climb, and Ψ has a form of $B\exp(-Q/kT)$, where B is a constant. If the stacking-fault energy is so large as to be able to maintain the equilibrium concentration of vacancies near the dislocation lines, Q is the activation energy for the atomic diffusion by vacancy mechanism in the metals. The above assumption will be valid in metals such as aluminium, lead and zinc. It is to be noted, however, that Franks and McLean,[5] and Semmel and Machlin[6] have found by etching technique such a dislocation climb to occur during creep at high temperatures even in copper or silver with the low stacking-fault energy.

In the following, we will draw attention to the creep in a superlattice alloy of AB_3 f.c.c. type. Since the rate of vacancy diffusion in such alloys is thought to depend upon the degree of order, the creep rate should be influenced by ordering if dislocation climb is rate-controlling for the creep as predicted by the theory. In beta brass, only one example in which tracer diffusion experiment has been done in an alloy with long-range order, the activation energy for the isotope diffusion has been found to be different from each other in the ordered state and in the disordered state.[7]* It is hence worth examining the variation of Q in Eq. (1) with atomic order not only from the points of the creep mechanism but from those of the order-disorder kinetics.

It is conceived that the vacancies in an well-ordered alloy diffuse by a highly correlated motion in such a way that the state of order is not destroyed by the movements of vacancies. Accordingly, the diffusion of vacancies resulting dislocation climb will be faster along the slip bands than in the perpendicular direction, since the slip dislocation introduces a disorder into the alloy along the slip bands. This situation is similar to the creep of tin crystals having anisotropic diffusion coefficients.[9] In such cases, it is expected that the dependence of creep rate on applied stress designated by the exponent m in Eq. (1) is different from what is expected for the case with the isotropic diffusion coefficient. In the present case, therefore, the value of m will depend on the initial degree of order.

As far as we know, there has been given one experiment on the creep of order-disorder alloy of beta brass done by Herman and Brown.[10] Although this is a pioneer work in this field, they interested only in the change of creep strength with temperature. They paid no attention to the problems as described above. Furthermore, beta brass is not necessarily adequate for the present aims, since the alloy equilibrated so rapidly that we cannot retain the disordered state by quenching.

§ 2. Experimental Procedure

An ingot of the alloy of about 10 cm length and 2 cm diameter was prepared by melting together of measured amounts of Mond nickel and electrolytic iron with 0.5% Mn in an alumina cruicible in vacuum. The ingot was hammered and drawn finally to the wire of 0.05 cm diameter for creep specimens. The specimen wires of 12 cm length were obtained and annealed in vacuum for about 1 day at 1000°C. The mean grain size thus obtained was smaller than the specimen diameter. The composition was checked by chemical analysis and found to be of 74.6 at. % Ni. Specimens for the measurements of specific heats were machined from the same ingot. They were obtained in a cylindrical form having a diameter of 1.5 cm and a length of 2.5 cm. Some were cold-worked in compression at room temperature and, then, a hole of 0.8

---

* Very recently, Goering and Nowick[8] have obtained a similar result in the alloy Cu_3Au by anelastic measurements.

cm diameter and 2 cm length was drilled with special care to avoid an excess heating, into which a heating coil of nichrome wire was inserted. One end of the differential thermocouple of Pt and Pt-Rh 13% was fixed to the specimen and the other end to the inner wall of a copper container surrounding the specimen. The apparatus and the methods were the same as one of the present authors used before for the measurements of heat emission associated with recovery of cold-worked copper.[11)]

The fully ordered specimens were obtained following Kaya's procedure,[12)] *i.e.*, by holding in vacuum for one week at 490°C (T_C=505°C) and then cooled to 450°C at a rate of 10° per day. The disordered specimens were quenched from 800°C in air as sealed in an evacuated quartz tube of 2 mm inner diameter and 0.5 mm wall-thickness.

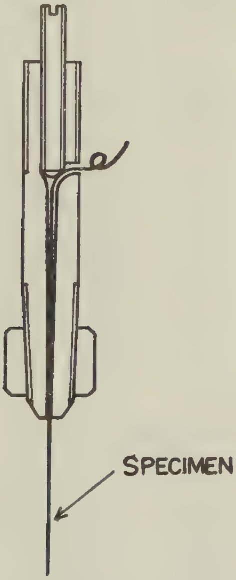

Fig. 1. A grip of specimen wire for creep testing.

The specimens were pulled in air at various temperatures and stresses in an apparatus with a special device,[13)] which applies a constant stress independent of the change of cross-section with elongation. Both ends of the specimen were gripped by pin-vices made of stainless steel after tightening each end by a bolt screwed into the vice as shown in Fig. 1. The effective length of the specimen between the grips was about 9 cm. The variable arm was set in a position to give a constant stress to the specimen during the test. The elongation was magnified by an optical lever system and it was read by telescope and scale. The sensitivity was 4.04×10^{-5} cm per millimeter of the scale at the distance of one meter.

The temperature of the specimen was kept constant within ±0.01°. Over most of the temperature range the specimen reached thermal equilibrium within eight minutes. The specimen were held for about thirty minutes at each temperature before the creep test being started.

§ 3. Results

Stress-strain curves for the ordered and disordered alloys were taken in compression at room temperature at the strain rate of 2×10^{-3} per second. As seen in Fig. 2, the disordred alloy (curve (a)) behaves similarly as most polycrystalline metals of face-centred cubic structure at relatively high temperatures. On the other hand, the stress-strain curve for the ordered alloy (curve (b)) is almost linear and has a high yield stress than that of the disordered alloy. It resembles to that of the above metals at low temperatures. It is very important, however, to remark that both polycrystals and single crystals of Cu_3Au behave in the opposite way such as the yield stress of the ordered alloy is lower than that of the disordered alloy.[14),15),16)] It is seen in Fig. 2 that after the rapid hardening stage the hardening rate of the disordered alloys decreases to the value smaller than that of the ordered alloys. Such a phenomenon is called dynamical recovery by Seeger *et al.*[17)]

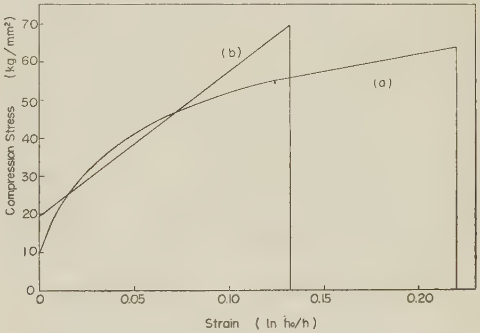

Fig. 2. Stress-strain curves in compression for the ordered and disordered alloys measured at room temperature: (a) disordered alloy which was quenched from 800°C in air; (b) ordered alloy.

The recovery in this case is induced by applied stress. At high temperatures, the corresponding recovery by the same or some other mechanism is greatly helped by thermal energy, which will have a close connection with creep to be studied here.

Before going further, it will be helpful to study the static recovery from a cold-worked state. We measured specific heats of cold-worked alloys at the heating rate of 1.5° per minute. Fig. 3 shows two cases; (a) an well-ordered alloy and (b) a disordered alloy. Curves (c) and (d) indicate specific heat *versus* temperature curves of undeformed alloys with the corresponding degree of order, respectively. The amounts of compression strain are shown in the figure. The recovery starts from about 300°C in both cases. There are two minima in both curves of (a) and (b). The corresponding minima are also found in the quenched specimen without cold-work. A similar result as shown by (d) was later obtained by Iida[18] and he studied it more in detail in connection with the ordering kinetics in Ni_3Fe. It is clearly seen from Fig. 3 that the heat generations corresponding to the two minima are accelerated by the presence of the dislocations. It suggests a close correlation between recovery and ordering through the atomic diffusion process. A peak in the specific heat *versus* temperature curves between 500° and 600°C relates to the atomic order-disorder and ferromagnetic transforma-

tions, which is not of interest in the present paper.

Creep curves of the ordered or disordred alloys were found to be quite similar to those of other metals like aluminium. The creep rate was constant over a large portion of the strain investigated. The observed steady-state creep rates of all the specimens have been listed in Table I along with the test temperatures and initial stresses.

The activation energy of creep can be found from a plot of the logarithm of the creep rate K times the absolute temperature T against the reciprocal of absolute temperature. Such plots are shown in Fig. 4. The two curves below the critical temperature T_C correspond to the specimens of ordered and disordered alloys, respectively. Each point was obtained at the stress of 28.2 kg/mm². Above T_C, however, creep rate at this level of stress is too fast to be observed by the present method. The plot in this region therefore was obtained at the stress of 12.5 kg/mm². Although the points at 380° and 420°C for the quenched specimens deviate appreciably, the linear part of the curve below T_C has approximately the same inclination as that of the curve above T_C. The activation energy thus obtained is 45.8 kcal/mol. On the other hand, the curve for the ordered alloy runs almost linearly up to 460°C and it gives the activation energy of 49.5 kcal/mol, slightly higher than that for the disordered alloy. No information of the activation energy for the atomic diffusion in Ni_3Fe to be compared with the above results has been given so far, however.

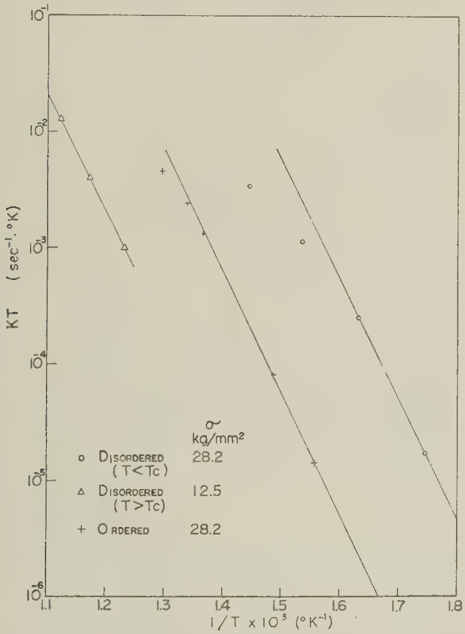

Fig. 4. Logarithm of KT *versus* inverse absolute temperature.

The last column of Table I lists the values of TK of all the specimens. Since a precise determination of Q below T_C seems to be rather difficult, the following tests were undertaken. Fig. 5 gives the plot of $TK \exp(Q/RT)$ *versus* the logarithm of stress for the disordered alloys. The points obtained at 300° and 340°C are on a straight line almost parallel to the one above T_C. This suggests that the estimated value of Q is sufficiently appropriate over the whole range of stress investigated. The inclination of the curves gives the value of m in Eq. (1) to be 3.1.

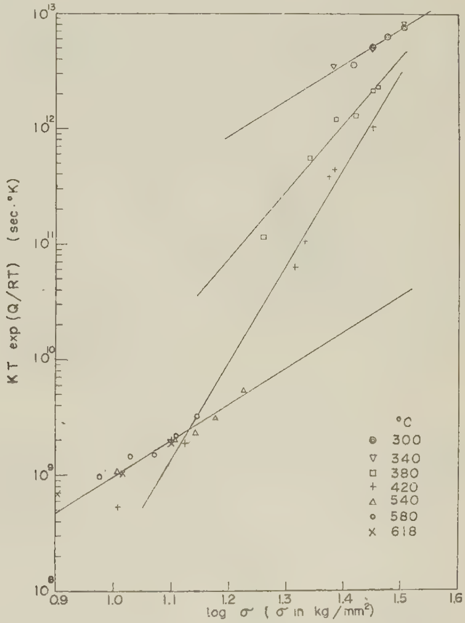

Fig. 5. Plot of $TK \exp(Q/RT)$ *versus* logarithm of stress for the disordered alloy.

The points at either 380° or 420°C are, however, on different straight lines with larger slopes, respectively. It appears that the slope of the curve in this region of temperature near T_C increases with testing temperature. It will be related to the increase of the degree of order in the specimen alloys by annealing before and during the tests. The similar plot on the ordered alloys in Fig. 6 must be compared with the above cases. Fig. 6 shows one example of the plot with $Q=49.5$ kcal/mol. The points are scattered as compared with those for the disordered alloy above T_C or at lower temperatures. The minimum scattering was obtained for $Q=47.5\pm2.0$ kcal/mol. It is conceivable that all the points are not on a single line, because the degree of order will change at temperatures such as 480° and 500°C in the neighbourhood of T_C. The slope of the straight lines shown in Fig. 6 gives $m=7.1$, which is remarkably larger than that for the disordered alloy.

The creep rates are plotted on a semi-logarithmic scale *versus* the reciprocal of absolute temperature for (a) $\sigma=31.6$ kg/mm², and (b) $\sigma=15.9$ kg/mm² in Fig. 7. The points in the figure are obtained by the relatively unambiguous extrapolation of the measured creep rates listed in Table I. There are a few points to be remarked:

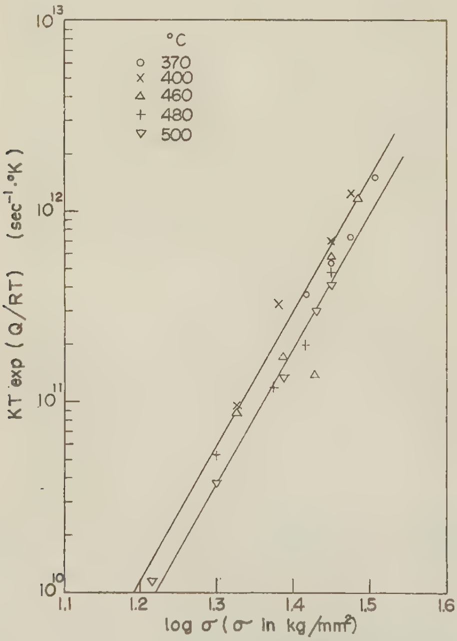

Fig. 6. Plot of $TK \exp(Q/RT)$ *versus* logarithm of stress for ordered alloy, using $Q=49.5$ kcal/mol.

(1) The activation energy Q, independent of applied stress, slightly increases with the degree of order.

(2) A discontinuity occurs in the curves of creep rate *versus* $1/T$ at the critical temperature, *i.e.*, 505°C.

(3) A remarkable acceleration of creep is found below T_C for both ordered and disordered alloys. The creep rate of the ordered alloy is lower for the stress of 15.9 kg/mm², but higher for the stress of 31.6 kg/mm² than the extrapolated values from above T_C corresponding to each stress, respectively where the creep is free from the configurational acceleration. Regarding this it should be added that the consistent dependence of creep rate on stress observed in the alloy, originally well-ordered, suggests an appreciable degree of order still maintained during creep over the whole range of stress investigated.

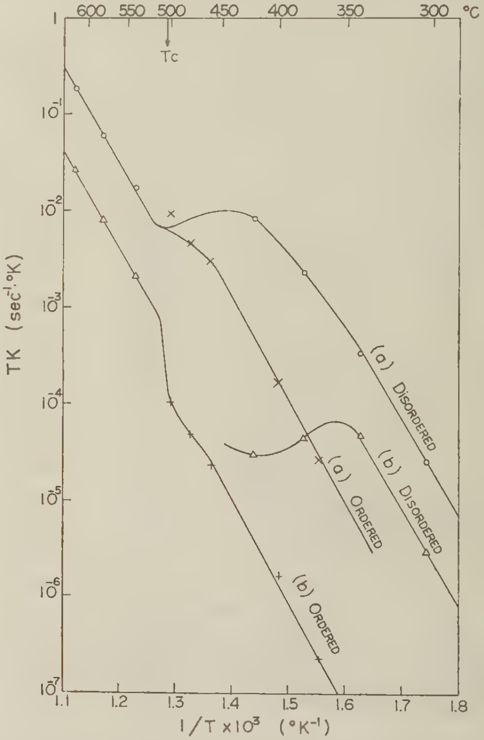

Fig. 7. Logarithm of creep rate times absolute temperature *versus* inverse absolute temperature; (a) $\sigma=31.6$ kg/mm² and (b) $\sigma=15.9$ kg/mm².

(4) For creep of the disordered alloy below T_C, the increase of stress appears to suppress the development of order above 360°C. This is not unconceivable, since the dislocations, increasing in number with applied stress, bring forth essentially the effect of disordering on atomic arrangements. The qualitative difference on this point from what we described in the last paragraph in (3) for the order-

ed alloy may be caused by a significant difference in the way of slip deformation, *i.e.*, the resulting distribution of the dislocations between both cases. This will be discussed below.

§ 4. Discussion

(a) Configurational acceleration of creep

The present results strongly support the theory that the observed creep is controlled by the process of dislocation climb through the vacancy diffusion. Such an influence of order-disorder on creep that gives rise to a configurational acceleration of creep (Fig. 7) is hardly expected from other mechanisms for high temperature creep such as, for instance, cross-slip. The activation energy of cross-slip is mainly determined by the stacking-fault energy according to Schoeck and Seeger.[19] It may give the variation of the activation energy for creep with atomic order, but it does not appear to result such a configurational acceleration as observed. It also does not seem to be significant to take into account non-crystalline flow through the vacancy diffusion such as stress-induced diffusion or grain boundary diffusion. There is an evidence concerning the crystalline nature of the observed creep, which will be discussed later in connection with the stress dependence of creep rates in the ordered and disordered alloys.

In the disordered alloy of AB_3 f.c.c. type a vacancy will jump preferentially to one of the neighbouring sites so as to reduce the configurational energy and the jump frequency is thus influenced by the configuration of its environment. The first problem is to find the total number of vacancy movements occuring in unit time, in which a vacancy moves from one lattice site to another at a given temperature and with a given environment. Using this result, it is possible to express the flux of vacancies along the concentration gradient of vacancies between two climbing dislocations. It will be taken that the total number of vacancy movements in unit time is linearly related with the net change of the degree of order. In doing this we assume the system to be homogeneous and describable solely by means of a long-range order parameter S. Accordingly, if the distribution of vacancies is not so heterogeneous, the rate of flow of vacancies will be given by

$$2\pi r(D+\alpha f_v^{-1}dS/dt)(\partial N/\partial r)\ ,$$

where α is a proportional factor equal to a^2N_0, a is the lattice constant, f_v is the fraction of vacancies, dS/dt is the rate of change of the long-range order parameter, $\partial N/\partial r$ is the concentration gradient of vacancies along the perpendicular distance from the dislocation line and D is the diffusion coefficient of the vacancies in a symmetrical environment, taking $D=D_A=D_B$. Following Weertman we assume that the lead dislocation in a piled-up group of n dislocations is the one to climb. Then, the vacancy concentration N_e in equilibrium with the lead dislocation is

$$N_e=N_O\exp(\pm n\sigma b^3/kT)\ ,$$

where N_O is the equilibrium concentration in a dislocation free crystal. Under steady-state conditions,

$$2\pi r\,\partial N/\partial r=N_0 n\sigma b^3/kT$$

when $n\sigma b^3/kT<1$. It thus follows that the rate of flow of vacancies P is

$$P=2\pi N_0(D+\alpha f_v^{-1}dS/dt)n\sigma b^3/kT\ . \tag{2}$$

The ordering rate dS/dt has been given analytically by Vineyard[20] as a function of S. According to him, it can be written as

$$F(S)=\frac{3(1-S)^2\exp(6VS/RT)-(3+S)(1+3S)\exp(-6VS/RT)}{6(1-S)\exp(3VS/RT)+2(5+3S)\exp(-3VS/RT)}\ .$$

In this expression, we simply assume $V=V_A=V_B$, where $V_A=\frac{1}{2}(V_{AA}-V_{AB})$, $V_B=\frac{1}{2}(V_{BB}-V_{AB})$, and V_{AA} *etc.* are the pairwise interaction energies between the nearest neighbours such as AA, BB and AB pairs, respectively. Inserting this into Eq. (2) one finds

$$P=2\pi N_O D(S)(1+16\alpha F(S))n\sigma b^3/kT\ . \tag{4}$$

It is clear from Eq. (4) that below T_C the climb rate of the dislocation, which is qual to b^2P, is larger by the factor $16\alpha F(S)$ than that above T_C, which is free from the influence of order. The above factor is an increasing function of S at $S\sim0$ at sufficiently low temperatures and it can be far larger than unity.* If the change of S during the observation of creep rate is small enough, which normally takes about one hour, the creep rate will be given as a function of the initial value of S. In fact, the creep rates shown in Table I were all obtained from the parts of creep curves with sufficiently constant slopes over the time of measurements. It is possible that $16\alpha F(S)$ is of the order of 100, which is the right order in magnitude in consistent with the observed results in taking account of a slight change of D with S. If we accept the Weertman's result, the creep rate K can be written as

$$K=(\text{climb rate}\times 1/h)MLL'b, \qquad (5)$$

where h is the climb height of the dislocation, which is determined by equality between the repulsive force given by the barrier in front of the piled-up group of dislocations and the applied force to induce the slip motion of the climbing dislocation. M is the number of the Frank-Read sources per unit volume, and L and L' are the slip distances of edge and screw parts of a dislocation loop, respectively. Eq. (5) is reduced to the form of Eq. (1), where A depends on S and changes slowly with temperature in the temperature range investigated.

The present experiments gave $m=3.1$ for the disordered alloy above T_C and at low temperatures below T_C. It is remarkable that the observed value of m on many metals except for a few examples like tin are almost 3 to 4. Theoretically Weertman has found m to be 3.6 for metals such as aluminium, although the theory is not so well established on this point.

(b) Dislocation climb and creep in an well ordered alloy

As well known, a single perfect dislocation in an well-ordered alloy of AB_3 f.c.c. type introduces an antiphase boundary along the half of slip plane through the crystal.[21),22)] Taking two neighbouring dislocations on the same slip plane, one may be called the disordering dislocation, while the other the ordering dislocation. The strips of disordered regions are arranged in parallel along the slip plane corresponding to the piled-up group of the dislocations which are illustrated in Fig. 8(a). In practice, however, the jogs formed rather at random in these dislocations by intersecting other dislocations will scatter the strips into irregular forms.* The scattered strips are illustrated schematically in Fig. 8(b), which shows the antiphase-domain boundaries by hatching in the same slip plane. These boundaries are distributed at random in the parallel planes, of which width depends on the distribution of positive and negative jogs and on their length. When slip occurs in the ordered alloy, therefore, the crystal region of certain width parallel to slip plane will become less-ordered.

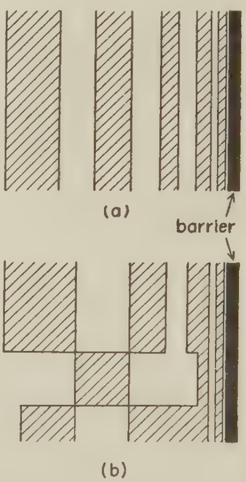

Fig. 8. Antiphase boundaries in a slip plane introduced by slip-dislocations piled up in front of a barrier. (a) An ideal pattern without any disturbance due to jogs; (b) random strips of antiphase boundaries formed by intersecting other dislocations, which are not rigidly fixed.

On the other hand, the vacancy in an well-ordered alloy is tightly bound to its original position, and any jump to the neighbouring position increases the configurational energy and such jumps will be immediately retraced. For the vacancy diffusion without creating disorder, therefore, it must need certain correlated processes as suggested by Elcock and McCombie.[23] The vacancy feels much more difficulty for its motion than in the disordered phase. As a result, the vacancy diffusion is faster within the slip bands than in the regions between the slip bands. In other words, the vacancy diffusion is anisotropic in this case. Therefore, a couple of the climb dislocations lying in the same slip band as close as possible will be preferentially chosen. The diffusion problem to be discussed now becomes effectively a one dimensional one.

---

* $F(S)$ has a zero at $S=0$. As discussed by Vineyard, the reason for this is that a completely disordered system has no preference for choosing any particular sublattice for A or B atom. We have to consider the effects of the short-range order to explain the acceleration of creep for $S=0$.

* The formation of jogs by intersecting other dislocations may explain a large part of the hardening in an ordered crystal by the same reason.

If we take the effective diffusivity of the vacancies within the slip band equal to D' and the diffusion length R, the rate of flow of vacancies from unit length of the dislocation through a volume along the slip band of width d is given by

$$P=(d/R)N_0D'F(S)16\alpha n\sigma b^3/kT \qquad (6)$$

instead of Eq. (4) for the isotropic diffusion case. The difference between the climb rates for the ordered and disordered phases is the factor (d/R) except for the diffusion coefficient. (d/R) should be of the order of $10^{-3}(D/D')$ at relatively low stress from the results shown in Fig. 7. Since it is reasonable to take $d=10b\sim100b$, R will be 10^4b to 10^5b. This is possible as the distance between the neighbouring piled-up groups of the dislocations in the same slip band.

The width d of slip bands must be a rapidly increasing function of stress so that the exponent m on the stress in Eq. (1) becomes larger than 3.6 for the isotropic diffusion if the stress dependence of other quantities is unchanged. Experimentally it is found that $m=7.1$ for the ordered alloy as already described. It is of interest to note that creep of tin crystals, where the diffusion coefficient in the c-direction is fairly smaller than that in the a-direction, has a similar stress dependence, *i.e.*, $m=4.6\sim5.0$,[9] although the situation such as the angle between the climb dislocation line and the c-axis is not necessarily 90 degrees renders the results more complex.

(c) Some note on stress-strain curves and specific heat-temperature curves

As Friedel[24] suggested, the initial part of stress-strain curve of polycrystalline metals resembles apparently to the second stage of that in single crystal of the same material. This will be reasonably explained by the fact that multiple slips take place in both cases and so the intersection between dislocations and the formation of the Lomer-Cottrell sessile dislocations occur to an appreciable extent, resulting the rapid hardening. While the stress-strain curve of the disordered alloy shows a typical form for the high temperature deformation of most face-centred cubic metals, the ordered alloy undergoes deformation typical for the low temperature deformation of those metals. Taking into account both facts, it will lead us to conclude that a dynamical recovery cannot easily set in the ordered alloy at room temperature as compared with that in the disordered alloy. This is possibly understood by the reason that either cross slip or breaking the sessile dislocations needs the additional activation energy, since it hardly expects the pairwise motion of the dislocations in such cases.

If such a recovery process takes place, slip lines becomes clustered and coarser. In fact, Taoka et al[25] have found electron-microscopically only fine slip lines in their ordered alloys of Cu_3Au and Ni_3Mn and coarse lines in their disordered alloys. The difficulty for the motion of jogs in an well-ordered phase, as discussed before, will of course strengthen the above tendency.

At the last on the stress-strain curves of Ni_3Fe alloys it remains to mention the yield stress of the ordered alloys. The change of yield stress with increasing degree of order in Ni_3Fe and Ni_3Mn is quite opposite to that in Cu_3Au alloys as described before. It seems to be difficult to explain the above disagreement between Ni_3Fe, Ni_3Mn and Cu_3Au at present.

Iida has studied the heat generations in Ni_3Fe quenched from various temperatures above T_C. His results are in consistent qualitatively with our results. He ascribes the first generation of heats to annealing and associated ordering of some lattice defects such as quenched vacancies and dislocations, and the second to the development of local order. The present investigation including additional works on cold-worked specimens supports in general his explanation. In more details, it should be added that with the increase of order and with the progress of recovery from the quenched state by the 'diffusion' of dislocations, it becomes harder gradually to advance such processes because of the increase of the activation energy for the vacancy diffusion as well as the decrease of the concentration gradient of the vacancies. The further development of order and recovery is therefore somewhat retarded to produce the second generation of heats, even though the reaction rate in the cold-worked specimen is still higher than in the quenched specimen without cold-work. The situation is well illustrated in Fig. 9, where the logarithm of electrical resistivity measured at room temperature is plotted against annealing time at 400°C. There are three stages of ordering and recovery. The first rapid change appears to correspond with the first generation of heats in the c_p-T curves and the next linear stage with the second generation of heats. The rates of the first and second changes are both faster in a cold-worked alloy than in the alloy without cold-work. It is seen, however, that the above relation becomes reverse at the third stage of ordering. The first rapid change of electrical resistivity in curve (a) shows an anomalous behaviour with a maximum typical for ordering of this alloy at relatively low temperatures, which may be caused by the nucleation of order.

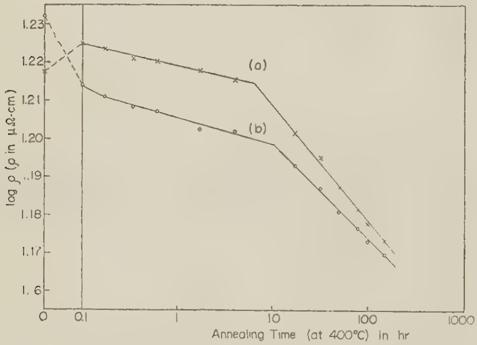

Fig. 9. Annealing curves of disordered alloys at 400°C. Electrical resistivity was measured at room temperature: (a) Without cold-work; (b) cold-worked in tension ($\ln l/l_0=0.137$). Specimen wires were originally quenched from 800°C in air.

Effect of Electron Bombardment on Sodium Chloride

By Shigetomo YOSHIDA and Toshio IKEDA

Research Institute for Scientific Measurements, Tohoku University, Sendai

(Received November 28, 1958)

The absorption spectra ranging from 360 to 960 mμ were measured on rock salt crystals bombarded with electrons at various temperatures. Three types of color centers, namely F, 590 mμ and colloidal centers were formed as a function of specimen temperature during bombardment. The thermal bleaching of these three color centers was also investigated.

From these results it is supposed that the color center with an absorption peak at about 590 mμ may correspond to a precursor of colloidal sodium. It is also suggested that there may be a correlation between coloration and dissociation of sodium chloride by electron bombardment.

§ 1. Introduction

The effects of ionizing radiation on non-metals have been investigated mainly on silver and alkali halides irradiated with ultraviolet light and X-ray, respectively1)2). However, the effects of electron bombardment on these materials have scarcely been reported†. In this respect, following our previous works3) of the electron bombardment on alkali-earth oxides, we studied the effect of electron bombardment on rock salt. In alkali-earth oxides, it was found that the dissociation into constituent components occured under electron bombardment. In this paper we report the coloring of rock salt bombarded at various temperatures and the thermal bleaching of it*. We also considered the correlation between coloration and dissociation of sodium chloride by electron bombardment.

§ 2. Specimens and Experimental Procedure

All specimens used in this investigation were cleaved from rock salt crystal obtained from the Halle Company in Germany. After cleaving to the size of about 5×5×1 mm, platinum electrodes were applied to the both ends of the specimen by painting the aqueous platinum and baking it at about 750°C. After baking, the specimens were furnace-cooled to room temperature with a mean cooling rate of 4°C/min. This procedure was repeated three times for obtaining the well conductive electrodes.

The apparatus for electron bombardment is shown in Fig. 1. The electron gun was constructed with a hairpin tungsten filament F and a special Wehnelt electrode W4). On the interior wall of glass tube the colloidal graphite (Aquadag) was painted and used for the anode. The first anode A_1 was in contact with that wall. The specimen was supported by two thin copper plates L, which also served

†

as the target leads, and placed in an electric furnace *H*. Between this furnace and glass wall the second anode A_2 was positioned and used as the thermal radiation shield. The Pt-PtRh junction *J* (0.08 mm ϕ) was attached to the opposite surface of the specimen. At the upper part of the specimen the grid *G* was placed and biased negatively so that the secondary electron from the specimen was suppressed. The sample, which was held at a distance of 35 cm from the filament, showed the blue fluorescent radiation under bombardment so that we could find the focusing condition of electron beam on the specimen. In order to obtain the fine adjustment of focusing we used a permanent magnet from the outside of the accelerating tube. In this arrangement, we could obtain the focal spot of about 0.1 cm² on the specimen at the bombarding voltage of 18 KV, the Wehnelt voltage of -60 V and the current density of about 40μA/cm².

The electron bombardment was carried out under the vacuum of $10^{-4} \sim 10^{-5}$ mm Hg. Before bombardment the sample was annealed in vacuo for 2 hours at about 450°C and then cooled slowly. The contamination of sample due to electron bombardment was produced especially at room temperature. Although the liquid air or dry ice trap was efficient for preventing the production of contamination, it was not possible to avoid it entirely. Under bombardment at higher temperature than about 200°C, the specimen was free from contamination.

The optical absorption spectra of the bombarded specimens were measured ranging from 360 mμ to 960 mμ by the photoelectric spectrophotometer (Hitachi EPU II).

§ 3. Experimental Results

(A) *Coloration at room temperature*

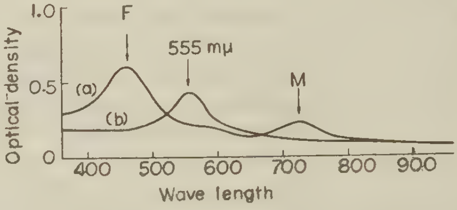

Fig. 2. Optical absorption curves for NaCl crystal bombarded with electrons at room temperature. Bombarding condition is $V=10$KV, $I=40\mu$A/cm² and $t=60$ minutes. (a) after bombardment (b) annealed at 200°C for 30 minutes.

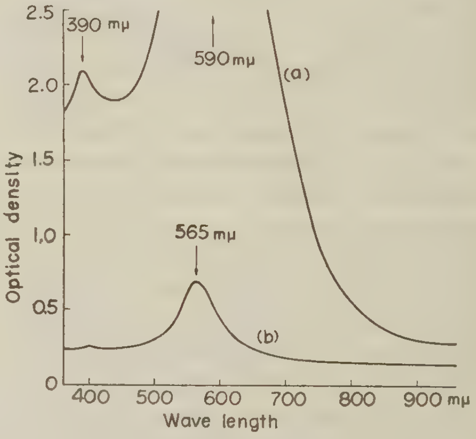

Fig. 3. Optical absorption curves for NaCl crystal bombarded with electrons at room temperature. Bombarding condition is $V=20$ KV, $I=40\mu$A/cm² and $t=60$ minutes. (a) after bombardment (b) annealed at 390°C for 60 minutes.

Initially electron bombardment was carried out at room temperature. The bombarding voltage employed ranged from 7 to 20 KV while the current density and bombarding time were fixed at 40μA/cm² and 60 minutes, respectively. The specimens were colored yellowish for the bombarding voltage below 13 KV. At the voltage higher than 16 KV, blue colored parts developed appreciably among yellowish ones. Under 20 KV bombardment the specimens acquired deep blue color. In these cases, the coloration was limited to the thin layers of bombarded surfaces. The absorption spectra of specimens bombarded at 10 KV and 20 KV are shown by the curve (a) of Figs. 2 and 3, respectively. The curve (a) in Fig. 2 shows distinct *F* and *M* bands familliar to sodium chloride. On the other hand the curve (a) in Fig. 3 shows the strong absorption band with a peak at about 590 mμ accompanied with the weak one at 390 mμ. The peak position of this strong absorption band was not constant and moved from 580 mμ to 600 mμ due to the difference of the bombarding condition. This absorption band was frequently observed in an asymmetrical form instead of the symmetrical bell shaped one. From these facts it is suggested that the blue coloration is due to the mixture of various degree of coloration centers which were probably generated owing to local non-uniformity of bombarding current on the specimen surface. For convenience we designated hereafter this absorption band as 590 mμ band. On the other hand, the peak position of 390 mμ band does not change appreciably.

Usually in the case of bombardment between 13 KV and 16 KV, the shape of absorption bands was not simple and it was difficult to obtain the reproducible results perhaps due to the coloration at the intermediate state between two conditions above mentioned. The absorption curve for the bombardment at 16 KV is shown in Fig. 4. As shown, it is characteristic of this absorption curve to spread over the wide wavelength range.

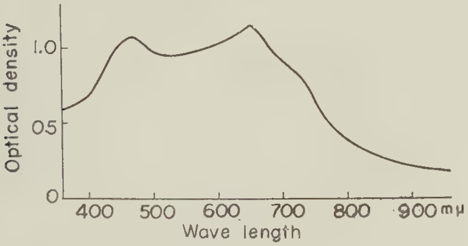

Fig. 4. Optical absorption curve for NaCl crystal bombarded with electrons at room temperature. Bombarding condition is $V=16$ KV, $I=40\mu A/cm^2$ and $t=60$ minutes.

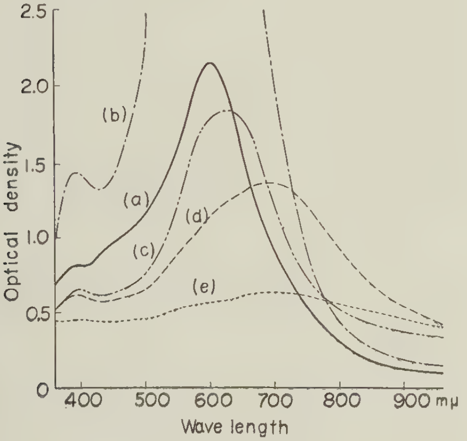

Fig. 5. Optical absorption curves for NaCl crystals bombarded with electrons at various temperatures. Bombarding condition is $V=18$ KV, $I=40\mu A/cm^2$ and $t=30$ minutes. The temperatures are as follows; (a) 15°C (b) 150°C (c) 234°C (d) 260°C (e) 283°C.

We also observed the coloration of specimens as a function of bombarding current. It was found that the blue coloration developed with increasing current density even at the low bombarding voltage. For example, the specimen bombarded at 10 KV and 40μA/cm^2 for 60 minutes displayed *F* and *M* bands as shown in the curve (a) of Fig. 2, but with the increase of current density to 140μA/cm^2 it acquired deep blue color corresponding to the strong absorption band at 590 mμ. From these results it is supposed that the blue coloration of sodium chloride bombarded with electrons is influenced greatly by the bombarding wattage. Although the rise of temperature was not noticed with the thermocouple attached to the back face of specimen, it may be considered that the increase in bombarding wattage is related to the rise of temperature on the bombarded surface.

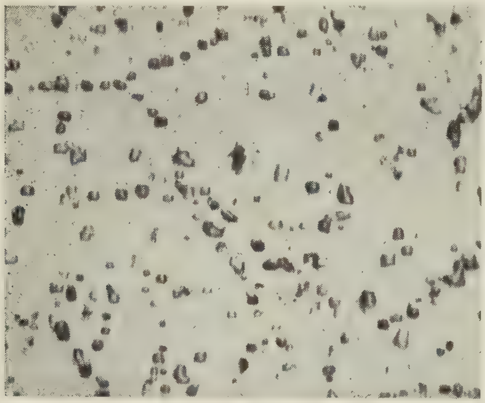
(B) *Temperature dependence*

We next observed the coloration as a function of temperature. In these cases the bombarding condition was fixed as follows; voltage is 18 KV, current 40μA/cm^2 and time 30 minutes. The temperature during bombardment was changed from room temperature to about 400°C. In Fig. 5 the absorption spectra of the coloration at 15°C, 150°C, 234°C, 260°C and 283°C are shown. The peak position shifted towards longer wavelength and the shape of absorption bands became less sharp with increasing temperature. Above 300°C, the specimens did not show any coloration and became cloudy. In Fig. 6 microphotographs of these specimens are shown. It was seen that a number of cubic pits was formed on the bombarded surfaces and the size of these pits became larger with increasing temperature.

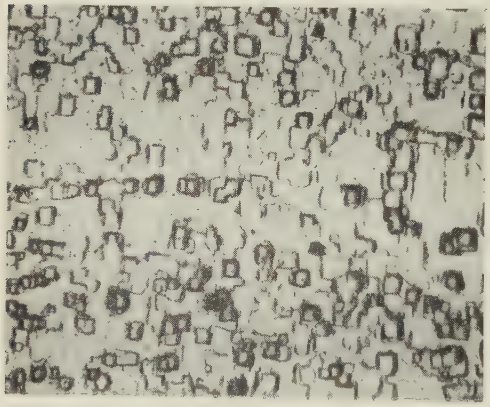
For the specimens showing the absorption peak at above 600 mμ which was produced under the bombardment at elevated temperature, we observed the scattering of dull red light from the bombarded surface. The dull red color corresponds to the complementary color of the pale blue one of the transmitted light. This behavior will be related to the scattering of light by colloidal particles. The weak absorption band with a peak at about 390 mμ was also found in this colloidal coloration but it seemed that the peak position shifted slightly towards the longer wavelength.

(C) *Effect of thermal bleaching*

The yellowish colored specimens which have *F* and *M* bands changed to reddish purple by heating them to 200°C in air. For example, the curve (b) in Fig. 2 is the absorption spectrum of the annealed specimen which changed thermally from curve (a). Heating to about 350°C, the specimen bleached out gradually without further alternation of coloration. In this process, the colloidal scattering from the colored part was not observed.



(a) Bombarded at 316°C.



(b) Bombarded at 373°C.

Fig. 6. Microphotographs for NaCl crystals bombarded with electrons at high temperatures. Bombarding condition is $V=18$ KV, $I=40\mu\text{A/cm}^2$ and $t=30$ minutes. (×180)

Although the yellowish colored specimens showed the optical bleaching at room temperature, the blue colored specimens with 590 mμ band were very stable under the same condition. In Fig. 3, curve (b) shows the effect of thermal bleaching on blue colored specimen. As shown, the peak position shifted towards shorter wavelength by annealing and reached to 565 mμ after heating to 390°C. At the same time, the scattered light of green color, which is complementary one of reddish purple of the transmitted light, became to be observed. Consequently it was concluded that the blue coloration with 590 mμ band changed to the colloidal coloration with an absorption peak shifted towards shorter wavelength. On the other hand, the colloidal coloration which was produced under the bombardment at high temperature did not change by annealing, and bleached out entirely at about 450°C.

§ 4. Discussion

(A) *Colloidal coloration*

As previously mentioned, if the temperature during bombardment was high the scattered light from the colored surface of specimens was detected. Since the color of this scattered light was complementary to that of the transmitted light, it may be concluded that the origin of coloration was the scattering of light by the colloidal particles, that is, perhaps the metallic sodium particles. According to Savostianowa[5)] the peak position of the absorption band of natural blue rock salt shifts towards the longer wavelength with increasing diameter of colloidal particles. For example, the absorption peaks at 600 mμ and 650 mμ may be related to the scattering by the colloidal particles with diameter of 40 mμ and 70 mμ respectively. Consequently the results of Fig. 5 show that the colloidal particles with larger diameter would be produced with increasing temperature. It may be also concluded that the broad width of absorption band at high temperature will be related to the mixing state of the colloidal particles with various dimensions.

In additive coloration of potassium chloride, Scott and Smith[6)] observed that the colloidal coloration was produced by the coagulation of F centers during thermal treatment and the colloidal centers were in thermal equilibrium with F centers. However, our colloidal coloration which is produced by electron bombardment at high temperature is different in manner of thermal bleaching from the one which is produced by additive coloration. In our case the colloidal layer was formed immediately near the surface, so these excess sodium atoms may sublimate from the surface before they are converted into F centers.

(B) *Blue coloration*

The blue coloration which has the absorption peak at about 590 mμ was produced under the bombardment at intermediate temperature, *i.e.* at lower temperature than the one where the colloidal center is produced and at higher temperature than the one where the *F* center is produced. Therefore, the blue coloration may correspond to the transition state from the *F* coloration to the colloidal one. This color centers changed to the colloidal particles with the small diameter of about 10 mμ (according to Savostianowa⁵⁾) by heating. From these observations it is supposed that the center of blue coloration may correspond to the aggregate of excess sodium atoms, *i.e.* the precursor of colloidal sodium. As previously mentioned, it was considered that this coloration originated in the mixing state of the various coloration centers having the different absorption peaks. It may be considered that they may correspond to the difference of the degree of coagulation and have probably the same nature as the *R′* center observed by Scott and Bupp⁷⁾.

It is notable feature that the blue or colloidal coloration has always the weak absorption band at about 390 mμ. This band may correspond to the peak of the photoconducting current curve plotted against the wavelength in blue or violet rock salt containing colloidal sodium⁸⁾.

(C) *Bombardment effect*

It was known that three types of color centers above mentioned were respectively formed as a function of specimen temperature under bombardment. According to the results of electron bombardment on BaO, SrO and MgO⁹⁾, it was recognized that oxygen molecules evolved from those samples and excess metal atoms were produced near the surface. Taking these results into consideration it was supposed that the excess sodium atoms were obtained as a result of the evolution of chlorine atoms and aggregated into colloidal or 590 mμ centers according to the degree of coagulation. On the bombardment at elevated temperature only cubic pits were formed on the surface and no coloration was observed. This result may be explained by the sublimation of equal quantity of sodium and chlorine atoms.

In conclusion the authors wish to express their cordial thanks to Prof. T. Hibi for his stimulating discussions and to the Electrical Communication Laboratory of Nippon Telegraph and Telephone Corporation for the grant in aid.

Configurational Coordinate Curves for Luminescence Center in $Ca_3(PO_4)_2$:Cu

By Keiji MAEDA

Matsuda Research Laboratory, Tokyo Shibaura Electric Co., Kawasaki, Japan

(Received December 5, 1958)

For $Ca_3(PO_4)_2$:Cu phosphor, measurements of spectral distributions of luminescence, reflectivity and quantum efficiency, temperature dependence of luminescence intensity and decay constants are carried out. The one-dimensional configurational coordinate curves for the luminescence center in this phosphor are determined by analysing spectral data. Some characteristics expected from these curves are compared with the observed; the agreement in the absorption band width and the disagreement in the activation energy for nonradiative transition are obtained. The relations between one- and many-dimensional models are investigated and the cause for the above disagreement is attributed to the simplicity of the assumed model. Discussions are also made on the nonradiative transitions in this center.

§ 1. Introduction

The configurational coordinate (hereafter abbreviated as C. C.) curves have been widely used to explain qualitatively some characteristics of the localized luminescence centers. Accompanying with the advance in our understanding, they have become to be discussed quantitatively[1)] and a review of the recent progress has been given by Klick and Schulman[2)].

The role of the C. C. diagram is quite important and it can be even said that the nature of luminescence center is thoroughly understood, if the C. C. diagram is completely determined for the center. There are two different ways of approach; one of these is by theoretical calculations and the other is by analysis of experimental results.

The first way is interesting in principle but very difficult in practice, because it requires to solve many electron systems accurately. Williams[3)] made detailed calculations for KCl: Tl and his results were in fair agreement with experiments. However, Knox and Dexter[4)] presented some critiques on his treatments suggesting that further improvements are necessary in calculations.

The second way is a very practical one, as it is to choose the C. C. curves so as to fit them with the measured characteristics. While this procedure becomes quite significant when we have other independent experimental values to be compared with those expected from the C. C. curves determined, because it is then possible to investigate the validity of the assumed model and the correlation among various characteristics. By this way, Klick and his colaborators derived the C. C. curves for the Mn-center in Zn_2SiO_4[5)] and the F-centers in several alkali halides[6)] and Hameka and Vlam[7)] derived those for the luminescence center in $CaWO_4$.

Following the second way we shall consider the C. C. diagram for the luminescence center in $Ca_3(PO_4)_2$:Cu phosphor, which has been extensively studied by Uehara and his colaborators[8)]. First we shall assume the one-dimensional model. Then we shall discuss the relations between the one- and many-dimensional models.

§ 2. C. C. Curves and Spectral Shape

As a large number of vibrational modes affect the energy of the luminescence center in solid, the C. C. space describing the center should be many-dimensional. To analyse experimental data, however, the many-dimensional treatment is too complex, so that we shall assume the simplified one-dimensional model, which is considered to represent the interaction of the center with the most important vibrational mode. Such a model has been adopted by all previous workers in their treatments of actual materials.[3),5)-7)]

In our simple model, the energies of the ground and excited states are represented by parabolic curves respectively. Accordingly, each state can be treated as a harmonic oscillator. Fig. 1 shows these C. C. curves. The vibrational frequencies are $\omega_g/2\pi$ in the ground state and $\omega_e/2\pi$ in the excited state respectively. The force constants are κ_g and κ_e for each of these two vibrations. The minimum point of the excited state curve is displaced by an amount U in the energy and by a distance x_0 in the coordinate from that of the ground state curve. The energy increase above the minimum at x_0 in the ground state is $X=\frac{1}{2}\kappa_g x_0^2$ and that at the origin of the coordinate in the excited state is $Y=\frac{1}{2}\kappa_e x_0^2$. These two curves intersect at the point, where the energy is W above the minimum of the excited state. Here W is the activation energy for the nonradiative de-excitation.

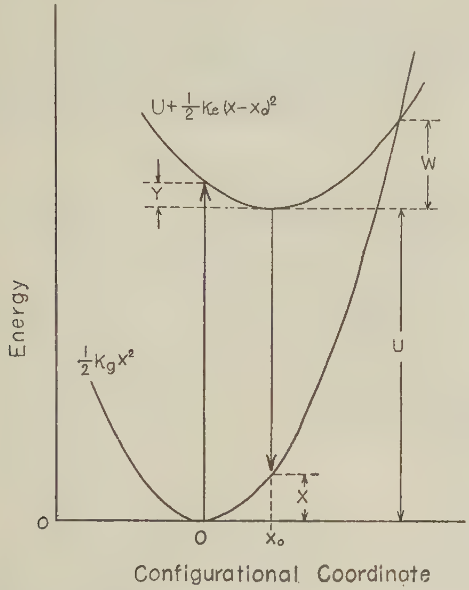

Fig. 1. One-dimensional configurational coordinate curves for a luminescence center. Arrows indicate optical transitions.

The energy difference between the m-th vibrational level in the ground state and the n-th vibrational level in the excited state is

$$E_{nm}=h\nu_{nm}=U+\hbar\omega_e(n+\tfrac{1}{2})-\hbar\omega_g(m+\tfrac{1}{2})\,. \quad (1)$$

When a transition occurs between these two levels, an absorption or emission of light is observed, the frequency of which is equal to ν_{nm} in Eq. (1). The absorption coefficient is proportional to $\nu_{nm}|M_{nm}|^2 w_m'$ and the luminescence intensity is proportional to $\nu_{nm}^4|M_{nm}|^2 w_n''$, where M_{nm} is the matrix element of dipole transition between these two levels and w_m' and w_n'' are the probabilities that the oscillator is in the m-th vibrational level in the ground state and that in the n-th vibrational level in the excited state respectively.

The wave function, from which the above matrix element is derived, may be decomposed into a product of electronic and nuclear wave functions. Here we assume the so-called Condon approximation; i.e., we neglect the dependence of electronic matrix element on nuclear positions. The observed absorption and emission bands consist of many line spectra with different combinations of m and n, overlapping one another. Considering all combinations of the vibrational levels, we obtain the distribution function for the absorption coefficient $\alpha(E)$ and that for the luminescence intensity $I(E)$;

$$\alpha(E)=\text{const}\times E\sum_n\sum_m\left|\int\psi_{en}^*(x)\psi_{gm}(x)\,dx\right|^2\exp\left\{-\left(m+\frac{1}{2}\right)\frac{\hbar\omega_g}{kT}\right\}\delta(E_{nm}-E)\,, \quad (2)$$

$$I(E)=\text{const}\times E^4\sum_n\sum_m\left|\int\psi_{gm}^*(x)\,\psi_{en}(x)\,dx\right|^2\exp\left\{-\left(n+\frac{1}{2}\right)\frac{\hbar\omega_e}{kT}\right\}\delta(E_{nm}-E)\,, \quad (3)$$

where ψ_{gm} and ψ_{en} are the vibrational wave functions of the m-th level in the ground state and that of the n-th level in the excited state respectively and x denotes the nuclear position.

In order to represent the shape of the normalized spectrum, $f(E)$, we shall use the semi-invariants. These are defined as the coefficients, λ_i, in the expansion

$$f(E)=\Phi_0(E)-\frac{\lambda_3}{6}\Phi_3(E)+\frac{\lambda_4}{24}\Phi_4(E)+\cdots\,, \quad (4)$$

where

$$\int f(E)\,dE=1\,,$$

$$\Phi_0(E)=\frac{1}{\sqrt{2\pi\lambda_2}}\exp\left\{-\frac{(E-\lambda_1)^2}{2\lambda_2}\right\},$$

$$\Phi_m(E)=\frac{d^m}{dE^m}\Phi_0(E).$$

By an ingenious method, Kubo and Toyozawa[9] derived the semi-invariants of the absorption band neglecting the E-dependency in Eq. (2). These are slightly modified when the E-dependency is taken into account. Making use of the relations among the semi-invariants and the moments, we have

$$\left.\begin{aligned}
\lambda_{1a}&=U+Y+\left\{\frac{1}{4}(\gamma^2-1)+\frac{\gamma^2 Y}{(U+Y)}\right\}\hbar\omega_g\coth\left(\frac{\hbar\omega_g}{2kT}\right)+\mathrm{O}\left\{\frac{(\hbar\omega_g)^2}{U}\right\},\\
\lambda_{2a}&=\gamma^2 Y\hbar\omega_g\coth\left(\frac{\hbar\omega_g}{2kT}\right)+\left\{\frac{1}{8}(\gamma^2-1)^2-\frac{\gamma^4 Y^2}{(U+Y)^2}+\frac{3}{2}(\gamma^2-1)\frac{\gamma^2 Y}{U+Y}\right\}\\
&\qquad\times(\hbar\omega_g)^2\coth^2\left(\frac{\hbar\omega_g}{2kT}\right)+\frac{\gamma^2 Y}{U+Y}(\hbar\omega_g)^2+\mathrm{O}\left\{\frac{(\hbar\omega_g)^3}{U}\right\},\\
\lambda_{3a}&=\gamma^2 Y(\hbar\omega_g)^2\left\{1+\frac{3}{2}(\gamma^2-1)\coth^2\left(\frac{\hbar\omega_g}{2kT}\right)\right\}+\mathrm{O}\{(\hbar\omega_g)^3\},
\end{aligned}\right\}\tag{5}$$

where

$$\gamma=\frac{\omega_e}{\omega_g}=\sqrt{\frac{\kappa_e}{\kappa_g}}.$$

In a similar way, the semi-invariants of the intensity distribution of luminescence given by Eq. (3) are calculated:

$$\left.\begin{aligned}
\lambda_{1f}&=U-X+\left\{\frac{4}{\gamma^2}\frac{X}{(U-X)}-\frac{1}{4}\left(\frac{1}{\gamma^2}-1\right)\right\}\hbar\omega_e\coth\left(\frac{\hbar\omega_e}{2kT}\right)+\mathrm{O}\left\{\frac{(\hbar\omega_e)^2}{U}\right\},\\
\lambda_{2f}&=\frac{X}{\gamma^2}\hbar\omega_e\coth\left(\frac{\hbar\omega_e}{2kT}\right)+\left\{\frac{1}{8}\left(\frac{1}{\gamma^2}-1\right)^2-\frac{6}{\gamma^2}\left(\frac{1}{\gamma^2}-1\right)\frac{X}{U-X}-\frac{4}{\gamma^4}\frac{X^2}{(U-X)^2}\right\}\\
&\qquad\times(\hbar\omega_e)^2\coth^2\left(\frac{\hbar\omega_e}{2kT}\right)-\frac{4}{\gamma^2}\frac{X}{(U-X)}(\hbar\omega_e)^2+\mathrm{O}\left\{\frac{(\hbar\omega_e)^3}{U}\right\},\\
\lambda_{3f}&=-\frac{X}{\gamma^2}(\hbar\omega_e)^2\left\{1+\frac{3}{2}\left(\frac{1}{\gamma^2}-1\right)\coth^2\left(\frac{\hbar\omega_e}{2kT}\right)\right\}+\mathrm{O}\{(\hbar\omega_e)^3\}.
\end{aligned}\right\}\tag{6}$$

The inclusion of the E- or E^4-dependency produces alterations of the second order terms in these expressions. Therefore, we may neglect these dependencies in a discussion of first order quantities of spectral shape when high accuracy is not required. But we must include them in a discussion of second order small quantities, e.g. the temperature dependence of the peak position. It should be noted that Eqs. (5) and (6) do not contain the mass of the harmonic oscillator. Accordingly, an ambiguous assumption about it is unnecessary in our later analysis of experimental results.

§ 3. Experimental Results

(1) *Sample preparation*

The sample is β-$Ca_3(PO_4)_2$:Cu powder phosphor which was fired at about 1100°C for 30 minutes in air and further 30 minutes in a reducing atmosphere (N_2+H_2)[8]. The activator concentration is 5×10^{-3} atoms of copper for three calcium atoms.

(2) *Luminescence spectrum*

Under excitation with 2537Å radiation this phosphor emits bright blue luminescence. The luminescence spectrum was measured at various temperatures. As an example the result taken at 284°K is shown in Fig. 2. The spectrum is nearly Gaussian in shape over all the temperature range, so that it is a single-component band.

The spectral width becomes broad with increasing temperature. In Fig. 3 the squared half-width is plotted against absolute temperature. According to Eq. (6), the squared width is proportional to $\hbar\omega_e \coth(\hbar\omega_e/2kT)$ in a first approximation. We can thus determine the vibrational frequency in the excited state by choosing it so as to fit the calculated temperature dependence with the observed. The curve in Fig. 3 is proportional to

$$\hbar\omega_e \coth(\hbar\omega_e/2kT)$$

with the frequency chosen, $6\times10^{12}\,\text{sec}^{-1}$, and the dotted line is its asymptote.

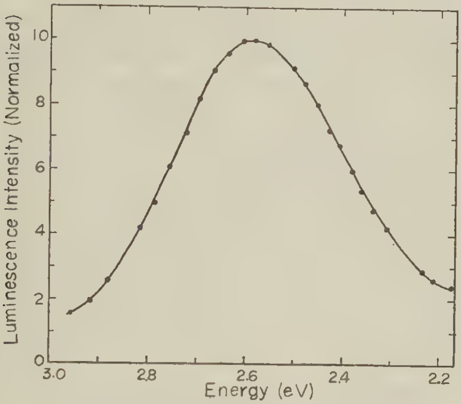

Fig. 2. Luminescence spectrum of $Ca_3(PO_4)_2$: Cu under 2537 A excitation at 284°K.

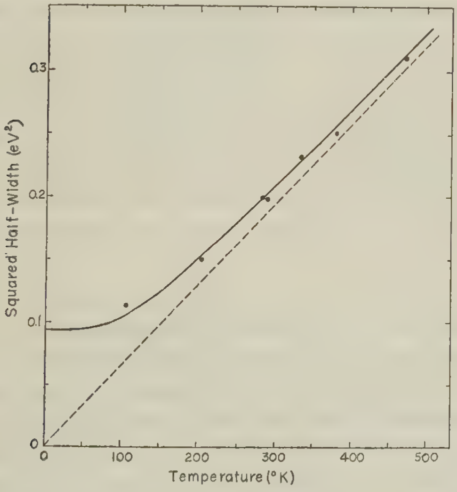

Fig. 3. Variation of the squared half-width of luminescence spectrum with temperature. Solid curve is calculated with the frequency 6×10^{12} sec^{-1} and dotted line is its asymptote.

The peak position of the luminescence band shifts to shorter wavelengths with increasing temperature and its variation is shown in Fig. 4 as a function of temperature.

The spectral shape is not strictly symmetric and in Fig. 5 the asymmetry defined by

$$S=\frac{h\nu_0-\frac{1}{2}(h\nu_++h\nu_-)}{h\nu_+-h\nu_-}\,, \tag{7}$$

is plotted against temperature, where $h\nu_0$ is the energy of the peak position and $h\nu_+$ and $h\nu_-$ are the energies of the half-maximum positions on the high- and low-energy side respectively.

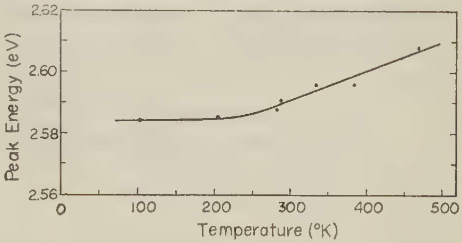

Fig. 4. Variation of the peak of luminescence spectrum with temperature.

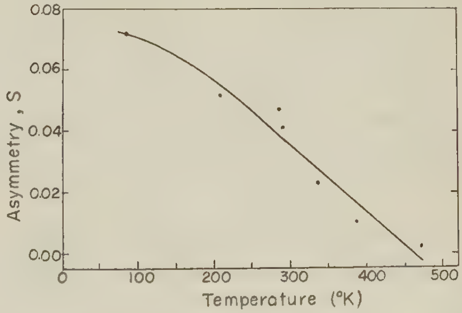

Fig. 5. Variation of the asymmetry of luminescence spectrum with temperature. The asymmetry S is defined by Eq. (7).

(3) *Spectral distributions of reflectivity and quantum efficiency*

The spectral distributions of the diffuse reflectivity and the quantum efficiency were measured for the phosphor and the pure host crystal by the apparatus made by Uehara and Masuda[10] in the writer's laboratory.* The results are shown in Fig. 6.

The quantum efficiency of luminescence is defined by the number of luminescence photons emitted per a photon absorbed by the center. The ratio of the energy absorbed by the luminescence center to that of the incident light is taken equal to the difference in the value of reflectivity between the phosphor and the host crystal without impurity. We make a correction, considering that the emission intensity measured on a thick layer of powder phosphor is $(1+R_l)/2$ of the total, where R_l is the diffuse reflectivity of the phosphor in the spectral region of the luminescence.**

---

* The method of measurement is as follows.[10] A layer of the powder sample of sufficient thickness, which do not transmit light through it, is placed before an exit slit of a monochrometer. The intensity ratios of the reflected light and the luminescent light to the incident light are measured separately by means of a combination of a filter and a photomultiplier, of which the spectral sensitivity is calibrated previously.

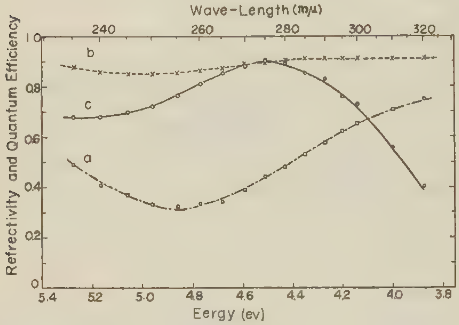

Fig. 6. Spectral distributions of (a) reflectivity of phosphor, (b) reflectivity of pure host crystal and (c) quantum efficiency of luminescence.

In Fig. 6 there is no characteristic absorption in the pure crystal and the reflectivity spectrum of the phosphor is symmetric in shape. On the contrary, the spectral distribution of the quantum efficiency is asymmetric, rapidly decreasing from the peak value on the low-energy side and slowly on the high-energy side. It should be noted that the peak position of the quantum efficiency curve is displaced by 0.35 eV to lower energy from the minimum position of the reflectivity curve.

(4) *Temperature dependence of luminescence intensity*

The temperature dependence of the luminescence intensity under 2537Å excitation is shown in Fig. 7. The luminescence intensity is nearly constant up to about 550°K and rapidly decreases above this temperature.

The probability of the nonradiative transition is given by $B\exp(-W/kT)$ and that of the radiative transition, A, is independent of temperature. Accordingly, the variation of the luminescence intensity with temperature is represented by

$$I=\frac{CA}{A+B\exp(-W/kT)}\,, \tag{8}$$

where C is a constant. For the best fit of Eq. (8) with the observed temperature dependence following values are chosen;

$$W=0.82\,\text{eV} \quad \text{and} \quad B/A=7.6\times10^5\,.$$

The calculated curve is shown in Fig. 7; here it is assumed that the gradual decrease observed in the lower temperature region superposes on the thermal quenching given by Eq. (8).

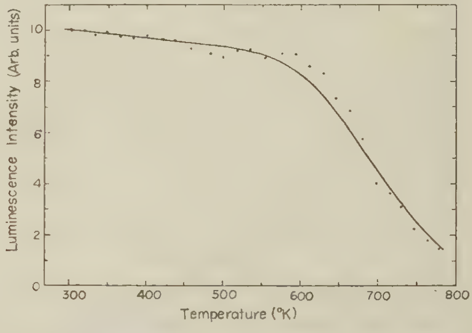

Fig. 7. Temperature dependence of luminescence intensity under 2537 A excitation. Solid curve is calculated to fit the experimental points.

(5) *Decay constant of luminescence*

The decay constants of luminescence were measured under the cathode ray pulse excitation. There are two exponentially decaying components; the fast component, being about a half of the total in intensity, has the time constant of 0.13 μsec and the slow component has the time constant of 1.5 μsec. From these results we can conclude that the radiative transition is the allowed and there is a trapping state from which a transition is easily made to the radiative state.

§ 4. Determination of C. C. Curves and Comparison with Experiments

From the conditions of preparation of the sample, we consider that the luminescence center is probably Cu^+ substituted for Ca^{++} in the lattice. The ground state of Cu^+ is

---

** As the phosphor particles emit light uniformly in all directions, a half of the emitted light appears directly from the surface of the phosphor layer but another half emitted backwards is reflected by the inner layers of the phosphor particles and then appears. Therefore, the observed luminescence intensity on the thick layer of phosphor is $(1+R_l)/2$ times of the total.

${}^1S_0(3d^{10})$ and the excited state is assumed to be ${}^3P_1(3d^94p)$.[8] The transition between these states is forbidden in the pure state by the spin selection rule but is allowed in the crystal due to the spin-orbit interaction.

We shall determine the C. C. curves for the luminescence center by analysing the experimental data on spectral shape. The values of U, X, Y and γ are calculated by Eqs. (5) and (6) using the following experimental values at 286°K;

position of maximum absorptance
4.85 eV,

position of maximum luminescence intensity
2.59 eV,

half-maximum width of luminescence spectrum 0.44_4 eV,

vibrational frequency in the excited state
$6\times10^{12}\,\mathrm{sec}^{-1}$.

The results are

$$U=3.49\,\mathrm{eV},\quad X=0.96\,\mathrm{eV},\quad Y=1.34\,\mathrm{eV}\quad \text{and}\quad \gamma^2=1.40.$$

Here, γ is surprisingly large. The energy diagram thus determined is shown in Fig. 8. Because the crystal structure of β-$Ca_3(PO_4)_2$ is unknown, the vibrational modes around the center are uncertain; even if the atomic configuration around the center is known, it is not unambiguous in detail what nuclear displacements are meant by the one-dimensional configurational coordinate. Accordingly, the values of x_0, κ_g and κ_e are not obtainable separately from X and Y.

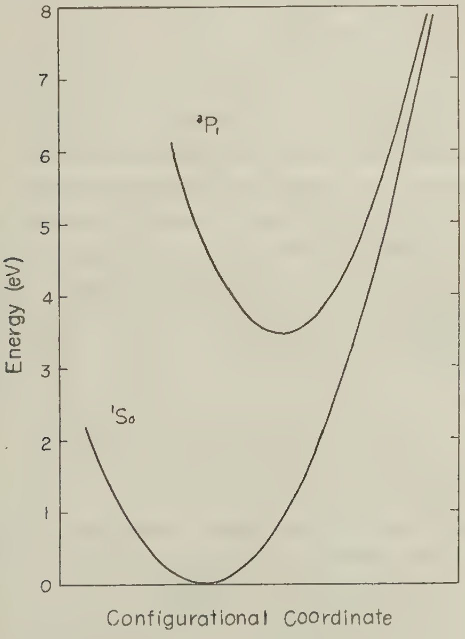

Fig. 8. One-dimensional configurational coordinate curves for the luminescence center, Cu^+, in $Ca_3(PO_4)_2$.

We shall compare the observed characteristics with those calculated from our C. C. curves by the help of Eqs. (5) and (6). In Section 3 we have made measurements of the diffuse reflectivity, since the sample is available only as powder. In order to obtain the shape of the absorption band, the following relation between the reflectivity, R, and the absorption coefficient, α, is used;

$$\alpha=\text{const}\times\frac{(1-R)^2}{R}.$$

This equation is derived by a crude approximation of a theory on the absorption and scattering and has been proved to hold within a wavelength range where the scattering is constant[11]. The spectral distribution of the relative absorption coefficient due to the luminescence center is calculated and is shown in Fig. 9.* The half-width of the absorption

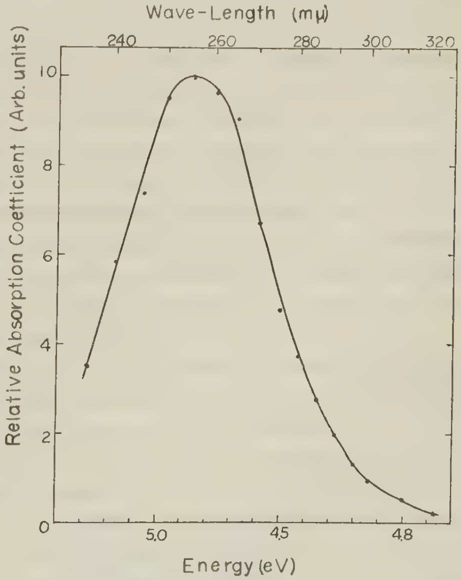

Fig. 9. Spectral distribution of relative absorption coefficient due to luminescence centers.

---

* The relative absorption coefficient shown is the difference between the calculated value from the reflectivity at the specified wavelength and that from the wavelength-independent reflectivity at longer wavelengths of the phosphor.

band is 0.71 eV in this figure whereas the expected value is 0.75 eV at room temperature. Thus the agreement is good.

Because the two curves do not intersect in Fig. 8, the activation energy for the nonradiative transition is expected to be infinitely large. On the other hand, the activation energy of 0.82 eV is obtained by analysing the temperature dependence of the luminescence intensity shown in Fig. 7. The variation of the peak of the luminescence band with temperature is 9×10^{-5} eV/deg by measurements and 1.7×10^{-4} eV/deg by the high temperature approximation of λ_{1f} in Eq. (6). The signs of variations with temperature are the same but the calculated value is about twice the observed. For the asymmetry of the luminescence spectrum, we expect the shape with slower decrease in the high-energy side than in the low-energy side at low temperatures and the opposite one at high temperatures. The experimental results in Fig. 5, however, show the asymmetry of the opposite direction at low temperatures, which diminishes as the temperature rises. The above disagreements are quite large.

§ 5. One-and Many-Dimensional Models

We shall consider possible reasons for the above discrepancies between the observed and calculated characteristics, especially, in the activation energy. (a) As there are several excited states in Cu^+ with comparable energy to $^3P_1$,[12] the nonradiative transition which contributes to the observed thermal quenching of luminescence may find an alternative way through another state from the excited to the ground state. However, we shall disregard here such a possibility because other disagreements than the activation energy are left unsettled. (b) Actually the potential energy would not be represented by a parabola up to a position where the nuclear displacement from the equilibrium position is large. The presence of anharmonic terms in the potential energy is suggested by the disagreement between the calculated and the observed asymmetry. By a qualitative calculation, however, it becomes clear that the anharmonic terms in the potential of the ground state, which lower the activation energy in the C. C. diagram, have an effect to increase the disagreement in asymmetry. (c) The assumption that the electronic matrix elements are independent of the nuclear positions may introduce an error. However, according to Dexter[13], the correction for this assumption introduces only a smaller change in the transition probability than the E^4-dependency which is proved in Section 2 to have no influence on the spectral shape to a first order approximation.

Fundamentally it is doubtful whether or not the many-dimensional C. C. shape can be replaced by the one-dimensional space for the sake of simplicity. The relations between one- and many-dimensional models will be investigated in the following. We assume that in the N-dimensional model, the energies of the ground and excited states are described by quadratic forms of the configurational coordinates with different origin, principal axis directions and curvatures respectively. The semi-invariants of the absorption band due to the optical transition between these two states are given by Kubo and Toyozawa[9] to a first approximation;

$$\left.\begin{aligned} \Lambda_{1a} &= \mathcal{E}_0 + \frac{1}{2}\Delta\Omega''^2\Delta\,, \\ \Lambda_{2a} &= \frac{\hbar}{2}\Delta\Omega''^2\Omega'^{-1}\coth\left(\frac{\hbar\Omega'}{2kT}\right)\Omega''^2\Delta\,. \end{aligned}\right\} \qquad (9)$$

In a similar way, the semi-invariants of the luminescence specrtum are also calculated;

$$\left.\begin{aligned} \Lambda_{1f} &= \mathcal{E}_0 - \frac{1}{2}\Delta\Omega'^2\Delta\,, \\ \Lambda_{2f} &= \frac{\hbar}{2}\Delta\Omega'^2\Omega''^{-1}\coth\left(\frac{\hbar\Omega''}{2kT}\right)\Omega'^2\Delta\,. \end{aligned}\right\} \qquad (10)$$

Here $\mathcal{E}_0$ is the energy separation between the minimum positions of the two electronic states, Δ is the N-dimensional vector denoting the the distance between these minimum positions and Ω'^2 and Ω''^2 are the N-dimensional tensors denoting the potentials of the ground and the excited state respectively. Since units are chosen here so as to the mass of the oscillators is unity, each element in Ω' and Ω'' is the vibrational frequency when these tensors are transformed into diagonal form.

If all the vibrational frequencies in the ground state and all those in the excited state are the same in their groups respectively while the former and the latter frequency are not necessarily equal, i.e. $\Omega'=\omega' I$ and $\Omega''=\omega'' I$, Eqs. (9) and (10) may be simplified to coincide with the first order terms in the corresponding Eqs. (5) and (6) of the one-dimensional model,* where we set Δ^2 equal to x_0^2. The same activation energy is also obtained in both models. Consequently the one-dimensional model in this special case represents the nature of the luminescence center correctly.

Although various vibrational frequencies would actually be involved, the experimental results on the temperature dependence of spectral width can usually be represented by assuming a single frequency. This is one of the reasons why the one-dimensional treatment has been used by many workers. However, the temperature dependence of the squared spectral width in the many-dimensional model as a sum of several hyperbolic cotangent terms of different vibrational frequencies can be approximated by a single hyperbolic cotangent term of suitably chosen frequency. We would not be able to discern experimentally the vibrational frequency spread within a range of several times in magnitude by measurements of the spectral width over the usual range of temperature. Consequently, the experimental results themselves cannot be the evidence supporting the one-dimensional treatment.

In the one-dimensional C. C. analysis, the vibrational frequency is determined by the ratio of the spectral width at 0°K to the rate of broadening at high temperatures. Thus the vibrational frequency in the ground state obtained from the analysis of the absorption band width is approximately equal to the following average of the actual frequencies; we have from Eqs. (5) and (9)

$$\omega_g=\frac{2k}{\hbar}\,\frac{A_{2a}(0^\circ\mathrm{K})}{(dA_{2a}/dT)_{T=\infty}}=\frac{\Delta\Omega''^2\Omega'^{-1}\Omega''^2\Delta}{\Delta\Omega''^2\Omega'^{-2}\Omega''^2\Delta}\,. \tag{11}$$

In the same way, the vibrational frequency in the excited state obtained from the analysis of the luminescence band width is approximately

$$\omega_e=\frac{2k}{\hbar}\,\frac{A_{2f}(0^\circ\mathrm{K})}{(dA_{2f}/dT)_{T=\infty}}=\frac{\Delta\Omega'^2\Omega''^{-1}\Omega'^2\Delta}{\Delta\Omega'^2\Omega''^{-2}\Omega'^2\Delta} \tag{12}$$

from Eqs. (6) and (10). Equating the expressions of the spectral width at 0°K in the two models to each other, the following relations among various quantities are obtained. We have for the absorption band width

$$x_0^2\frac{\omega_e^4}{\omega_g^2}=\Delta\Omega''^2\Omega'^{-2}\Omega''^2\Delta \tag{13}$$

from Eqs. (5), (9) and (11) and for the luminescence band width

$$x_0^2\frac{\omega_g^4}{\omega_e^2}=\Delta\Omega'^2\Omega''^{-2}\Omega'^2\Delta \tag{14}$$

from Eqs. (6), (10) and (12). It is clear from these equations that the value of each quantity in the one-dimensional model does not generally have any direct significance to the actual situation of the luminescence center.

The many-dimensional C. C. surfaces cannot be determined since the number of unknown parameters is larger than that of the experimental data even in the two-dimensional treatment. As an example indicating the validity of the one-dimensional treatment, the following procedures are adopted. Two-dimensional C. C. surfaces are arbitrarily assumed, from which similar characteristics result to those of the luminescence center in $Ca_3(PO_4)_2$:Cu. Then, by the help of Eqs. (5), (6), (9), (10), (12) and (14), the corresponding one-dimensional C. C. curves are determined, which give the same characteristics as those of the above two-dimensional C. C. diagram, i.e., the peak positions of the absorption and luminescence bands, the luminescence band width and its temperature dependence. Comparing other characteristics, which are not used in the determination of the one-dimensional diagram, we see that the absorption band width does not differ greatly in these two models but the activation energy for the nonradiative transition in the one-dimensional model is several times larger than that in the two-dimensional model.

Therefore it depends on the particularity of a center whether or not a one-dimensional model represents the nature of the luminescence center consistently. Even if it does, the configurational coordinate involved is the fictitious one. We must be rather satisfied with it when a spectral characteristic, e.g. the width of the absorption band in our case of $Ca_3(PO_4)_2$:Cu, is predicted reasonably. However, the activation energy for the nonradiative transition, which is the height of the lowest intersection point of two paraboloidal surfaces with different origins, principal axis directions and curvatures, cannot be generally predicted by the one-dimensional model. Further, the actual situation is more complex, when the anharmonicity of the potentials and the resonance between these two states in the vicinity of the intersection point are important.

---

* In the following discussions we shall be concerned with the first order terms alone in Eqs. (5) and (6).

§ 6. Nonradiative Transitions

We have obtained the ratio of the frequency factor in the nonradiative transition probability to the radiative transition probability by the analysis of the temperature dependence of the luminescence intensity. The latter is also determined in Section 3 by the measurement of the decay constant of luminescence. From these results the former is calculated to be $5.8 \times 10^{12}\,\mathrm{sec}^{-1}$. The frequency factor is generally considered to be the same order of or smaller than the vibrational frequency depending on the situations of the two electronic states near the lowest point where they intersect in the C. C. space. It is noteworthy that the frequency factor determined above is approximately equal to the vibrational frequency in the excited state ($6 \times 10^{12}\,\mathrm{sec}^{-1}$) obtained by the one-dimensional analysis of the thermal broadening of the luminescence spectrum.

The displacement of the peak of the quantum efficiency spectrum to the low-energy side by an amount of 0.35 eV from that of the absorption band and the asymmetry of the former curve in contrast to the latter as shown in Fig. 6 are considered due to the nonradiative transition mechanism proposed by Dexter et al.[10),14)] The position, to which the optical transition occurs from the ground state, is 1.34 eV above the minimum of the excited state in Fig. 8 and the height of the potential barrier for the nonradiative transition is experimentally 0.82 eV. Therefore, the former is probably higher than the latter in the many-dimensional C. C. diagram, when corrections are made to the one-dimensional value as discussed in the preceding section. In the way to the new equilibrium in the excited state after the absorption of light, the luminescence center may find itself in the vicinity of the intersection of these two electronic states. They considered that nonradiative return to the ground state occurs at this instant with so large probability that the luminescence efficiency becomes very low. In our measurements, however, the quantum efficiency at the peak of the absorption band is slightly smaller than the maximum value. Accordingly, if our interpretation is correct, their process does not seem to occur so frequently as they thought.

Acknowledgement

The author expresses his sincere thanks to Dr. Y. Uehara for his encouragements and informations indispensable to this research and to Prof. Y. Uemura of Tokyo University for his helpful discussions. The sample was prepared by Mr. Y. Kobuke and the temperature dependence of the luminescence intensity was measured by Mr. I. Masuda. The author is also grateful for their kindness.

Electron Diffraction Study on Polish Layers of Gold, II*

By Masao KURIYAMA**

Institute of Physics, College of General Education, University of Tokyo,
Komaba, Meguro-ku, Tokyo

(Received July 5, 1958)

Polish layer of gold was examined by means of the transmission method of electron diffraction. The diffraction pattern from the highly polished layer of gold (the Beilby layer) consists of three haloes, as reported in the previous paper (J. Phys. Soc. Japan **12** (1957) 151). The radial distribution function of atoms in the layer was calculated by Fourier transformation of the observed intensity. The observed intensity was compared with those calculated from appropriate models of atomic arrangement. It was found that the Beilby layer has an amorphous arrangement in which the first and the second coordination number are about 10 and 8, respectively.

§ 1. Introduction

In the previous paper,[1)]*** we reported the structure of polish layer of gold studied by the transmission method of electron diffraction. We found at advanced stages of polishing that the breadth of the Debye rings depends upon scattering angle. We concluded that the broadening is caused by both the small grain size and the inhomogeneous strain.

Two models have been proposed for the atomic arrangement in the Beilby layer.[2)] One is that the layer is composed of minute crystallites containing probably several unit cells, and another is that the layer is in the amorphous state. Raether and his collaborator[3)] supported the former and reported that the crystallites are not distorted. According to our result mentioned above, there is a considerable amount of strain in the polish layer even at the medium stage of polishing. We can suppose, therefore, that the crystallites in the Beilby layer which is obtained at more advanced stages of polishing are severely distorted. In this paper, we shall discuss the structure of the Beilby layer in detail.

The diffraction pattern from the Beilby layer obtained by the transmission method consists of three haloes: outer two have been observed by various authors[2)] and the first inner halo with the Bragg spacing 4.1Å have first been reported by Nonaka and Kohra.[4)] The Bragg spacing of the inner halo is nearly equal to (100) spacing of crystalline gold. So this inner halo may be explained by the non-vanishing structure factor violating the extinction rule for (100) reflection because of small grain size. Raether[5)] showed how subsidiary maxima of Laue's diffraction function became prominent when crystal size became very small. Boersch[6)] calculated the intensity for parallelepiped crystallites with the face centered cubic arrangement including 14 and 23 atoms. We also calculated the intensity for an octahedral crystallite, which was composed of a central atom surrounded by twelve nearest neighbours and six next nearest neighbours of the f.c.c. arrangement. However, the intensities of the first inner halo for these three models were too small to explain the observed intensity. Accordingly, the direct determination of the structure is desirable. We adopted in the present experiment the the radial distribution analysis.

Contaminations cannot be entirely eliminated even if the transmission method is adopted. Cochrane[7)] observed in his transmission pattern a sharp faint ring with the Bragg spacing 3.1Å and attributed it to some foreign substance on the film. Our first halo is neither sharp nor faint but diffuse and strong as much as the outer two haloes. The effect of contamination is, however, carefully studied in the present experiment and it is confirmed that the first inner halo is caused by polished gold, as will be described in § 5.

§ 2. Experimental

The experimental procedures of preparing thin polished films of gold and obtaining the electron diffraction pattern were described in (I)***. Gold films electro-plated on copper or zinc were polished by chamois leather. The polished face was washed in benzene and then examined by the reflection method. After confirming the halo pattern, the polished film was removed from the substrate, rinsed in distilled water and then examined by the transmission method of electron diffraction. About ten specimens thus prepared produced the halo pattern characteristic of the Beilby layer. For three of the specimens prepared on Cu substrates, the intensity distribution of the pattern was measured in the following manner.

Five diffraction photographs were taken successively from each specimen with different exposures, and photographic density was measured by micro-photometry. For each pair or successive photographs, the density on a plate was plotted against the density at the corresponding position of another. The curve thus obtained was linear in the range of low density. With the repetition of this procedure for successive pairs, density on each plate was expressed in terms of the density on the plate with the shortest exposure time. The latter density is proportional to the intensity at any point except in the vicinity of the incident spot.[8]

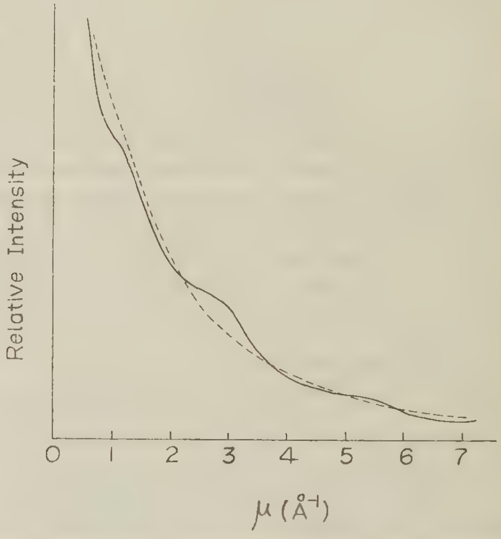

Fig. 1. Intensity distribution curve (solid curve) and background scattering curve (broken curve).

The average intensity distribution determined from three independent series of such photographs is shown in Fig. 1. The Bragg spacings corresponding to each halo are listed in Table I of (I).

§ 3. Radial Distribution Function

The radial distribution function $4\pi r^2\rho(r)$ is obtained by the following formulae:

$$4\pi r^2\rho(r)=4\pi r^2\rho_0+\frac{2r}{\pi}\int_0^\infty \mu i(\mu)\sin\mu r d\mu\ , \quad (1)$$

$$\mu=4\pi\sin\frac{\phi}{2}\Big/\lambda\ ,$$

$$i(\mu)=I_{ia}/NE^2(\mu)$$

$$E(\mu)=\frac{8\pi^2me^2}{h^2}\ \frac{Z-F(\mu)}{\mu^2} \quad (2)$$

Here ρ_0 is the mean density of atoms; ϕ, the scattering angle; λ, the wave length of electrons; I_{ia}, the *interatomic* scattering given below; N, the number of atoms; Z, the atomic number and $F(\mu)$, the atomic scattering factor for X-rays. The observed intensity consists of the interatomic scattering and the background scattering,

$$I_{obs}=CI_{ia}+I_{bac}\,, \tag{3}$$

where C is a constant factor to be determined later, and I_{bac} is given by

$$I_{bac}=CNE^2(\mu)+x(\mu)+y(\mu)\,. \tag{4}$$

Here NE^2 is the atomic scattering: $x(\mu)$, the atomic inelastic scattering; $y(\mu)$, the multiple and instrumental scattering.

In the study of gas molecules[8], we can replace NE^2 in the denominator in (2) by I_{bac}, because $y(\mu)$ is negligible and $x(\mu)$ is almost similar to NE^2. So, we can put

$$i_{gas}(\mu)=(I_{obs}-I_{bac})/I_{bac}\,. \tag{5}$$

In the case of solid materials, however, this approximation can hardly be applicable, since $y(\mu)$ is not negligible and we must use

$$i(\mu)=(I_{obs}-I_{bac})/CNE^2\,. \tag{6}$$

The background scattering was separated from the observed intensity by the trial and error method first used by M. Takagi[9] in the study of liquid bismuth; trial background curves are improved by imposing the condition that the atomic distribution function should be zero for the values of r smaller than the atomic diameter d. From (1) this condition is expressed as

$$u(r)\equiv\int_0^\infty [C\mu i(\mu)]\sin\mu r\,d\mu\sim-2\pi^2Cr\rho_0 \qquad \text{for } r<d. \tag{7}$$

Fig. 2 shows $\mu i(\mu)$ curve obtained by the improved background curve.

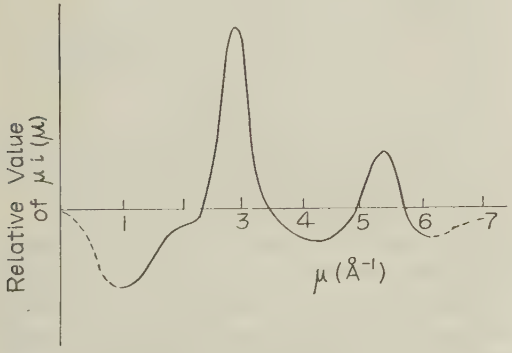

Fig. 2. $\mu i(\mu)$ curve obtained from the improved background curve.

For large values of μ, $\mu i(\mu)$ computed from the experimental value of $i(\mu)$ has large relative error. So, the values of $\mu i(\mu)$ beyond its fourth zero point, μ_0, was approximated by an analytic function $(\mu-\mu_0)I_0\exp\{-k^2(\mu-\mu_0)^2\}$. The constants I_0 and k are determined by taking into account the continuity relation of the function and its first derivative at the third minimum point (Fig.2). In the present experiment μ_0 is equal to 5.7Å^{-1}. This substitution does not cause a serious error in a few inner peaks of the radial distribution function and also this may exclude the effect caused by terminating $\mu i(\mu)$ abruptly.

In the range of small r, $u(r)$ must be proportional to the theoretical value $-2\pi^2r\rho_0$, as in (7). Assuming ρ_0 to be equal to the atomic density of the normal gold, the proportionality factor C is determined from the slope of the curve $u(r)$. The radial distribution curve can thus be obtained from (1). Fig. 3 shows the radial distribution curve.

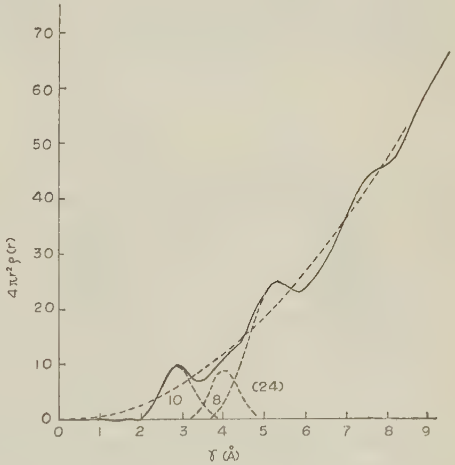

Fig. 3. Radial distribution function. Figures under each peak indicates the number of neighbours. The third coordination number is a estimated value.

The radial distribution curve can be divided into a few peaks, assuming a symmetrical profile for each peak (Fig. 3). Figures inscribed in Fig. 3 indicate the numbers of atoms under the peaks. The position of peaks and the number of atoms under each peak are summarized in Table I. It is noted that 1) the number of the first nearest neighbour is 10 and that of the second neighbour is 8, respectively, as compared with the values 12 and 6, respectively, of the face-centered arrangement, and 2) the radial distribution curve approaches the curve obtained from the random arrangement, with increase in r, as rapidly as in liquid.

§ 4. Intensity Distribution Calculated from Amorphous Models

The above mentioned result that the numbers of the first and second nearest neighbours in the Beilby layer are considerably different from those in the face-centered cubic arrangement is an important result of the radial distribution analysis. We now examine this point by a different method, *i.e.* by comparing the observed intensity with that calculated from appropriate models of atomic arrangement. If the intensity curves obtained from two models, one with the coordination numbers of normal gold and another with those obtained above, lie within the range of experimental errors, the above result may be spurious. If, on the contrary, two calculated intensity curves are distinctly different, we can decide which of the models represents the true atomic arrangement.

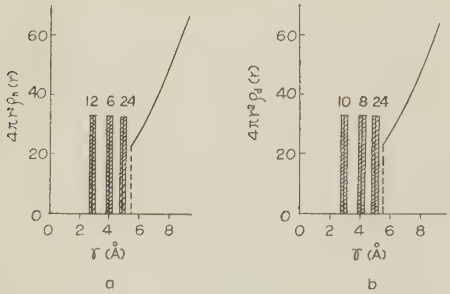

Fig. 4a and 4b. Schematic examples of the average radial distribution around an atom. *a* and *b* correspond to Model I and II, respectively, with $R=5.57$ Å.

It is assumed, for simplicity, that the atomic arrangement in the Beilby layer can be represented by the average radial distributions which are schematically shown in Fig. 4a and 4b. Within a sphere of radius R, atoms are situated on spherical shells with radii equal to the atomic distances in the perfect crystal, and in the range $r>R$, atoms are randomly distributed with the mean density ρ_0. The value of R is determined by the relation that the number of atoms in the sphere is equal to the mean density ρ_0 multiplied by the volume of the sphere. The number of atoms on each shell and the value of R are listed in Table II, for four models empolyed. The size effect corresponding to the extremly small size will be excluded by taking into account the average density of atoms for $r>R$.

Table II. The numbers of coordination in the amorphous models.

	Model I		Model II	
	a	b	a	b
No. of coordination 1st	12	12	10	10
No. of coordination 2nd	6	6	8	8
No. of coordination 3rd	24	—	24	—
No. of atoms within the sphere of radius R	43	19	43	19
Value of R (Å)	5.57	4.25	5.57	4.25

The intensity is calculated by the following formula:

$$I(\mu)=NE^2(\mu)\left\{1+\sum N_k\frac{\sin\mu r_k}{\mu r_k}-\frac{4\pi\rho_0}{\mu^3}(\sin\mu R-\mu R\cos\mu R)\right\},\quad (8)$$

where N_k is the number of atoms on the spherical shell of radius r_k. Fig. 5 shows the *interatomic* scattering curves for the above mentioned models. The first inner halo is not found in the curves for Model I a and b. Model II b shows the first inner halo resembling to the observed one. As R increases, the first inner halo becomes more intense, but other haloes split into crystalline reflection (Model I a). In the present calculation, the variation of the atomic distance is not taken into account. In the real substance, the displacement of atoms may alter not only

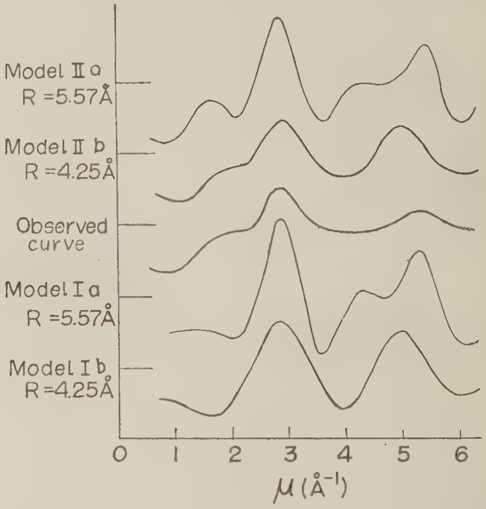

Fig. 5. Curves of $i(\mu)$ calculated by models and the observed curve of $i(\mu)$. $i(\mu)$ is derived from (8) by the relation; $i(\mu)=I(\mu)-NE^2(\mu)/NE^2(\mu)$.

the number of atoms on spherical shells, but also broaden the thickness of the shell. If the thickness of shells is taken into account in the model, the *interatomic* scattering curve for Model II will have more simillar appearance of the observed one. Thus, the coordination numbers obtained in § 3 is found to be reliable.

§ 5. Discussions

The effect of contaminations

The result given in §§ 3 and 4 concerning the numbers of coordination is mainly due to the exsistence of the first inner halo. So, the effect of contamination which might produce the observed first halo was examined carefully, and it was concluded that the present first halo was given by the polished film from the following reasons.

1) The diffraction pattern from debrises of chamois leather was intentionally obtained by the transmission method. The pattern obtained consists of two faint outer haloes and an intense diffuse one which resembles the present first halo. Careful examinations show, however, that the Bragg spacing of the intense halo differs from that of the present first halo by about 15%, and moreover, that the intensity profiles of the haloes are different from each other.

2) If the first inner halo was due to debrises of leather or other contaminations, it would appear also in the ring pattern obtained at medium stages of polishing. However, we have never observed the first inner halo superimposed on the ring pattern, though a *faint sharp* ring sometimes appeared in the ring pattern. This *faint sharp* ring, probably due to some contaminations, was entirely different from the present first halo.

3) All specimens yield the sharp ring pattern of gold, after annealing at various temperatures.

4) Oils contaminated on the surface might also be the origin of the first halo. However, the Bragg spacing of the present haloes did not coinside with those of oils.[10]

The effect of substrate

Atoms of the substrate metal may diffuse into gold film during polishing. However, if the solid solution of gold and copper gave the halo pattern obtained in the present experiment, we could have observed the pattern from copper or copper alloy after heat treatment. The same halo pattern was also obtained from the polished layer on zinc substrate. So, it is concluded that the halo pattern is not dependent on substrates.

Comparison with the results of liquid gold

Hendus[11] reported in the X-ray diffraction study of liquid gold at 1100°C that the nearest neighbour distance was 2.86 Å and the first coordination number was eleven. This result resembles the result of the present experiment. The intensity distribution, however, differs from the present result, especially in that the first halo was not observed. Suzuki[12] observed the first halo in the electron diffraction pattern from super-cooled liquid gold. The atomic arrangement may rather resemble that in the super-cooled liquid gold than that in liquid gold.

§ 6. Conclusions

The diffraction pattern from the Beilby layer of gold which is obtained at the highly advanced stage of polishing consists of three haloes. The intensity distribution of this halo pattern cannot be explained by the small size of crystallites. The radial distribution function obtained from the observed intensity distribution has a similar feature to that for liquid metals. However, the number of the first and second coordinations are about 10 and 8, respectively, while 12 and 6 for the f.c.c. arrangement.

It is, therefore, concluded that the Beily layer is in an *amorphous* state rather than the *micro-crystalline* state. The result given in (I) shows that the polish layer obtained at medium stages of polishing is composed of small crystallites with large amount of strain. So, the layer obtained at highly advanced stages may be composed of extremely minute crystallite with severe distortion, if the *micro-crystalline* view is preserved. An aggregate of such crystallites, however, cannot be discriminated from an amorphous state. Therefore, the result in (I) supports the present conclusion.

It is, moreover, noted that the Beilby layer, of the thin foil, easily recrystallizes at room temperature as well as at elevated temperatures. The amorphous state is found to be unstable, particularly when the Beily layer is removed from substrates.

The present auther wishes to express his sincere thanks to Prof. S. Takagi for his kind advice and encouragement throughout this work, and to Prof. K. Kohra for his continued interest and discussion. His thanks are also due to Prof. Y. Morino for allowing him to use punched cards and to Dr. K. Kuchitsu for his advice and his work in computation of Fourier integrals. This work was partly supported by a research grant of the Ministry of Education.

Nuclear Magnetic Double Resonance Experiment on Two Proton System

By Junkichi ITOH and Riichiro KUSAKA

Department of Physics, Faculty of Science, Osaka University

(Received July 7, 1958)

Nuclear magnetic double resonance studies were done on two proton system in $K_2HgCl_4 \cdot H_2O$ single crystal. Applying a strong r.f. field with the frequency nearly equal to that of one line in the doublet of two proton resonance, the line shape of the other line of the doublet was measured for various values of the intensity and frequency of the strong r.f. field. Generally, the observed line shape shows further doublet structure, and the separation and relative intensities of this doublet depend upon the intensity and frequency of the strong r.f. field. Some calculations were made for the line structure of two proton system under the influence of a strong r.f. field. The experimental results agree qualitatively with the calculation, but there exist some descrepancies in the absolute magnitudes of the splitting of the induced doublet.

§ 1. Introduction

In recent years, double nuclear magnetic resonance has called much attentions, and several works have been done both theoretically and experimentally[1)-8)]. Generally, the magnetic resonance intensity, line shape and also spin-lattice relaxation time for one species of spins will change when another r.f. field having the resonance frequency of other species is applied.

In a two proton system, the characteristic feature lies in the fact that the resonance line shows doublet structure, split by the dipolar interaction between two protons, and a r.f. field with a frequency nearly equal to the resonance frequency of one line of the doublet will have several interesting effects on the other line. Bloembergen[9)] treated the problem theoretically, but no experiment has been done.

We made extensive investigations on two

proton system with single crystals of $K_2HgCl_4 \cdot H_2O$. In this report, we shall describe the results of the double resonance experiments using strong r.f. field. The results of our works concerning temperature dependence of the spin-lattice relaxation time and doublet separation, nuclear Overhauser effect, and also their correlation with the motions of the water molecules will be reported in near future.

The resonance figure of one of the doublet in a two proton system changed appreciably when another strong r.f. field having a frequency close to the other line of the doublet was applied. This occurs by the mixing of the Zeeman levels induced by this r.f. field. In the case of a single spin system, Bloch²⁾ showed that, by a strong r.f. field, single resonance line will split into doublet, whose separation and relative intensities depend upon the frequency difference between Zeeman frequency and the frequency of the applied strong r.f. field, and also upon the intensity of the r.f. field. Bloch also treated more general cases of multiple spin system with exchange coupling among them.

However, since the problem concerning two proton system is of a special one, we made some calculation, which will be shown in § 2. In § 3, the experimental results of the double resonance studies will be presented together with comparison with the calculation.

§ 2. Theoretical Calculation

The Hamiltonian of an isolated two proton system, mutually interacting by magnetic dipolar interaction, under a strong static field, H_0, and a r.f. field, $2H_1 \cos \omega t$, which is perpendicular to the static field, is given by

$$\begin{aligned}\mathscr{H} = &-(\mu/I)H_0(I_{1z}+I_{2z})\\ &-(\mu/I)\cdot 2H_1 \cos \omega t \cdot (I_{1x}+I_{2x})\\ &+(\mu/I)^2[(\boldsymbol{I}_1\cdot\boldsymbol{I}_2)r^{-3}-3(\boldsymbol{I}_1\cdot\boldsymbol{r})(\boldsymbol{I}_2\cdot\boldsymbol{r})r^{-5}] \qquad (1)\end{aligned}$$

where the direction of the static field is taken as the z-axis, that of the r.f. field as the x-axis, $\boldsymbol{r}$ is the interproton vector, $\boldsymbol{I}_1$ and $\boldsymbol{I}_2$ are the spin vectors of the proton 1 and 2, respectively, and μ and I are the magnetic moment and spin of the proton.

The r.f. field $2H_1 \cos \omega t$ can be devided into two circularly rotating field about the z-axis with frequencies ω and $-\omega$, and one of them with the frequency $-\omega$ alone can have perturbing effect on the magnetic resonance line. Hence we can discard the rotating field with the frequency ω which has little effect on the resonance line. We now transform the coordinate system (x, y, z) to (ξ, η, ζ), the latter being rotating about the z-axis with angular frequency $-\omega$. The ζ-axis is taken so as to coincide with the z-axis, and the ξ-axis is taken to have a phase to coincide with the rotating r.f. field. Then the Hamiltonian is transformed to the following form:

$$\begin{aligned}\mathscr{H}_r = &-(\mu/I)(I_{1\zeta}+I_{2\zeta})(H_0-\omega/\gamma)\\ &-(\mu/I)(I_{1\xi}+I_{2\xi})H_1+(\mu/I)^2(\tfrac{3}{2}\cos^2\theta-\tfrac{1}{2})r^{-3}\\ &\times(\boldsymbol{I}_1\cdot\boldsymbol{I}_2-3I_{1\zeta}\cdot I_{2\zeta})+(\text{time dependent}). \qquad (2)\end{aligned}$$

In this Hamiltonian, (time dependent) represents terms which depend upon time, and can be neglected in the following calculation as Redfield discussed already¹⁰⁾. γ is the gyromagnetic ratio of proton, and θ is the angle between the static field and the $p-p$ direction.

Then, the Hamiltonian (2) is time independent one, and the eigen-values and the corresponding eigen-functions can be obtained by solving the wave equation

$$i\hbar(\partial\phi/\partial t) = \mathscr{H}_r\phi\,. \qquad (3)$$

Now, with the Hamiltonian (2), one can show easily that two spins from one singlet and one triplet states, which are mutually independent and no transition can be realized between them. Therefore the singlet state has no contribution to the magnetic resonance phenomena as far as we deal with an isolated two proton system and it is suffice to solve triplet levels alone. The zero order spin functions of three levels of the triplet are $\phi_1=\alpha(1)\alpha(2)$, $\phi_0 = 1/\sqrt{2}\,[\alpha(1)\beta(2)+\beta(1)\alpha(2)]$, and $\phi_{-1}=\beta(1)\beta(2)$, respectively, where α and β represent the states having the ζ-component of the spin of 1/2 and $-1/2$, respectively. The secular equation with respect to this representation is given by

$$\begin{vmatrix} -Z-D-W & -\sqrt{2}R & 0 \\ -\sqrt{2}R & 2D-W & -\sqrt{2}R \\ 0 & -\sqrt{2}R & Z-D-W \end{vmatrix} = 0 \qquad (4)$$

where, W is the eigen-value of the energy, and, for simplicity, we denote that

$$\left.\begin{aligned} Z&=(\mu/I)(H_0-\omega/\gamma)\,,\\ D&=(1/4)(\mu/I)^2(3\cos^2\theta-1)r^{-3}\,,\\ R&=(\mu/I)\cdot H_1/2\,. \end{aligned}\right\} \qquad (5)$$

Further, if we denote $Z/D=A$, $R/D=B$, and $W/D=X$, the secular equation is transformed into

$$(X+A+1)(X-2)(X-A+1)=4B^2(X+1)\,. \tag{6}$$

Though D depends upon the orientation of the static field with respect to the proton-proton direction, equation (6) does not explicitly include this angle and is useful for the general discussions of the problem.

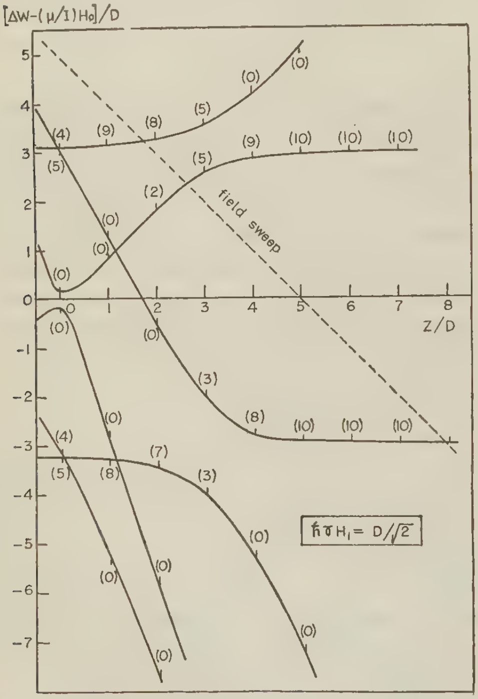

Fig. 1. Theoretical resonance energies, ΔW, of two proton system measured from the Zeeman energy of proton under a strong static and a r.f. magnetic fields, as a function of the difference between the energy of photons of the applied r.f. field and the Zeeman energy of proton, both in the unit of D (one-sixth of the doublet separation of two proton resonance). In the case shown in the figure, the intensity of the applied field, H_1, is equal to $D/\hbar\gamma\sqrt{2}$. Relative intensities are shown in the brackets.

Equation (6) cannot be solved analytically, and to get numerical values of the eigen-values, (6) must be solved numerically for given values of A and B.

Corresponding to the three eigen-values of the energy, E_a, E_b, E_c, the eigen-functions can be expressed by linear combinations of three spin functions ϕ_1, ϕ_0, and ϕ_{-1}. The time dependent Schrödinger wave functions are given by

$$\left.\begin{aligned}\phi_a&=(a_1\phi_1+a_0\phi_0+a_{-1}\phi_{-1})\exp(i\Delta\omega_a t)\,,\\ \phi_b&=(b_1\phi_1+b_0\phi_0+b_{-1}\phi_{-1})\exp(i\Delta\omega_b t)\,,\\ \phi_c&=(c_1\phi_1+c_0\phi_0+c_{-1}\phi_{-1})\exp(i\Delta\omega_c t)\,,\end{aligned}\right\}\tag{7}$$

where a_i, b_i, and c_i $(i=1, 2, 3)$ are normalized weights of the states 1, 0 and -1 for three eigen-states, respectively, and $\Delta\omega_j$ stands for $-E_j/\hbar$ $(j=a, b, c)$.

If we return to the original (x, y, z) system (laboratory coordinate system), ϕ_a, ϕ_b and ϕ_c are transformed into ψ_a, ψ_b and ψ_c, given by following equations:

$$\begin{aligned}\psi_a=a_1\phi_1\exp[i(\omega+\Delta\omega_a)t]+a_0\phi_0\exp[i\Delta\omega_a t]\\ +a_{-1}\phi_{-1}\exp[i(-\omega+\Delta\omega_a)t]\end{aligned} \qquad (8$$

and similar two equations.

When one more r.f. field is applied in the direction perpendicular both to H_0 and H_1, that is in the y-direction, transitions between these levels will occur. Let this r.f. field be $2H_2\cos\omega' t$. Then, since this field is harmonic in time, absorption will occur only when the exponential time factor of $\psi_i{}^*\psi_j$ $(i, j=a, b, c)$ is compensated by $\exp(\pm i\omega' t)$ of the applied field, and the intensity of the absorption is proportional to the square of the matrix element of I_y with respect to the initial and final states. Thus the resonance frequencies and relative intensities are given by

$$\left.\begin{array}{ll}\textit{resonance frequency} & \textit{relative intensity}\\ \omega+(\Delta\omega_a-\Delta\omega_b) & |a_1{}^*b_0+a_0{}^*b_{-1}|^2\\ \omega-(\Delta\omega_a-\Delta\omega_b) & |a_0{}^*b_1+a_{-1}{}^*b_0|^2\\ \omega+(\Delta\omega_a-\Delta\omega_c) & |a_{1*}c_0+a_0{}^*c_{-1}|^2\\ \omega-(\Delta\omega_a-\Delta\omega_c) & |a_0{}^*c_1+a_{-1}{}^*c_0|^2\\ \omega+(\Delta\omega_b-\Delta\omega_c) & |b_1{}^*c_0+b_0{}^*c_{-1}|^2\\ \omega-(\Delta\omega_b-\Delta\omega_c) & |b_0{}^*c_1+b_{-1}{}^*c_0|^2\end{array}\right\}\tag{9}$$

We solved the wave equation for several values of A and B. Fig. 1 shows calculated deviation of transition energies from Zeeman value as a function of A for the case $B=1/2\sqrt{2}$, or $\hbar\gamma H_1=D/\sqrt{2}$. Figures shown in the bracket are the relative intensities, the intensity of one of the doublet line in the case $H_1=0$ being taken as 10. As will be seen from this figure, doublet lines when $H_1=0$ split into six lines in general when $H_1\neq 0$. However, when H_1 is not very large, several lines have vanishing intensities, and when the frequency of the perturbing r.f. field is close to the resonance frequency of one of the doublet lines, the general feature of the resonance is as if each of the original doublet lines split into further doublets. Separation of these doublets and their relative intensities depend upon the values of Z and R. When R is small, the separation is also small, and the intensity of one of the doublet lines disappears when Z becomes large.

The above calculation is based upon the assumption that a two proton system is isolated from other nuclei, which is not the actual case. But general feature of the double resonance effect on two proton system in real crystal will be well represented by this simplified treatment. In next section, the calculation will be compared with the experimental results.

§ 3. Experimental Results and Discussions

a) *Experimental apparatus and procedure*

The detection of nuclear magnetic resonance was done by Pound-Watkins device. The detector coil was of usual solenoid type, while one more coil system, which was of Helmholtz coil type, was inserted so as to produce a perturbing r.f. field ($2H_1 \cos \omega t$) in the direction perpendicular both to the static and detecting fields. These Helmholtz coils were excited by a 807 oscillator and overall coil voltage amounted upto about 300 volt. But, because the gap of two coils was rather large, which was necessary to put the detector coil into this gap, H_1 amounted only about 2.8 gauss at its maximum.

The sample used was a single crystal of $K_2HgCl_4 \cdot H_2O$. Two proton character of water molecules in this crystal has been already investigated by us[11]. The separation of the doublet amounted about 86 kc/sec at its maximum, when the direction of the static field was parallel to $p-p$ direction within a water molecule. The width of each of the doublet lines originates mainly from magnetic dipolar interaction between protons, each belonging to the neighboring water molecules.

Though the detecting coil and Helmholtz coils were nearly perpendicular to each other, and moreover the relative orientation of the coils was adjusted to minimize stray field in the detector coil, pick-up of the perturbing r.f. field in the detector coil was considerably large, because the frequency difference between two r.f. frequencies was always less than 100 kc/sec. Therefore, in the out-put signal of the detector, there existed considerable amount of beat between two r.f. frequencies. Using a resonance amplifier tuned to the frequency of the static field modulation and a phase-sensitive detector, this could be almost eliminated. But when the intensity of the perturbing r.f. field was increased as large as 300 volts, the effect of the stray in the detecting system became so large that the nuclear magnetic resonance signal became unstable. So, the experiment was done upto the coil voltage of about 260 volts. It was preferable to keep the detecting r.f. field, H_2, as low as possible to avoid saturation effect. However, since the disturbing effect to the stray field increased as H_2 decreased, we could not use very low value of H_2 and the experiments were done with the value of H_2 by which the resonance signal saturated by a small amount. With this H_2 and when $H_1=0$, the signal intensity was about 75% of that in perfectly unsaturated condition. However, this may not affect the line structure appreciably.

It is preferable to sweep the frequency of the detector over the resonance range, fixing the static field and the frequency of the perturbing field. But, as the pick-up voltage changed violently with the change in the frequency difference between two r.f. systems, it was impossible to do the experiment with this procedure. Therefore, fixing the frequencies of the two r.f. fields, the static field was swept over the range of the expected resonances. In this case, the observed resonance figures correspond to those expected when A and B defined in § 2 are varied simultaneously with the value of the static field, or, the expected resonance fields are given by the intersections of a line which inclines $-45°$ with the ordinate axis with the curves given in Fig. 1. An example of this line was shown in Fig. 1. The A coordinate of the intersection of this line with the A-axis, transformed to the frequency scale, corresponds to the frequency difference between the two r.f. fields. In the example shown in Fig. 1, the frequency difference between the two fields is $5D/h$, and the reasonance figure consists of one singlet and one doublet. In the latter case, the frequency of the perturbing field is very close to that of the other line of two proton doublet and the perturbation of the energy levels occurs, while in the case of the singlet, the frequency of the perturbing field is very much apart from the two proton lines and no effect is expected.

A single crystal of $K_2HgCl_4 \cdot H_2O$ which was cut in the *c*-plane was used, and the experiments were done with the static field in the direction of interamolecular proton-proton line in one case, and in the direction of the *a*-axis in the other case. In the former case, the the separation of the doublet is about 86 Kc/sec, while in the latter case, about 65 Kc/sec. There exist two types of water molecules in the unit cell, having different orientations with respect to the crystal axes. In the case of the static field along each one of the crystallographic axis, proton-proton directions of these two types of water molecules make equal angles with the static field. Therefore, the resonance intensity is doubled in these cases and the measurements can be done more accurately than in other cases.

b) *Experimental results and discussions*

Fig. 2 shows the results of the measurements of derivatives of the absorption curves in the case of the static field in the direction of the *a*-axis. As shown in § 2, one line of the two proton doublet is not disturbed by the perturbing field; hence in this figure we only show the other line which is affected by the perturbing field. The top curve shows the resonance figure for the $H_1=0$. The lower curves correspond to the resonance curves when $H_1=1.7$ gauss. Here, the magnetic field was swept slowly over the region of the resonance, keeping both frequencies of two r.f. fields constant. $\Delta\nu$, the difference in frequency between the perturbing and detecting fields was taken as a parameter, and was shown in each curve. When $\Delta\nu$ was equal to the separation of the two proton doublet, the perturbing r.f. frequency just coincided with one line of the doublet at the static field strength which brought the detecting frequency to coincide with the other line, and then two lines with nearly equal intensities were seen in both sides of the original position of the two proton line. As $\Delta\nu$ was increased from the frequency difference of the two proton doublet, one line came closer to the original position with increasing intensity, while the other line displaced further from the original position with decreasing intensity.

By analysing each of the curves in Fig. 2 into two lines, the exact positions of these two lines were determined. To compare with the calculated values, the displacement of the resonance positions from the original one was plotted against $\Delta\nu-\Delta\nu_0$, where $\Delta\nu_0$ is the doublet separation of the two proton line, both in the unit of D (which is equal to $\nu_0/6$ in frequency scale). When the oscillation intensity of the perturbing coil was increased over 100 volts in terminal voltage, the tem-

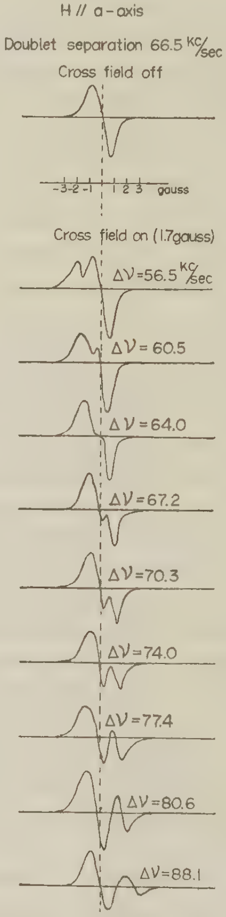

Fig. 2. Line shapes of one of the doublet lines in two proton system when a r.f. field with the frequency close to that of the other line of the doublet is applied. $\Delta\nu$ is the frequency difference of the detecting and perturbing fields. The direction of the static field is parallel to the *a*-axis.

perature of the Helmholtz coil rised and soon the temperature of the sample also rised considerably. Since the two proton doublet separation slightly decreases when the temperature rised, the value $\varDelta\nu_0$ and D in the above discussions should correspond to those at the equilibrium temperature, somewhat higher than room temperature. We estimated the temperature of the crystal and the plots in Fig. 3 were drawn with the corrected values of $\varDelta\nu_0$ and D. Though this correction was negligible for D, it had some effect on $\varDelta\nu-\varDelta\nu_0$, as this value was alway less than about 1/6 of $\varDelta\nu_0$ itself. To avoid this slight ambiguity, we plotted the separation of two lines in Fig. 4, which was scarcely affected by small possible error in determining the value of $\varDelta\nu_0$. Both in Figs. 3 and 4, two typical examples of the calculated curves were also shown. General tendency of the experimental plots is quite well represented by the calculation, but the experimental line-displacement or separation is somewhat smaller than the calculated one. This may be due to errors in the evaluation of the values of H_1, the uncertainty in the analyses of curves shown in Fig. 2, the effects on the transition mataices coming from the finite line width, and/or the change in the line shape by the perturbing field.

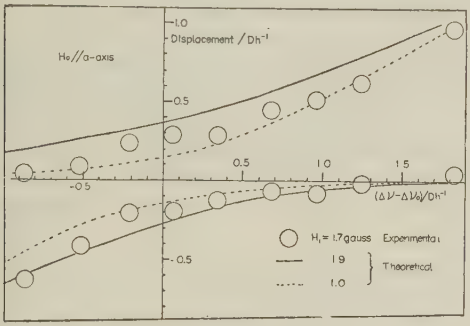

Fig. 3. Displacement of the resonance frequencies from the unperturbed frequency of one of the doublet lines, when a perturbing r.f. field is applied, as a function of the difference in frequency between the perturbing field and the other line of the doublet, both in the unit of $D/\hbar$. In this case the direction of the static field is parallel to the a-axis. Circles: the experimental values, solid and dotted curves: the calculated curves for different values of H_1.

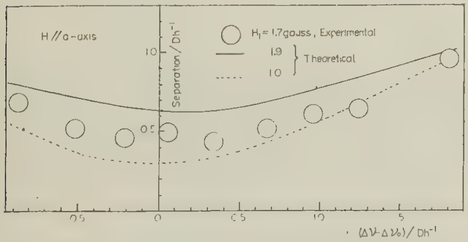

Fig. 4. Separation of two lines shown in Fig. 3, as a function of the difference in frequencies of the perturbing field and one of the doublet lines, both in the unit of $D/\hbar$. In this case, the static field is parallel to the a-axis. Circles: the experimental values, solid and dotted curves: the calculated curves for two different values of H_1.

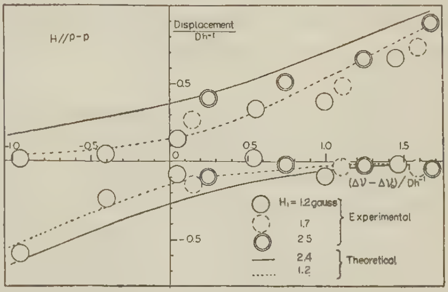

Fig. 5. Displacement of the resonance frequencies from the unperturbed frequency of one of the doublet lines, similar to Fig. 3, in the case where the static field is parallel to p-p direction.

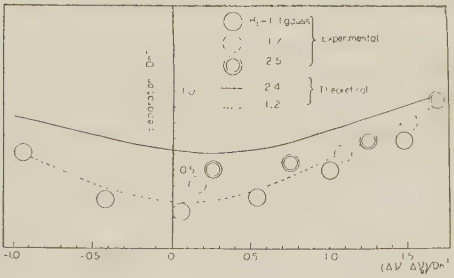

Fig. 6. Separation of two lines shown in Fig. 5.

In the case when the static field is in the direction of $p-p$ line, we made the experiments with three values of H_1, from 1.1 gauss to 2.5 gauss. The results of the experiments were shown in Figs. 5 and 6. Fig. 5 shows positions of the resonance fields, and Fig. 6 shows the separation of two lines. It can be seen from these figures that the separations or displacements increase with increasing H_1. In both figures the calculated curves for $H_1=1.2$ and 2.4 gauss were shown. Again the general tendency of the experimental plots is quite in agreement with the calculation, but a slight disagreement in the absolute values is recognized, as in the case of the static field in the direction of the *a*-axis.

As for relative intensities of the separated lines, quantitative comparison with the calculation seems to be difficult, because the line shape and the population difference of the levels in concern are difficult to be calculated, and also the analyses of the measured resonance curves cannot be carried out without ambiguity. However, general tendency of the calculation is well demonstrated by the experiments.

It seems more difficult to evaluate the line shape or width. The width of the resonance lines under strong r.f. perturbing field will be narrowed by the narrowing effect due to the perturbing field on the dipolar interaction from the neighboring water molecules having the same $p-p$ orientation, and at the same time the width will be broadened by the short life time of each Zeeman level due to the induced transitions by the perturbing field. The situation seems quite complicated and more detailed consideration will be needed for further discussions of the problem.

The authors would like to express their thanks to Professor K. Tomita for his valuable discussions.

The Electronic Structure of the Protonated Methane CH_5^+

By Masatoshi YAMAZAKI

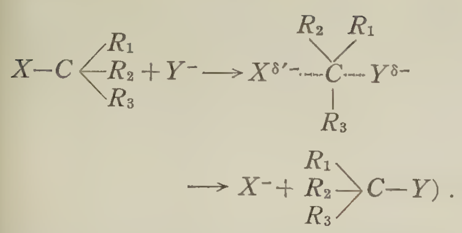
Department of Physics, Faculty of Science, Kanazawa University, Kanazawa, Japan

(Received November 12, 1958)

The electronic structure of the ground state of the protonated methane CH_5^+ is studied by the Heitler-London-Slater-Pauling method extended by Voge and by Kotani and Siga. The wave functions are constructed without the assumption of the electron pair bond and with taking $(2s)^2(2p)^2$, $(2s)(2p)^3$, and $(2p)^4$ configurations of the carbon atom into account. Assuming a probable model for this ion, we obtain seventeen $^1A_1'$ states. The energy matrix for these states is computed by means of the representation matrices of the symmetric group. By solving the secular equations thus obtained for two different sets of parameters, the binding energy (or the proton affinity) and the equilibrium proton-carbon distance are estimated.

§1. Introduction

The stable protonated methane CH_5^+ has been found by mass spectrometer and by other means[1]. This ion shows the simplest prototype of the intermediate transient state for the substitution reaction of the methyl compounds, (in general



$$X-C\begin{smallmatrix}R_1\\R_2\\R_3\end{smallmatrix}+Y^-\longrightarrow X^{\delta'-}\cdots\overset{R_2\ \ R_1}{\underset{R_3}{C}}\cdots Y^{\delta-}\longrightarrow X^-+\begin{smallmatrix}R_1\\R_2\\R_3\end{smallmatrix}C-Y)\,.$$

The methane molecule is a saturated hydrocarbon, and CH_5^+ ion is an interesting example of the electron deficient compounds. The geometrical structure of this cation has not been established, but those for diborane and H_3 suggest the possibility of three hydrogen atoms and a carbon atom being coplanar, the remaining two hydrogen atoms being situated on the equivalent sites before and behind this plane, and the latter two hydrogen atoms making the so-called three-center bond with the carbon atom and sharing with the positive charge of the ion*. Little is known experimentally about this ion, so a detailed theoretical study of it would be of some interest.

In this paper we assume the symmetry group D_{3h} for this ion, and calculate the energy of the ion as the function of the carbon-proton distance by means of the atomic orbital method. If we wish to know the potential energy curve for the nuclear distance larger than the equilibrium value, internal energies of atoms become more and more important. These intratomic energies are not duly taken into account by the usual electron pair bond approximation. So we follow the general method similar to Voge[2) and Kotani and Siga[3) for the methane molecule, and Itoh, Ohno, and Kotani[4) for the methyl radical. Moreover in this general method, there is no need to worry about the choice of hybridized orbitals of the carbon atom, since the result by this method is invariant against any unitary transformation of the carbon orbitals.

§ 2. Construction of Wave Functions

A rectangular coordinate system is taken in such a way that the carbon nucleus C and the five hydrogen nuclei H_a, H_b, H_c, H_d, H_e have coordinates $(0, 0, 0)$, $(R, 0, 0)$, $(-\frac{1}{2}R, \frac{1}{2}\sqrt{3}R, 0)$, $(-\frac{1}{2}R, -\frac{1}{2}\sqrt{3}R, 0)$, $(0, 0, \overline{R})$, $(0, 0, -\overline{R})$, respectively (See Fig. 1.). We call H_a, H_b, and H_c the covalent hydrogen atom, and H_d, H_e the ionic hydrogen atom, as we assume all ionic structures except those which involve ionic H_d and H_e can be disregarded. Besides that, we assume the value of the $C-H$(covalent) internuclear distance R is kept to be 1.09A (the value for CH_4). Electrons in the K shell of the carbon atom are not taken explicitly in our calculations, and we treat the CH_5^+ ion as a eight-electron problem. The ground state of the ion is considered to be ${}^1A_1'$, so that the ${}^1A_1'$ part of the energy matrix is to be constructed in the present study.

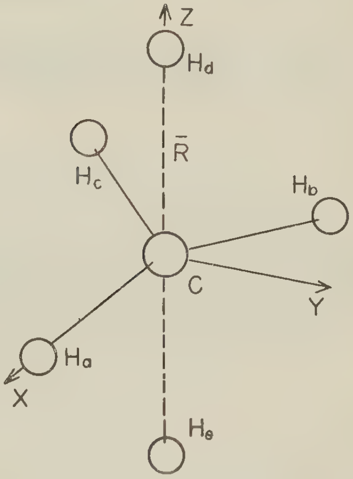


Fig. 1. Notations for CH_5^+

The number of basic ${}^1A_1'$ was functions is found as follows: In order to take account of the symmetry of the ion, we divide the ion into three zones C, H_3, and H_2^+. The C-zone has a spherical symmetry, but its atomic states can be reduced as the representation of D_{3h}. The H_3-zone gives ${}^2E'$ and ${}^4A_2'$, and the H_2^+-zone gives ${}^2A_1'$ and ${}^2A_2''$, if all hydrogen atoms are in the normal state. Combining these three zones, we find that each of $sp^3\ {}^3S^0$, ${}^5S^0$, ${}^1P^0$, ${}^3P^0$ states of the carbon atom gives rise to one ${}^1A_1'$ state of CH_5^+, each of $s^2p^2\ {}^1D$, ${}^3P$, $sp^3\ {}^1D^0$, $p^4\ {}^1D$, ${}^3P$ two, and $sp^3\ {}^3D^0$ three. Thus there are seventeen ${}^1A_1'$ states in all. This situation is the same as that of the ${}^2A_1$ state of the methyl radical with the C_{3v} symmetry.[4)

In order to calculate the matrix elements of the hamiltonian we construct the wave function as follows.[3),4),5),6) We denote by κ

---

* This suggestion is due to Prof. S. Nagakura.

(and λ), μ (and ν), and σ $(=2)$ (and ρ $(=2)$) the spin multiplicity of the C-, H_3-, and H_2^+-zone. We denote by $U_{\kappa;kl}(P)$ ($U_{\mu;mn}(Q)$) the k, l (m, n) matrix element for the permutation $P(Q)$ in the irreducible representation corresponding to spin multiplicity $\kappa(\mu)$ for the C-(H_3-) zone. The wave functions for the C-zone are

$$\Phi^{C,\alpha}_{\kappa M;k}=\Phi^{C,\alpha}_{S,M,k}=\frac{1}{\sqrt{f_\kappa}}\sum_l \Psi^{C,\alpha}_{\kappa;kl}\Theta_{S,M,l}$$

$$\Psi^{C,\alpha}_{\kappa;kl}=\sqrt{\frac{f_\kappa}{2^{\eta_\alpha}4!}}\sum_P U_{\kappa;kl}(P^{-1})P\phi_{\alpha_1}(1)\phi_{\alpha_2}(2)\phi_{\alpha_3}(3)\phi_{\alpha_4}(4)^*,$$

(f_κ=the dimension of the representation U_κ)

where α_1, α_2, α_3, α_4 are a set of orbitals taken from the available orbitals $2s$, $2px$, $2py$, and $2pz$, η_α is the number of orbitals in that set which are occupied by two electrons, and 1, 2, 3, 4 denote the position coordinates of four electrons in the carbon atom. These functions belong to a definite multiplicity κ, but generally they do not transform according to a definite irreducible representation of D_{3h}. Actually examining the transformation properties of $\Psi^{C,\alpha}_{\kappa;kl}$, we can construct appropriate linear combinations of them

$$\Psi^{C}_{\kappa\mu;hl}=\sum_{k\alpha} C_{\kappa\mu h;k\alpha}\Psi^{C,\alpha}_{\kappa;kl}\ ,$$

which form the bases of irreducible representations of D_{3h}. The wave functions for the H_3-zone are

$$\Phi^{H_3}_{\mu M;m}=\Phi^{H_3}_{S,M,m}=\frac{1}{\sqrt{f_\mu}}\sum_n \Psi^{H_3}_{\mu;mn}\Theta_{S,M,n}$$

$$\Psi^{H_3}_{\mu;mn}=\sqrt{\frac{f_\mu}{3!}}\sum_Q U_{\mu;mn}(Q^{-1})Q\phi_a(6)\phi_b(7)\phi_c(8)\ ,$$

---

* The forms of the matrices $U(P)$, which are used in the present study, correspond to the following definitions of the bases of the matrices $V(P)$ $(U(P)V(P)=\varepsilon_P)$.

for the C-zone: $\Theta_{S,M,l}$

$$S=2,\ M=2\qquad \Theta_{l=1}=\alpha(1)\alpha(2)\alpha(3)\alpha(4)\ ,$$

$$S=1,\ M=1\begin{cases}\Theta_{l=1}=\frac{1}{2}\{\alpha(1)\alpha(2)\alpha(3)\beta(4)+\alpha(1)\alpha(2)\beta(3)\alpha(4)-\alpha(1)\beta(2)\alpha(3)\alpha(4)-\beta(1)\alpha(2)\alpha(3)\alpha(4)\}\\ \Theta_{l=2}=\frac{1}{\sqrt{2}}\{\alpha(1)\beta(2)\alpha(3)\alpha(4)-\beta(1)\alpha(2)\alpha(3)\alpha)\}\\ \Theta_{l=3}=\frac{1}{\sqrt{2}}\{\alpha(1)\alpha(2)\beta(3)\alpha(4)-\alpha(1)\alpha(2)\alpha(3)\beta(4)\}\ ,\end{cases}$$

$$S=0,\ M=0\begin{cases}\Theta_{l=1}=\frac{1}{2}\{\alpha(1)\beta(2)-\beta(1)\alpha(2)\}\{\alpha(3)\beta(4)-\beta(3)\alpha(4)\}\\ \Theta_{l=2}=\frac{1}{\sqrt{3}}\Big[\frac{1}{2}\{\alpha(1)\beta(2)+\beta(1)\alpha(2)\}\{\alpha(3)\beta(4)+\beta(3)\alpha(4)\}\\ \qquad\qquad -\alpha(1)\alpha(2)\beta(3)\beta(4)-\beta(1)\beta(2)\alpha(3)\alpha(4)\Big]\ ,\end{cases}$$

for the H_3-zone: $\Theta_{S,M,n}$

$$S=\frac{3}{2},\ M=\frac{3}{2}\qquad \Theta_{n=1}=\alpha(6)\alpha(7)\alpha(8)\ ,$$

$$S=\frac{1}{2},\ M=\frac{1}{2}\begin{cases}\Theta_{n=1}=\frac{1}{\sqrt{2}}\{\alpha(6)\alpha(7)\beta(8)-\alpha(6)\beta(7)\alpha(8)\}\\ \Theta_{n=2}=\frac{1}{\sqrt{6}}\{2\beta(6)\alpha(7)\alpha(8)-\alpha(6)\alpha(7)\beta(8)-\alpha(6)\beta(7)\alpha(8)\}\ .\end{cases}$$

where ϕ_a, ϕ_b, ϕ_c denote the 1*s* orbitals of the hydrogen atoms H_a, H_b, H_c, respectively, and 6, 7, 8 denote the position coordinates of three electrons in three covalent hydrogen atoms. These wave functions belong to a definite multiplicity μ, and transform according to a definite irreducible representation of the point group D_{3h} ($\Psi_{\mu;mn}$'s are ${}^2E'$ for $\mu=2$ and ${}^4A_2'$ for $\mu=4$). The wave functions for the H_2^+-zone are

$$\Phi^{H_2^+,\beta}_{\sigma M;t} = \phi_d(5)\alpha(5) \quad \text{or} \quad \phi_e(5)\alpha(5)\ ,$$

where ϕ_d, ϕ_e denote the 1*s* orbitals of the hydrogen atoms H_d, H_e, respectively, and 5 denotes the position coordinate of the electron in the so-called ionic hydrogen atoms. The linear combinations

$$\frac{1}{\sqrt{2}}(\phi_d(5)+\phi_e(5))\ ,\quad \frac{1}{\sqrt{2}}(\phi_d(5)-\phi_e(5))$$

will form the bases of irreducible representations of D_{3h}.

The ${}^1A_1'$ wave functions of the whole system CH_5^+ are constructed as follows: We denote by $W_{pq}(S)$ the irreducible representation of the symmetric group $\mathfrak{S}_8$ corresponding to the singlet state, which is reduced with respect to the subgroup $\mathfrak{S}_4(1, 2, 3, 4)\times\mathfrak{S}_3(6, 7, 8)$**. Thus for any element of the subgroup $G=PQ$ ($P\in\mathfrak{S}_4(1, 2, 3, 4)$, $Q\in\mathfrak{S}_3(6, 7, 8)$),

$$W_{pq}(G)=W_{\kappa\mu km,\lambda\nu ln}(PQ)=\delta_{\kappa\lambda}\delta_{\mu\nu}U_{\kappa;kl}(P)U_{\mu;mn}(Q)\ .$$

The singlet wave functions of CH_5^+ are

$$\Phi^{\alpha,\beta}_{\kappa\mu\sigma(=2)M;\,km\jmath(=1)}=\Phi^{\alpha,\beta}_{S=0,M=0,km\jmath(=1)}=\sqrt{\frac{1}{14}}\sum_q \Psi^{\alpha,\beta}_{\kappa\mu\sigma(=2)km\jmath(=1),q}\,\Theta_{S-0,M=0,q}$$

$$\Psi^{\alpha,\beta}_{\kappa\mu\sigma(=2)km\jmath(=1),q}=\sqrt{\frac{14}{2^{\eta_\alpha}8!}}\sum_S W_{\kappa\mu km,q}(S^{-1})S\phi_{\alpha_1}(1)\phi_{\alpha_2}(2)\phi_{\alpha_3}(3)\phi_{\alpha_4}(4)\phi_\beta(5)\phi_a(6)\phi_b(7)\phi_c(8)\ .$$

Using the same coefficients as defined above for the *C*-zone and the H_2^+-zone, we obtain the ${}^1A_1'$ wave functions of CH_5^+ as follows:

$$\Phi_{\kappa\mu km}=\Phi_{S=0,M-0,km}=\sqrt{\frac{1}{14}}\sum_q\sqrt{\frac{1}{f_\mu}}\sum_{k\alpha\beta h}C_{\kappa\mu h;k\alpha\beta}\Psi^{\alpha,\beta}_{\kappa\mu kh,q}\Theta_{S,M,q}=\sum_q\sqrt{\frac{1}{14}}\Psi_{\kappa\mu,q}\Theta_{S=0,M=0,q}$$

$$\Psi_{\kappa\mu,q}=\sqrt{\frac{1}{f_\mu}}\sum_{k\alpha\beta h}C_{\kappa\mu h;k\alpha\beta}\Psi^{\alpha,\beta}_{\kappa\mu kh,q}\ .$$

These functions are given explicitly in Table I. These are similar to those for the methyl radical.[4)]

§ 3. Calculation of Matrix Elements

The elements of the hamiltonian are computed by the formula

$$\int\Psi^{\alpha,\beta}_{p,q}H\Psi^{\bar\alpha,\bar\beta}_{r,q}d\tau=\frac{1}{\sqrt{2^{\eta_\alpha+\eta_{\bar\alpha}}}}\sum_S W_{p,r}(S^{-1})\int(S\Psi^{\alpha,\beta})H\Psi^{\bar\alpha,\bar\beta}d\tau$$

$$\Psi^{\alpha,\beta}=\phi_{\alpha_1}(1)\phi_{\alpha_2}(2)\phi_{\alpha_3}(3)\phi_{\alpha_4}(4)\phi_\beta(5)\phi_a(6)\phi_b(7)\phi_c(8)$$

$$\Psi^{\bar\alpha,\bar\beta}=\phi_{\bar\alpha_1}(1)\phi_{\bar\alpha_2}(2)\phi_{\bar\alpha_3}(3)\phi_{\bar\alpha_4}(4)\phi_{\bar\beta}(5)\phi_a(6)\phi_b(7)\phi_c(8)\ .$$

** The irreducible representation of $\mathfrak{S}_8$ corresponding to the singlet state is given explicitly in Serber's paper (J. Chem. Phys. **2** (1934) 697). The transformation matrix ***T*** between Serber's matrix and *W*(*S*), which is reduced with respect to $\mathfrak{S}_4(1, 2, 3, 4)\times\mathfrak{S}_3(6, 7, 8)$, is also given explicitly in Itoh, Ohno, and Kotani's paper.[4)]

Table I. Wave function

17	^3P	$\frac{1}{\sqrt{2}}\phi^{zzxyd}_{3421,q}+\frac{1}{\sqrt{2}}\phi^{zzxye}_{3421,q}$

In constructing these matrix elements, we have neglected the non-orthogonality integrals between atomic orbitals belonging to different atoms, except that we take these integrals into account in the numerical values of the exchange integrals. The assumption of the atomic orbitals being orthogonal is indeed crude, so there seems to be some ambiguity about the definition of $H^{(1,2)}$. Under these circumstances, a strict non-empirical calculation is out of question but we may obtain better results by using good semi-empirical values for the various parameters. Although we cannot judge what kind of experimental results we should most reliably depend upon, we use the semi-empirical values existing in the literatures for some parameters (see § 4).

The parameters which appear in the present study are defined as follows:

1) intracarbon integrals

$$F^0(s,\ s),\ F^0(s,\ p),\ F^0(p,\ p),\ G^1(s,\ p),\ F^2(p,\ p)\ \text{and}\ I_p-I_s\ ,$$

(These notations are due to Slater.[7])

2) $C-H$ (covalent) integrals

$$M_{\alpha\beta}=\iint\phi_\alpha(1)\,\phi_a(2)\left(\frac{1}{r_{12}}+\frac{1}{R_{CHa}}-\frac{1}{r_{Ha1}}-\frac{1}{r_{C2}}\right)\phi_\beta(1)\phi_a(2)d\tau_1d\tau_2$$

$$N_{\alpha\beta}=\iint\phi_\alpha(2)\,\phi_a(1)\left(\frac{1}{r_{12}}+\frac{1}{R_{CHa}}-\frac{1}{r_{Ha1}}-\frac{1}{r_{C2}}\right)\phi_\beta(1)\phi_a(2)d\tau_1d\tau_2\ ,$$

3) H(covalent)$-H$(covalent) integrals

$$K_{HH}=\iint\phi_a(1)\phi_b(2)\left(\frac{1}{r_{12}}+\frac{1}{R_{HaHb}}-\frac{1}{r_{Ha2}}-\frac{1}{r_{Hb1}}\right)\phi_a(1)\phi_b(2)d\tau_1d\tau_2$$

$$J_{HH}=\iint\phi_a(2)\phi_b(1)\left(\frac{1}{r_{12}}+\frac{1}{R_{HaHb}}-\frac{1}{r_{Ha2}}-\frac{1}{r_{Hb1}}\right)\phi_a(1)\phi_b(2)d\tau_1d\tau_2\ ,$$

4) $C-H$(ionic) integrals

$$\overline{M}_{\alpha\beta}=\iint\phi_\alpha(1)\phi_d(2)\left(\frac{1}{r_{12}}+\frac{1}{R_{CHd}}+\frac{1}{R_{CHe}}-\frac{1}{r_{Hd1}}-\frac{1}{r_{He1}}-\frac{1}{r_{C2}}\right)\phi_\beta(1)\phi_d(2)d\tau_1d\tau_2$$

$$\overline{N}_{\alpha\beta}=\iint\phi_\alpha(2)\phi_d(1)\left(\frac{1}{r_{12}}+\frac{1}{R_{CHd}}+\frac{1}{R_{CHe}}-\frac{1}{r_{Hd1}}-\frac{1}{r_{He1}}-\frac{1}{r_{C2}}\right)\phi_\beta(1)\phi_d(2)d\tau_1d\tau_2\ ,$$

5) H(covalent)$-H$(ionic) integrals

$$\overline{K}_{HH}=\iint\phi_a(1)\phi_d(2)\left(\frac{1}{r_{12}}+\frac{1}{R_{HaHd}}+\frac{1}{R_{HaHe}}-\frac{1}{r_{Hd1}}-\frac{1}{r_{He1}}-\frac{1}{r_{Ha2}}\right)\phi_a(1)\phi_d(2)d\tau_1d\tau_2$$

$$\overline{J}_{HH}=\iint\phi_a(2)\phi_d(1)\left(\frac{1}{r_{12}}+\frac{1}{R_{HaHd}}+\frac{1}{R_{HaHe}}-\frac{1}{r_{Hd1}}-\frac{1}{r_{He1}}-\frac{1}{r_{Ha2}}\right)\phi_a(1)\phi_d(2)d\tau_1d\tau_2\ ,$$

6) $C-H_d-H_e$ integrals

$$\overline{\overline{M}}_{\alpha\beta}=\iint\phi_\alpha(1)\phi_d(2)\left(\frac{1}{r_{12}}+\frac{1}{R_{CHd}}+\frac{1}{R_{CHe}}-\frac{1}{r_{Hd1}}-\frac{1}{r_{He1}}-\frac{1}{r_{C2}}\right)\phi_\beta(1)\phi_e(2)d\tau_1d\tau_2$$

$$\overline{\overline{N}}_{\alpha\beta}=\iint\phi_\alpha(2)\phi_d(1)\left(\frac{1}{r_{12}}+\frac{1}{R_{CHd}}+\frac{1}{R_{CHe}}-\frac{1}{r_{Hd1}}-\frac{1}{r_{He1}}-\frac{1}{r_{C2}}\right)\phi_\beta(1)\phi_e(2)d\tau_1d\tau_2\ ,$$

7) H(covalent)$-H_d-H_e$ integrals

$$\overline{K}_{HH}=\iint\phi_a(1)\phi_d(2)\left(\frac{1}{r_{12}}+\frac{1}{R_{HaHd}}+\frac{1}{R_{HaHe}}-\frac{1}{r_{Ha2}}-\frac{1}{r_{Hd1}}-\frac{1}{r_{He1}}\right)\phi_a(1)\phi_e(2)d\tau_1d_2$$

$$\bar{J}_{HH}=\iint\phi_a(2)\phi_d(1)\left(\frac{1}{r_{12}}+\frac{1}{R_{HaHd}}+\frac{1}{R_{HaHe}}-\frac{1}{r_{Ha2}}-\frac{1}{r_{Hd1}}-\frac{1}{r_{He1}}\right)\phi_a(1)\phi_e(2)d\tau_1 d\tau_2\ ,$$

8) $$\bar{\bar{K}}=\int\phi_d(1)\left(\frac{1}{R_{HdHe}}-\frac{1}{r_{He1}}\right)\phi_d(1)d\tau_1+3\int\phi_a(1)\left(\frac{1}{R_{HaHe}}-\frac{1}{r_{He1}}\right)\phi_a(1)d\tau_1\ .$$

The explicit forms of the energy matrix are given in Table II.

Table II. Elements of energy matrix.

Any element $\boldsymbol{H}_{ij}$ may be devided into three parts H_{ij}, $\bar{H}_{ij}$, and $\bar{\bar{H}}_{ij}$. ($\boldsymbol{H}_{ij}=H_{ij}+\bar{H}_{ij}+\bar{\bar{H}}_{ij}$), where H_{ij} are those containing $W(C)$, $W(H)$, $M_{\alpha\beta}$, $N_{\alpha\beta}$, K_{HH} and J_{HH}, $\bar{H}_{ij}$ containing $\bar{M}_{\alpha\beta}$, $\bar{N}_{\alpha\beta}$, $\bar{K}_{HH}$ and $\bar{J}_{HH}$, and $\bar{\bar{H}}_{ij}$ containing $\bar{\bar{M}}_{\alpha\beta}$, $\bar{\bar{N}}_{\alpha\beta}$, $\bar{\bar{K}}_{HH}$ and $\bar{\bar{J}}_{HH}$. ($\bar{\bar{K}}_{HH}$ are contained only in the diagonal elements.) They are all zero but those given in the following.

1) H_{ij}. The explicit forms for H_{ij} are given in Itoh, Ohno, and Kotani's paper[4] for the methyl radical. By putting $\theta=90°$ in their Appendix III, our H_{ij} are obtained. Our definition of $M_{\alpha\beta}$, $N_{\alpha\beta}$ are opposite in sign to theirs. $4W_H(^2S)$ must be added to each diagonal element instead of $3W_H(^2S)$.

2) $\bar{H}_{ij}$

$\bar{H}_{1,1}=2\bar{M}_{\pi\pi}+2\bar{M}_{ss}-\bar{N}_{\pi\pi}-\bar{N}_{ss}+3\bar{K}_{HH}$

$\bar{H}_{2,2}=\bar{M}_{\pi\pi}+\bar{M}_{\sigma\sigma}+2\bar{M}_{ss}-\frac{1}{2}\bar{N}_{\pi\pi}-\frac{1}{2}\bar{N}_{\sigma\sigma}-\bar{N}_{ss}+3\bar{K}_{HH}$

$\bar{H}_{3,3}=\bar{M}_{\pi\pi}+\bar{M}_{\sigma\sigma}+2\bar{M}_{ss}+\frac{1}{2}\bar{N}_{\pi\pi}+\frac{1}{2}\bar{N}_{\sigma\sigma}-\bar{N}_{ss}+3\bar{K}_{HH}-2\bar{J}_{HH}$

$\bar{H}_{4,4}=2\bar{M}_{\pi\pi}+2\bar{M}_{ss}-2\bar{N}_{\pi\pi}-\bar{N}_{ss}+3\bar{K}_{HH}+\bar{J}_{HH}$

$\bar{H}_{5,5}=2\bar{M}_{\pi\pi}+\bar{M}_{\sigma\sigma}+\bar{M}_{ss}-\frac{1}{2}\bar{N}_{\sigma\sigma}+\frac{1}{2}\bar{N}_{ss}+3\bar{K}_{HH}-2\bar{J}_{HH}$

$\bar{H}_{6,6}=2\bar{M}_{\pi\pi}+\bar{M}_{\sigma\sigma}+\bar{M}_{ss}-\bar{N}_{\pi\pi}-\frac{1}{2}\bar{N}_{\sigma\sigma}-\frac{1}{2}\bar{N}_{ss}+3\bar{K}_{HH}$

§ 4. Estimations of Integrals

The values in *ev* of intracarbon integrals used are as follows:

$$F^0(s,\ s)=17.82,\quad F^0(s,\ p)=16.07$$
$$F^0(p,\ p)=14.75,\quad G^1(s,\ p)=2.18,$$
$$F^2(p,\ p)=0.188,\quad I_p-I_s=12.79.$$

These are taken from Van Vleck's paper.[8] The coulomb integrals $M_{\alpha\beta}$, $\overline{M}_{\alpha\beta}$, $\overline{\overline{M}}_{\alpha\beta}$ are obtained from Kotani-Amemiya's table[9] by using the carbon effective charge 3.18. (For $\overline{M}_{\alpha\beta}$ and $\overline{\overline{M}}_{\alpha\beta}$, we have also used some approximate values of the various three-center integrals. See below). The empirical values for $C-H$(covalent) integrals $N_{\alpha\beta}$ have been given by Van Vleck[10], Penney[11], and Voge[2], but we have no such information for $\overline{N}_{\alpha\beta}$ and $\overline{\overline{N}}_{\alpha\beta}$. Therefore we carry out in the present study two parallel calculations with two different sets of parameters, i.e., (a) with the exchange integrals $N_{\alpha\beta}$, $\overline{N}_{\alpha\beta}$, $\overline{\overline{N}}_{\alpha\beta}$ being computed from Kotani-Amemiya's table[9] and, if necessary, incorporated with approximate values of the various three-center integrals, and (b) with the exchange integrals $\overline{N}_{\alpha\beta}$, $\overline{\overline{N}}_{\alpha\beta}$, $N_{\alpha\beta}$ being those computed in "case (a)" multiplied by certain factors. The factors are determined from the ratios of the empirical values to those computed from the table for $N_{\alpha\beta}$ (i.e., 0.6831 for N_{ss}, $\overline{N}_{ss}$, N_{ss}, 1.288 for $N_{\sigma\sigma}$, $\overline{N}_{\sigma\sigma}$,

$\bar{\bar{N}}_{\sigma\sigma}$, 0.8322 for $N_{\pi\pi}$, $\bar{N}_{\pi\pi}$, $\bar{\bar{N}}_{\pi\pi}$, and 0.6238 for $N_{s\sigma}$, $\bar{N}_{s\sigma}$). The coulomb and exchange integrals between hydrogen atoms are, as usual, assumed to be 1/10 and 9/10 of the Morse function, respectively.

There appear some three-center integrals to be evaluated. We estimate their values by the same method as that of Ellison,[12] which he has used in his calculation of the water molecule. The estimated values of three-center integrals are given in Table III. The values of various integrals used are given in Table IV.

§ 5. Solution of Secular Equations

The secular equation is of the seventeenth degree. We have solved them for six values of the $C-H$(ionic) distance $\bar{R}$, i.e., for $\bar{R}=$ 0.8174, 0.9196, 1.022, 1.124, 1.226, and 1.328A by the iteration method.

The electronic energy of the ground state is given in Table V for various values of $\bar{R}$ and illustrated by curve a (using parameters $N_{\alpha\beta}$, $\bar{N}_{\alpha\beta}$, $\bar{\bar{N}}_{\alpha\beta}$ without factor) and b (using parameters $N_{\alpha\beta}$, $\bar{N}_{\alpha\beta}$, $\bar{\bar{N}}_{\alpha\beta}$ with factor) in Fig. 2., from which we can see that the value of the equilibrium $C-H$(ionic) distance is nearly equal to that of the covalent $C-H$ distance for both (a) and (b). The calculated dissociation energy from the potential minimum is 21.98 ev for (a) "using parameters $N_{\alpha\beta}$, $\bar{N}_{\alpha\beta}$, $\bar{\bar{N}}_{\alpha\beta}$ without factor" and 19.75 eV for (b)

“ using parameters $N_{\alpha\beta}$, $\overline{N}_{\alpha\beta}$, $N_{\alpha\beta}$ with factor ”. If we subtract 16.9 eV, the experimental dissociation energy of the methane molecule from it, we obtain the proton affinity of the methane molecule to be 5.08 eV for (a) and 2.85 eV for (b). There is the difference of about 2.2 eV.

§ 6. Discussion

According to the experiences in similar calculations of molecular energies the computed binding energies, when we use the parameters $N_{\alpha\beta}$, $\bar{N}_{\alpha\beta}$, $\bar{\bar{N}}_{\alpha\beta}$ without factor – "case (a)" – (not with factor – "case (b)" –), are generally larger than those experimentally known. This is due to the neglects of the non-orthogonalities of the atomic orbitals and the higher order permutations of electrons. So we can suppose the value for "case (a)" may be a little too large to be accepted. According to the experiences, too, we obtain rather surprising good results when we use good semi-empirical values for intermolecular integrals. In our treatment "case (b)", the values used for $N_{\alpha\beta}$ are the empirically better ones, but we do not know wether it is true for $\bar{N}_{\alpha\beta}$ and $\bar{\bar{N}}_{\alpha\beta}$. So there remains a little uncertainty in our confidence on the result for the "case (b)". Besides, in our calculation there are some questions about the neglects of overlap integrals and of ionic structures except those which involve ionic H_a and H_e. In this respect, Itoh, Ohno, and Kotani[4] have obtained the dissociation energy of 12.97 ev by the treatment of the methyl radical similar to our treatment "case (b)". The experimental value of it is 13.12 eV. The agreement is very good. Stevenson and Schissler have experimentally obtained the value more than 5.0 eV for the proton affinity of the methane molecule.[1]

Woods[13] has obtained the value 1.01A for the equilibrium $C-H$ distance for the methane molecule with using sp^3 hybridized orbitals and with considering the non-orthogonalities of the atomic orbitals and the higher order permutations of electrons, and Nakamura and Kakiuchi[14] have obtained the value 0.98A by performing more detailed calculations than that of Woods. The experimentally known value is 1.09A. Accordingly there may be the possibility of our value 1.10A obtained for the $C-H$(ionic) distance being smaller by about 0.1A than the truth. It is interesting that the resulted values of the $C-H$(ionic) distance are nearly the same for two different sets of parameters.

The contributions of s^2p^2, sp^3, and p^4 configurations of the carbon atom in the "case (b)" are very similar to those for the methane molecule and the methyl radical as seen from Table VII.

If we want to know the behaviour at large values of the $C-H$ distance, where the ion has the type C_{3v} of symmetry, each of the seventeen eigenfunctions is separated into two, one containing ϕ_d, the other ϕ_e, and we must solve the thirty-fourth degree secular equation (numbering: 1d, 1e, 2d, 2e, $\cdots$, 17d, 17e). Then our matrix elements H_{ij} and $\overline{H}_{ij}$ become $H_{id,jd}$, $\overline{H}_{id,jd}$ or $H_{ie,je}$, $\overline{H}_{ie,je}$, and $\overline{H}_{ij}$ become $H_{id,je}$. Our formulae of matrix elements can be used in this general case.

In the present study, we have assumed that the ground state of the protonated methane is ${}^1A_1'$ state, disregarded ionic structures except those which involve ionic H_a and H_e and overlap integrals, and chosen some arbitrary values for the various parameters. These points are open to questions.

The author wishes to express his sincere thanks to Professor K. Niira and Professor S. Nagakura for their kind guidances and suggestions. This work is indebted to the Ministry of Education for its research grant.

Thermo-Remanent Magnetism in the Systems La_2O_3-Fe_2O_3 and Nd_2O_3-Fe_2O_3

By Hiroshi WATANABE

The Research Institute for Iron, Steel and Other Metals,
Tohoku University, Sendai

(Received December 3, 1958)

$LaFeO_3$, which is reported to be antiferromagnetic at room temperature, has, however, a small amount of remanent magnetization. By measuring the hysteresis loops of a sample before and after a thermomagnetic treatment, it is found that the hysteresis loop is shifted along the magnetization axis, especially for specimens cooled in a magnetic field below the magnetic transition temperature, *ca* 450°C. The phenomenon can well be interpreted as a sort of thermo-remanent magnetization. A similar phenomenon has also been found for $NdFeO_3$.

§ 1. Introduction

In the course of study on the thermomagnetic properties of perovskite-like compounds, it has been found that $LaFeO_3$, which is reported to be antiferromagnetic at room temperature, still has weak ferromagnetism and its hysteresis loop shows a quite unusual behavior; the hysteresis loop is shifted along the magnetization axis.

Hysteresis loops which are asymmetrical with respect to the coordinate axes have recently been reported in a few cases; Meiklejohn and Bean[1] found that an oxide-coated cobalt or iron particle had a hysteresis loop displaced along the field axis, if it had been cooled from temperatures above the antiferromagnetic Curie temperature of the relevant oxide; they attributed the anomalous magnetic behavior observed to the exchange contact of the metal particle with the oxide-coating.

Lin and Kaufmann[2] studied the magnetic properties of UMn_2, which, in spite of its several antiferromagnetic behaviors, showed a small remanence below 230°K if it had been cooled in a magnetic field. Samples so-treated showed an asymmetry in their hysteresis loop, although the displacement along the magnetization axis was very small.

These data are extremely interesting because ordinary ferromagnetics always show symmetrical hysteresis loops. In the exceptional cases as cited above, the phenomenon seems to be associated with antiferromagnetism or with some interaction between antiferromagnetic and ferromagnetic regions. The phenomenon dealt with here could also be closely related to the antiferromagnetism of $LaFeO_3$, although it can, in principle, be understood on the basis of Néel's theory of thermo-remanent magnetism[3].

$LaFeO_3$ is a magnetic compound with perovskite-like structure, in which the larger cation, La^{3+}, is nonmagnetic, and the smaller one, Fe^{3+}, is magnetic. Its crystal structure has been studied by a few authors[4][5] and reported to be cubic, but Geller and Wood[6] in a more precise measurement using single crystals have determined the crystal symmetry to be orthorhombic with $a=5.556$Å, $b=5.565$Å, $c=7.862$Å, and the probable space-group to be D_{2h}^{16}-Pbnm.

Its magnetic structure has been investigated by Koehler and Wollan[7]; each Fe^{3+} ion is surrounded by six Fe^{3+} neighbors whose spins are antiparallel to the given ion, superexchange interaction between near-neighboring Fe^{3+} ions *via* the intervening 0^{2-} ion being negative.

Weak ferromagnetism in $LaFeO_3$ was first reported by Forestier and Guiot-Guillain[8], who located its Curie temperature at 465°C. Paramagnetic susceptibility above the Curie temperature was measured by the author[9] and it was found that in some cases some amount of thermal hysteresis was present* immediately above the Curie temperature (450°C).

---

* The hysteresis could be reduced by annealing the sample at temperatures lower than the sintering temperature. At present, however, it is still doubtful whether the hysteresis is related to some complicated nature of the phase diagram, or not.

Jonker[10] considered the Curie temperature to be identical with the Néel temperature. Although it was felt that magnetization at room temperature was dependent on thermal or magnetic-field treatment, no systematic study concerning this point has ever been undertaken. The problem has not been solved completely, but the displacement of the hysteresis loop is a definite conclusion of the present study.

An attempt has been made to see if a similar phenomenon would be observed in other compounds. It is known from the work of Geller and Wood[6] that $YFeO_3$ as well as many rare-earth orthoferrites are isomorphous with $LaFeO_3$. An experiment on $NdFeO_3$ has, actually, given a positive result.

§ 2. Experimental

2.1. *Preparation of samples*

In view of the importance of the purity of the constituent oxides, powders of high purity La_2O_3 of different sources has been used and the results were compared. Experimental data varied slightly with different sources of constituent reagents. Nevertheless it was seen that this was not serious in the final conclusion. Fe_2O_3, prepared by calcination of FeC_2O_4 at 1200°C in air was used as the other constituent. Intimate mixtures of these constituent oxides were sintered, mostly in air, at various temperatures and then quenched or furnace-cooled or annealed.

X-ray powder photographs have been taken of some of the samples and were seen to be insensitive to heat-treatment. For stoichiometric $LaFeO_3$, the patterns were compatible with the crystallographic data reported in references. For samples richer in Fe_2O_3, lines of α-Fe_2O_3 appeared. Films of samples richer in La_2O_3 contained, besides the lines of $LaFeO_3$, additional lines, but no analysis of them has been intended.

2.2. *Thermomagnetic curves*

Thermomagnetic curves were taken with samples of various compositions (molar ratios of La_2O_3 to Fe_2O_3) and of various sintering temperatures. Typical examples of this series of measurements are shown in Fig. 1. The measuring field was about 6500 Oe.

As can be seen from the Figs. 1 (b) and 1 (c), $LaFeO_3$ and $La_{0.8}Fe_{1.2}O_3$ sintered at 1300°C are contaminated with α-Fe_2O_3 (Fig. 1 (d)),

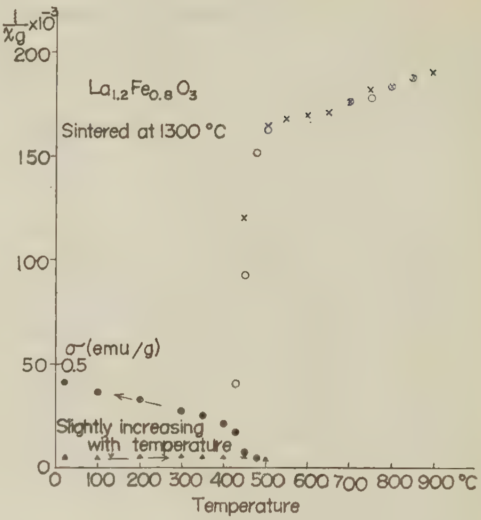

Fig. 1 (a)

Fig. 1. Thermomagnetic curves of $La_2O_3-Fe_2O_3$ system.
× and ⊙ are the experimental points for $(1/\chi_g)\times10^{-3}$ measured during heating and subsequent cooling, respectively. ▲ and ● those for magnetization σ.

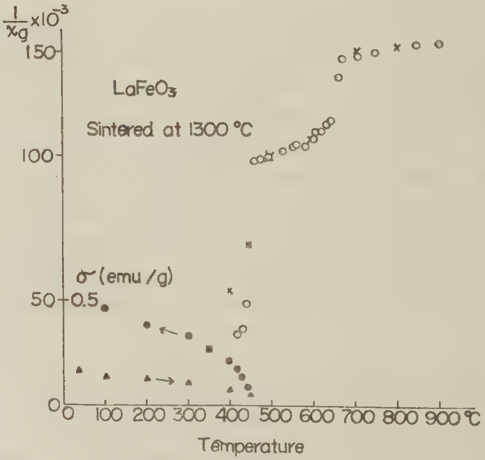

Fig. 1 (b)

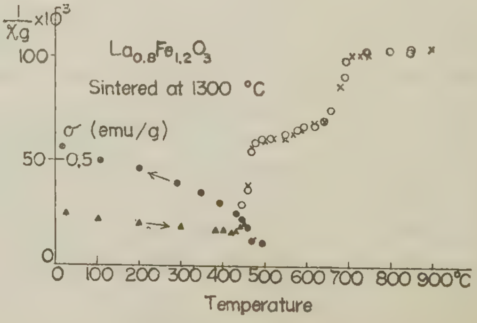

Fig. 1 (c)

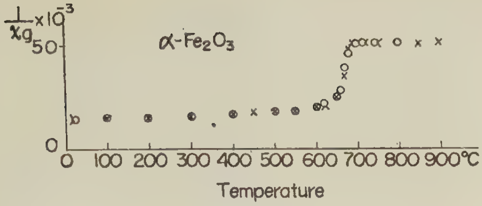

Fig. 1 (d)

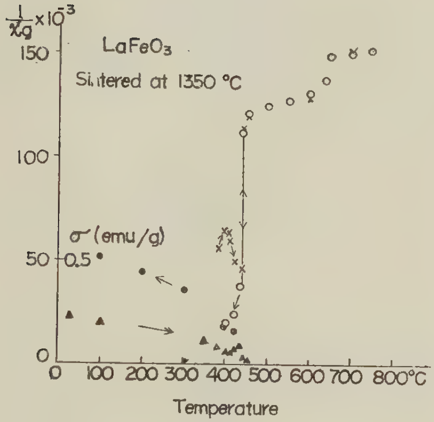

Fig. 1 (e)

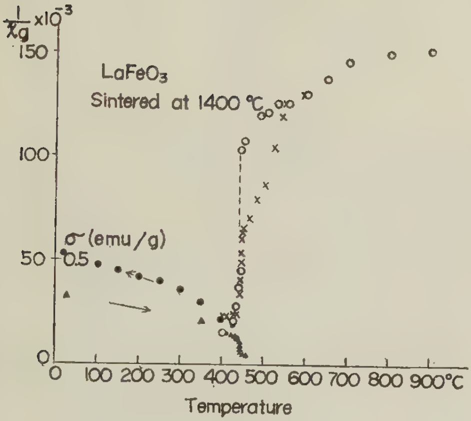

Fig. 1 (f)

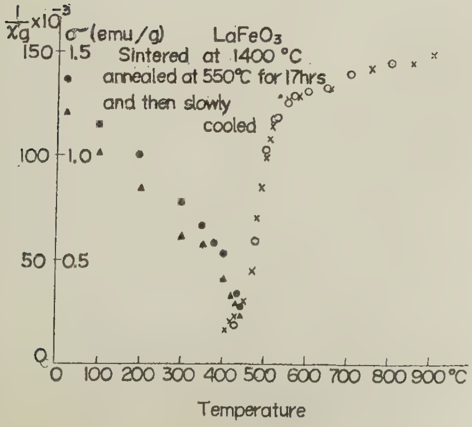

Fig. 1 (g)

since they have a magnetic transition at 680°C, which corresponds to the Curie temperature of the parasitic ferromagnetism of α-Fe_2O_3. From Fig. 1 (g) it may be seen that α-Fe_2O_3-free $LaFeO_3$ is only possible when it is sintered at 1400°C*. This was corroborated with the X-ray powder patterns.

Thermal hysteresis as is found in $LaFeO_3$ sintered at 1400°C (Fig. 1 (f)) usually occurs when the sample has been quenched from the sintering temperature. In this case the susceptibity in the cooling run undergoes a very sharp increase at 440°C. If this sample is annealed above the transition temperature, say at 550°C, the thermal hysteresis disappears and at the same time the magnetic transition becomes less sharp, the transition temperature becoming slightly higher. For this sample only can we calculate a reliable number of Bohr magnetons per Fe^{3+} ion in the paramagnetic region. It is, if the susceptibilities are corrected for diamagnetism of ion cores, equal to 5.80, slightly lower than the predicted spin-only value of 5.92. The paramagnetic Curie temperature, then, is about-1270°K.

All of the samples in Fig. 1 have a lower magnetization, in the initial heating (the initial state is the virgin state, *viz.*, the sample has never been treated in magnetic field at high tempepatures), and higher magnetization in the subsequent cooling. It was established in a separate experiment that this increase in magnetization was due to the presence of the remanent magnetic field (~30 Oe) of the electromagnet. Probably the field was most effective immediately below the magnetic transition temperature. This can be seen, *e.g.*, from the unusual behavior of the magnetization during heating of the sample in Figs. 1 (a), 1 (c), 1 (e) or 1 (g). Since the phenomenon was much like the Hopkinson effect usually met with in ferromagnetic materials, except that here the measuring field was exceptionally high, it was decided to compare the hysteresis loop of the virgin sample with that of the thermomagnetically treated one.

2.3. *Displaced hysteresis loops*

Hysteresis-loop measurement was made with the pendulum magnetometer which was also used for the thermomagnetic measurement.

---

* Strictly speaking, even this sample had a trace of α-Fe_2O_3.

In Fig. 2 are shown the loops of samples with and without magnetic heat-treatment. Although these data were taken with powdered samples, they were checked with cylindrically-pressed specimens with substantially the same results, so that it is impossible that the abnormal effect should have originated from any mechanical motion of the powders with the application of a magnetic field.

As can be seen from the figures, even the loops of virgin samples are slightly shifted along the magnetization axis. The sign of this shift is determined by the direction of the field applied first; if the field is applied in the +direction in the first place, then the loop becomes shifted in the +direction. The shift is usually less than 0.1 emu/g.

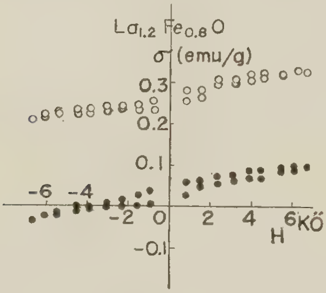

Fig. 2 (a)

● Experimental points for the virgin state.

⊙ Experimental points for a thermomagnetically treated state.

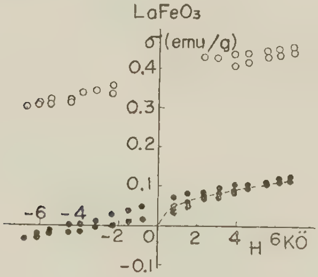

Fig. 2 (b)

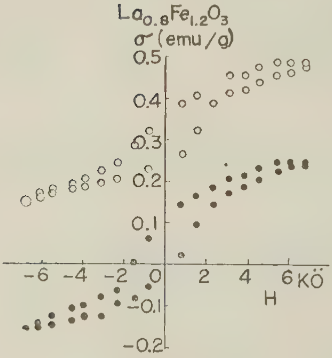

Fig. 2 (c)

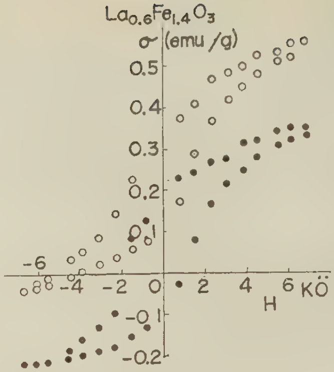

Fig. 2 (d)

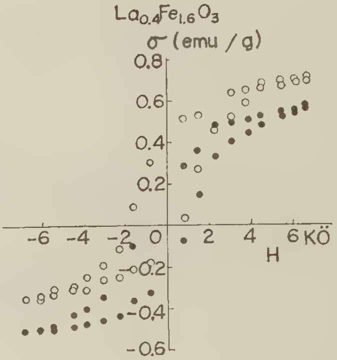

Fig. 2 (e)

When the sample has been cooled from temperatures above the magnetic transition temperature, *ca* 450°C, in a magnetic field of 30 Oe or stronger, apparently greater shifts result. The direction of the shift is in the direction of the magnetic field applied at high temperatures. The amount of this shift is maximum near the composition $LaFeO_3$, and decreases as the Fe^{3+} content increases, vanishing completely for α-Fe_2O_3. On the other hand, the richer the sample in Fe^{3+}, the greater the height of the hysteresis loop (here the height is defined as $\sigma_{H=H_{max}}-\sigma_{H=-H_{max}}$, where σ is magnetization per gram of the sample). Probably α-Fe_2O_3 which is not soluble in the perovskite phase is mostly responsible for the height of the hysteresis loop. Since both the amount of shift and the height of the hysteresis loop vary with the lanthanum oxide used in the sample preparation, and since there seems to be no correlation between them, it should be noted that the curves in Fig. 2 are pertinent to a particular series of samples. The phenomenon of the shift itself, however, is very common to these materials.

2.4. *The system* Nd_2O_3-Fe_2O_3

High purity Nd_2O_3 and Fe_2O_3 were mixed in equimolar proportion and the mixture was sintered at 1300°C. Thermomagnetic curves in Fig. 3 indicate that the Curie temperature of the weak ferromagnetism is about 450°C. As in La_2O_3-Fe_2O_3 system, the magnetization measured during cooling is higher than that measured during heating, and the hysteresis loops are displaced as well (Fig. 4).

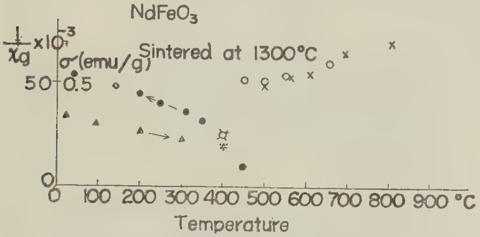

Fig. 3. Thermomagnetic curves of $NdFeO_3$.

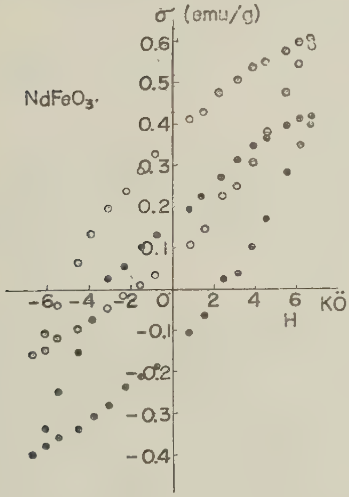

Fig. 4. Hysteresis loops of $NdFeO_3$. The symbols are the same as those in Fig. 2.

§ 3. Discussion

Weak ferromagnetism in antiferromagnetic compounds has been considered by several workers. Some of them attribute it to an intrinsic nature of the material[11], while others to some structure-sensitive character of the material, *e.g.*, domain boundaries[12], free surfaces at grain boundaries[13], dislocations[14] *etc.* It is very difficult to select the correct one out of these possibilities. The same is the case with the matter presented in the present study but some tentative discussion will be given below.

Hysteresis loops as shown in Fig. 2 will result if the material is composed of two magnetically independent parts, one with a usual (symmetric) hysteresis loop (A) and the other with a very hard magnetization in one direction (B) (Fig. 5). As already stated it is very probable that (A) is caused by the α-Fe_2O_3, non-soluble in the perovskite-like $LaFeO_3$ phase; the height of the hysteresis curve (A) is of the right order of magnitude if it corresponds to the parasitic ferromagntism of α-Fe_2O_3[15]. Then the essential problem is how the curve (B) is caused. This can be understood on the basis of Néel's theory of thermo-remanent and isothermal remanent magnetization. The small amount of magnetization (B) of a sample in the virgin state is due to grains with coercive forces less than the maximum field applied, which is far smaller than the overall coercive force. To remove this magnetization a field in the opposite direction slightly higher than that first applied will be sufficient. Indeed its magnetization can be reduced if, instead of applying from the outset a strong field in one direction, we apply a field with alternating

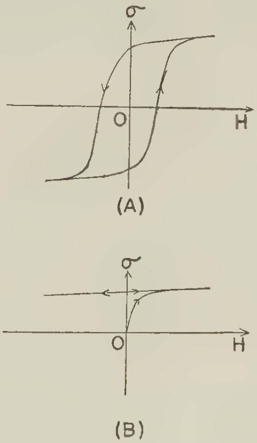

Fig. 5. Displaced hysteresis loop as decomposed into two components, (A) a normal one, and (B) an extremely hard one.

directions and increasing amplitude. In any case, comparing the magnitudes of thermoremanent and isothermal remanent magnetizations, one may recognize how large the overall coercive force is in this case.

The ferromagnetic meterial concerned here, however, is still in quesion. If we consider it to be orthoferrite, not completely antiferromagnetic but with small, uncompensated, parasitic ferromagnetism, the exceedingly large coercive force mentioned above should be interpreted as due to smallness of the saturation magnetization; with the formula for intrinsic coercive force

$$H_c \sim 0.64\, K/I_s\,,$$

where K and I_s, are the anisotropy constant and the saturation magnetization respectively, and with the values of $I_s \sim 0.5 \times$(X-ray density ~ 7)~ 3.5 gauss and $K \sim 10^6$ ergs/cc which is reasonably expected for a substance with magnetic ions in d^5 configuration, H_c becomes 2×10^4 Oe. With this picture, the Curie temperature of the parasitic ferromagnetism in $LaFeO_3$ should be coincident with the Néel temperature. Bozorth$^{16)}$ has recently considered the weak ferromagnetism of rare-earth and yttrium orthoferrites on the basis of an idea similar to Dzyaloshinsky's$^{11)}$, and has concluded that the net magnetic moment in most of the ferrites is directed along the c-axis of the orthorhombic crystal. Since this moment is very hard against rotation away from this axis, the value of K in the above expression should be taken to be much greater and we expect an even larger value of H_c.

An alternative picture which attributes the ferromagnetism (B) to small crystals of α-Fe_2O_3, in the form of thin films and closely attached to the lattice of orthoferrite seems to contradict the observations of domain patterns by Sherwood *et al.*,$^{17)}$ who have produced strong evidence for the fact that the weak ferromagnetism in many orthoferrites is a uniform body property of these substances.

Acknowledgments

I should like to express my hearty thanks to Dr. R. M. Bozorth for giving me the opportunity of knowing his recent work and experimental studies on orthoferrites by Sherwood *et al.* prior to publication, and also for helpful discussion. Thanks are also due to Prof. T. Nagamiya, Dr. E. P. Wohlfarth and Dr. S. Iida for stimulating discussions, to Mr. K. Ito for assistance in the measurements, and to members of the X-ray research laboratory of this Institute for taking powder photographs of the samples. A part of the expenditure of this study has been defrayed from the Scientific Research Funds of the Ministry of Education.

Stabileco de du-dimensia fluo de Szymański

De Hideo TAKAMI

Departemento de Fiziko, Fakultato de Scienco, Universitato de Tokio

(Received January 8, 1959)

Stability of two-dimensional Szymański flow

Stability of a two-dimensional transient flow of an incompressible viscous fluid is investigated by the method of small oscillations. The basic flow is such that the fluid begins to move from rest between two parallel and infinitely large planes under a pressure of constant gradient applied along them and eventually attains the parabolic velocity distribution.

By the use of Lin's procedure the relation between the Reynolds number of the basic flow and the wave number of the antisymmetrical neutral oscillation (the neutral curve of stability) and also the minimum critical Reynolds number are calculated numerically for each of five representative stages of the transient flow, and the variation of its stability characteristics is discussed.

§ 1. Enkonduko

La problemo de la stabileco de fluo estas diskutita de multaj esplorantoj. Ĝenerala metodo de malgrandaj osciloj estas starigita pri fluo preskaŭ konstanta laŭlonge de ĝia direkto kaj en tempo, kaj ankaŭ estas kalkulitaj la karakterizaĵoj de stabileco de kelkaj konkretaj fluoj.

En ĉi tiu traktato ni konsideras la stabilecon de du-dimensia transira fluo de nekunpremebla viskoza fluido inter du paralelaj senlime larĝaj ebenoj sub premo de konstanta gradiento aplikata laŭlonge de ili.

Pri ĉiu de kvin apartaj specimenoj el la transira fluo estas nombre kalkulata, per la procedo de Lin²⁾, la rilato inter la nombro de Reynolds de la baza fluo kaj la ondnombro de la neŭtrala oscilo (t.e. la neŭtrala kurbo de stabileco) kaj ankaŭ estas kalkulata la minimuma kriza nombro de Reynolds. Per ĉi tiuj rezultoj ni esploras la laŭtempan ŝanĝiĝon de la stabileco de la fluo ĉe malgrandaj osciloj.

Koncerne nian problemon ni menciu precipe la esploron de Hahneman k.a.¹⁾ pri la stabileco de du-dimensia fluo ĉe la enirejo de ŝanelo.

§ 2. Bazaj fluoj

Ni konsideru nekunpremeblan viskozan fluidon kiu ripozas inter du paralelaj senlime larĝaj ebenoj $y=\pm h$ (Fig. 1). Se, post iu momento $t=0$, ni aplikados al la fluido premon de konstanta gradiento laŭlonge de la ebenoj (ekzemple en x-direkto), ĝi komencos kaj daŭros flui ŝanĝante la distribuon de rapido (U, V) laŭ sekvantaj ekvacioj:

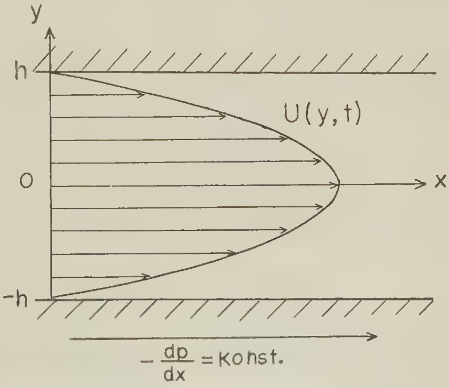

Fig. 1. Baza fluo.

$$\left\{\begin{aligned} &\frac{\partial U}{\partial t}+U\frac{\partial U}{\partial x}+V\frac{\partial U}{\partial y}=-\frac{1}{\rho}\frac{dp}{dx}+\nu\left(\frac{\partial^2 U}{\partial x^2}+\frac{\partial^2 U}{\partial y^2}\right), &(2.1)\\ &\frac{\partial V}{\partial t}+U\frac{\partial V}{\partial x}+V\frac{\partial V}{\partial y}=\qquad\qquad\nu\left(\frac{\partial^2 V}{\partial x^2}+\frac{\partial^2 V}{\partial y^2}\right), &(2.2)\\ &\frac{\partial U}{\partial x}+\frac{\partial V}{\partial y}=0, &(2.3)\end{aligned}\right.$$

kun la kondiĉo ĉe la komenco:

$$(U, V)=0 \qquad \text{ĉe} \quad t=0\,, \tag{2.4}$$

kaj la kondiĉoj ĉe la muroj:

$$(U, V)=0 \qquad \text{ĉe} \quad y=\pm h\,, \tag{2.5}$$

en kiuj U kaj V estu respektive la x- kaj y-komponantoj de rapido de la fluo, ρ la denseco, ν la koeficiento de kinematika viskozeco, p la premo kies gradiento estu konstanta, kaj la fluo estu du-dimensia.

Se ni supozas ke la rapido ne dependas de x, ni vidas el (2.3) ke $V=V(t)$, el ĉi tio kaj (2.5) ke $V\equiv 0$, sekve (2.2) estas bagatela kaj ni havas la ekvacion por $U(y, t)$:

$$\frac{\partial U}{\partial t}=-\frac{1}{\rho}\frac{dp}{dx}+\nu\frac{\partial^2 U}{\partial y^2}\,, \tag{2.6}$$

kun

$$\begin{cases} U(y, 0)=0\,, & (2.7)\\ U(\pm h, t)=0\,. & (2.8)\end{cases}$$

Ni difinu sendimensiajn kvantojn:

$$\left.\begin{aligned} &\tau\equiv\frac{\nu}{h^2}t\,, \qquad \eta\equiv\frac{y}{h}\,, \qquad u(\eta,\tau)\equiv\frac{h}{\nu}U\left(h\eta, \frac{h^2}{\nu}\tau\right),\\ &P\equiv-\frac{h^3}{\rho\nu^2}\frac{dp}{dx}=\text{konst.}>0\,,\end{aligned}\right\} \tag{2.9}$$

kaj nia ekvacio fariĝas

$$\frac{\partial u}{\partial \tau}-\frac{\partial^2 u}{\partial \eta^2}=P\,, \tag{2.10}$$

kun

$$\begin{cases} u(\eta, 0)=0\,, & (2.11)\\ u(\pm 1, \tau)=0\,, & (2.12)\end{cases}$$

kies solvo estas akirata en serio de Fourier:

$$u(\eta,\tau)=\frac{P}{2}\left[1-\eta^2-4\sum_{n=0}^{\infty}\frac{(-1)^n}{(n+\frac{1}{2})^3\pi^3}\cos\{(n+\tfrac{1}{2})\pi\eta\}\exp\{-(n+\tfrac{1}{2})^2\pi^2\tau\}\right], \tag{2.13}$$

aŭ, por malgranda τ, u estas ankaŭ esprimata en rapide konverĝanta serio:

$$u=P\tau\left[1-4\sum_{n=0}^{\infty}(-1)^n\left(\mathbf{i}^2\operatorname{erfc}\frac{2n+1+\eta}{2\sqrt{\tau}}+\mathbf{i}^2\operatorname{erfc}\frac{2n+1-\eta}{2\sqrt{\tau}}\right)\right] \tag{2.14}$$

kiel estus montrate per transformigo de Laplace; en (2.14) staras

$$\begin{aligned}\mathbf{i}^2\operatorname{erfc} x&=\frac{2}{\sqrt{\pi}}\int_x^\infty dt\int_t^\infty ds\int_s^\infty e^{-r^2}\,dr\\ &=\frac{1}{2\sqrt{\pi}}\left\{(2x^2+1)\int_x^\infty e^{-t^2}\,dt-x\,e^{-x^2}\right\}.\end{aligned} \tag{2.15}$$

En Fig. 2 estas montrataj la profiloj de rapido respondaj al diversaj valoroj de τ, kaj en Fig. 3 la maksimuma rapido kiel funkcio de τ. Ni vidas ke la profilo proksimiĝas al tiu de du-dimensia fluo de Poiseuille kiam τ senlime pligrandiĝas. Ni rememoru ke la responda tri-dimensia transira fluo tra ronda tubo estas kalkulita de Szymański[3].

§ 3. Stabileco ĉe malgrandaj osciloj

Nun ni esploru la stabilecon de la supre kalkulita fluo ĉe malgrandaj osciloj surmetitaj al ĝi.

Kiel oni ofte faras, ni supozas ke la rapido (u', v') de la malgranda oscilo estas esprimata per la flufunkcio ψ kiel

$$\left\{\begin{aligned} u' &= \frac{1}{\rho}\frac{\partial\psi}{\partial y}\,, \\ v' &= -\frac{1}{\rho}\frac{\partial\psi}{\partial x}\,, \end{aligned}\right. \tag{3.1}$$

en kiuj ψ havu la sekvantan formon (la ondo de Tollmien-Schlichting):

$$\psi = \phi(y)\exp\{i\tilde{\alpha}(x-\tilde{c}t)\}\,, \tag{3.2}$$

tiam ni havas la ekvacion por la amplekso $\phi(y)$:

$$(U-\tilde{c})\left(\frac{d^2\phi}{dy^2}-\tilde{\alpha}^2\phi\right)-\frac{\partial^2 U}{\partial y^2}\phi = \frac{\nu}{i\tilde{\alpha}}\left(\frac{d^4\phi}{dy^4}-2\tilde{\alpha}^2\frac{d^2\phi}{dy^2}+\tilde{\alpha}^4\phi\right), \tag{3.3}$$

kun la kondiĉoj ĉe la muroj:

$$\phi=0 \quad \text{kaj} \quad d\phi/dy=0 \qquad \text{ĉe} \quad y=\pm h\,. \tag{3.4}$$

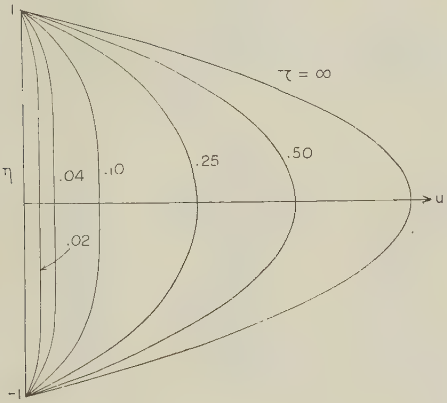

Fig. 2 (a). Profiloj de rapido $u(\eta,\tau)$ por diversaj valoroj de τ (vidu (2.9)).

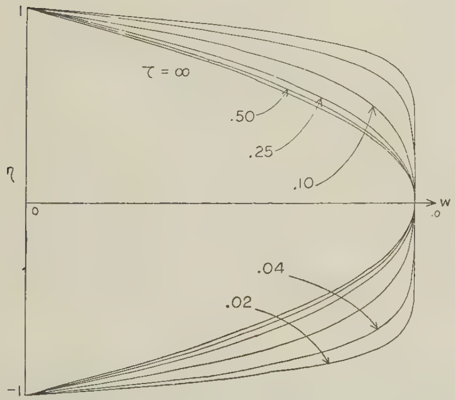

Fig. 2 (b). Profiloj de rapido $w(\eta,\tau)$ por diversaj valoroj de τ (vidu (3.5)).

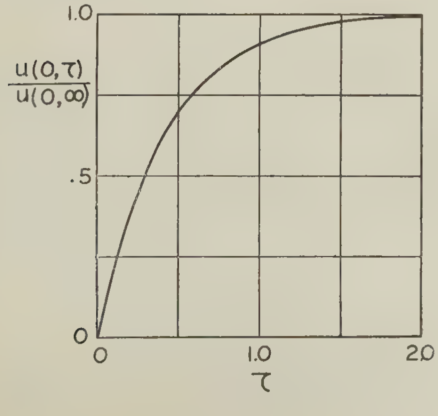

Fig. 3. La maksimuma rapido kiel funkcio de τ.

Metinte (3.2), ni supozas ke la relativa vario de la baza fluo $(\partial U/\partial t)/U$ estas multe pli malgranda ol la frekvenco $\tilde{\alpha}\tilde{c}$ de la surmetita oscilo, kaj ni rigardas la tempan variantan t en U kiel parametron nur karakterizantan la bazan fluon, kiu, ni postulas, daŭru senŝanĝa dum granda nombro da periodoj de la konsiderata oscilo. Ni memoru ke ĉi tiu kondiĉo ne povus esti realigata por malgrandega τ, t.e. dum la komenca tempo de la movo de fluido (vidu § 4).

Per sendimensiaj kvantoj:

$$w \equiv \frac{U}{U_m}\,, \quad \eta = \frac{y}{h}\,, \quad \alpha \equiv h\tilde{\alpha}\,, \quad c \equiv \frac{\tilde{c}}{U_m}\,, \tag{3.5}$$

en kiuj

$$U_m = \max_y U(y,t) = U(0,t)\,, \tag{3.6}$$

ekvacio (3.3) transformiĝas en la ekvacion de Orr-Sommerfeld:

$$(w-c)\left(\frac{d^2\phi}{d\eta^2}-\alpha^2\phi\right)-\frac{\partial^2 w}{\partial\eta^2}\phi = -\frac{i}{\alpha R}\left(\frac{d^4\phi}{d\eta^4}-2\alpha^2\,\frac{d^2\phi}{d\eta^2}+\alpha^4\phi\right), \tag{3.7}$$

kun

$$\left.\begin{aligned} \phi &= 0\,, \\ \frac{d\phi}{d\eta} &= 0 \end{aligned}\right\} \qquad \text{ĉe} \quad \eta=\pm 1\,, \tag{3.8}$$

en kiu R estu la nombro de Reynolds $U_m h/\nu$ de la fluo ĉe la momento τ.

Ekvacio (3.7), kun la kondiĉoj (3.8), donas kompleksvaloran rilaton inter realvaloraj R, α kaj kompleksvalora c. Se ni konsideras neŭtralan oscilon kies amplekso ne pliiĝos nek malpliiĝos, t.e. ni metas la imagan parton de *c* kiel nulon, tiam ni havas realvaloran rilaton inter R kaj α (neŭtralan kurbon de stabileco) kun la reala parto de c kiel parametro. Ĝi estas tio, kion ni kalkulas en ĉi tiu traktato.

§ 4. Nombraj rezultoj kaj diskutoj

La bone starigita procedo de Lin[2] estas aplikata por kalkuli la rilaton inter la nombro de Reynolds R kaj la ondnombro α de la neŭtrala oscilo antisimetria pri la ebeno $y=0$. Nombraj kalkuloj estas farataj por $\tau=0.02$, 0.04, 0.10, 0.25, 0.50 kaj ∞.* Tabelo. I kaj Fig. 4 montras niajn rezultojn. Per ĉi tio ni nun povas diskuti la laŭtempan ŝanĝiĝon de stabileco de la transira fluo komencinta de ripozo.

Tabelo. I. La rilato inter c, α kaj R de la neŭtrala oscilo.

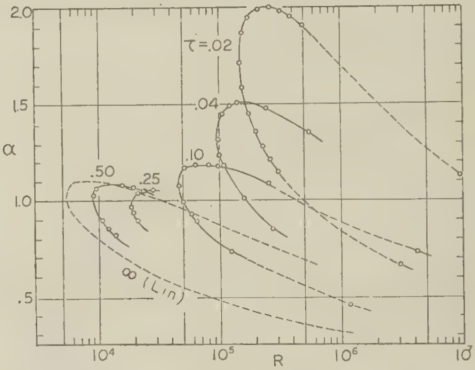

Fig. 4. Neŭtralaj kurboj de stabileco por diversaj valoroj de τ.

Ni povas rigardi la nombron de Reynolds R kiel funkcion de P kaj τ:

$$R(P,\tau)=\frac{hU_m}{\nu}=u(0,\tau)=\frac{P}{2}\{1-f(\tau)\}\,, \tag{4.1}$$

en kiu

$$f(\tau)=4\sum_{n=0}^{\infty}\frac{(-1)^n}{(n+\frac{1}{2})^3\pi^3}\exp\{-(n+\tfrac{1}{2})^2\pi^2\tau\}\,, \tag{4.2}$$

kaj

$$f(\infty)=0\,.$$

---

* Kalkulo pri $\tau=\infty$ nur servas por kontroli nian kalkulan procedon, ĉar oni jam havas rezulton kalkulitan de Lin pri ĉi tiu fluo.

Tabelo. II. La minimumaj krizaj nombroj de Reynolds $R_{kr}^{(\tau)}$ kaj respondaj krizaj ondnombroj $\alpha_{kr}^{(\tau)}$ por diversaj valoroj de τ.

τ	$R_{kr}^{(\tau)}$	$\alpha_{kr}^{(\tau)}$
0.02	15.0 $\times 10^4$	1.808
.04	9.54 〃	1.385
.10	4.63 〃	1.095
.25	1.88 〃	0.988
.50	0.906 〃	1.027
∞ (Lin)	0.531 〃	1.041

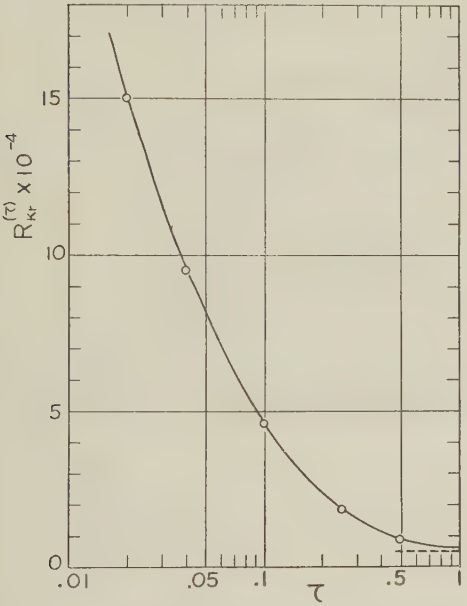

Fig. 5. La minimuma kriza nombro de Reynolds kiel funkcio de τ.

Por fiksa P, $R(P,\tau)$ pligrandiĝas paralele kun τ, dum la kriza nombro de Reynolds $R_{kr}^{(\tau)}$ (la plej malgranda valoro de R sur la kurbo de neŭtrala stabileco de la fluo karakterizata de τ) primalgrandiĝas (Tabelo. II aŭ Fig. 5). Sekve, la ekvacio

$$R(P,\tau)=R_{kr}^{(\tau)} \tag{4.3}$$

donas la rilaton inter la gradiento P de la aplikata premo kaj la kriza momento τ, antaŭ kiu la fluo estas absolute stabila sed post kiu ĝi ne estas tia. Ni atingos ĉi tiun rilaton, aŭ prefere la rilaton inter P kaj la maksimuma rapido $u_m(\tau)$ $(=u(0,\tau))$ ĉe la kriza momento, kiel jene. El ekvacioj:

$$R(P,\tau)=\frac{P}{2}\{1-f(\tau)\}=R_{kr}^{(\tau)}\,, \tag{4.4}$$

$$R(P_\infty,\infty)=\frac{P_\infty}{2} \qquad =R_{kr}^{(\infty)} \doteqdot 5.3\times 10^3\,, \tag{4.5}$$

kaj (4.1), ni ricevas

$$\frac{P}{P_\infty}=\frac{R_{kr}^{(\tau)}}{R_{kr}^{(\infty)}}\frac{1}{1-f(\tau)}=\frac{R_{kr}^{(\tau)}}{R_{kr}^{(\infty)}}\frac{u_m(\infty)}{u_m(\tau)}\,. \tag{4.6}$$

Ĉi tio estas montrata en Fig. 6. En (4.5) kaj (4.6), P_∞ estu tia valoro de P, ke sub la premo de konstanta gradiento P_∞ la fluo fariĝos ne absolute stabila unuafoje ĉe $\tau=\infty$.

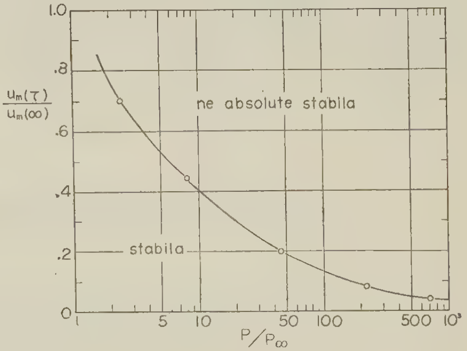

Fig. 6. La rilato inter la gradiento de premo kaj la maksimuma rapido ĉe la kriza momento.

Kiel estis jam rimarkite en § 3, nia kalkula procedo estus pravigita nur por osciloj multe pli rapidaj ol la ŝanĝiĝo de la baza fluo. Oni vere vidos ke ĉi tiu kondiĉo estas plenumita pri niaj kalkulitaj ekzemploj.

La periodo T de la oscilo estas:

$$T=\frac{2\pi}{\tilde{\alpha}\tilde{c}}=\frac{2\pi}{(\alpha/h)U_m c}=\frac{2\pi h}{\alpha c U_m}\,, \tag{4.7}$$

tial la proporcio de ŝanĝiĝo de la maksimuma rapido de la baza fluo al la rapido mem dum unu periodo de la surmetita oscilo estas kalkulata proksimume:

$$\begin{aligned}\frac{1}{U_m}\frac{dU_m}{dt}\cdot T&=\frac{\nu}{h^2}\frac{1}{U_m}\frac{dU_m}{d\tau}\cdot\frac{2\pi h}{\alpha c U_m}\\&=\frac{2\pi}{\alpha c R}\frac{d(\log U_m)}{d\tau}\,.\end{aligned} \tag{4.8}$$

Ni povas meti por malgrandega τ:

$$\frac{d(\log U_m)}{d\tau}=\frac{1}{\tau}\,, \tag{4.9}$$

ĉar tiam U_m estas proporcia al τ pro (2.14).

Kunkonsiderante ke U_m pligrandiĝas pli kaj pli malrapide kiam τ pliiĝas (Fig. 3), ni havas

$$\frac{1}{U_m}\frac{dU_m}{dt}\cdot T \lesssim \frac{2\pi}{c\tau}\frac{1}{\alpha R}\,. \tag{4.10}$$

La dekstra flanko de (4.10) prenas valorojn pli malgrandajn ol 0.7×10^{-2} en ĉiuj niaj ekzemploj, kaj tial estas pravigita nia procedo.

Aliflanke, iu nesimila aliro estus necesa por pli malgrandaj τ aŭ por pli malrapidaj osciloj.

Dankesprimo

Mi kore dankas profesoron Isao Imai por liaj gvidado kaj multvaloraj konsiloj tra la tuta esplorado, kaj ankaŭ la membrojn de lia laboratorio kaj profesoron Tomomasa Tatsumi por diskutoj kun ili. Ĉi tiu esploro povis esti efektivigita per la subvencio de la Ministerio de Eduko.

The Forces experienced by a Lattice of Elliptic Cylinders in a Uniform Flow at Small Reynolds Numbers

By Sinzi* KUWABARA

Department of Physics, Faculty of Science, University of Tokyo

(Received January 8, 1959)

Using Imai's general method of solving two-dimensional Oseen's equations, the drag and lift coefficients for a lattice of parallel, equal and equidistant elliptic cylinders in a uniform flow at small Reynolds numbers are calculated. When the stagger is not present and the thickness ratio of the elliptic cylinders is taken to be unity, the expressions for these coefficients reduce to the case of a lattice of equal and equidistant circular cylinders which has been investigated by Tamada and Fujikawa.

§1. Introduction

The flows past a lattice consisting of equal and equidistant cylinders have been investigated for the case of circular cylinders by Tamada and Fujikawa[1] and by Miyagi[2] and for the case of flat plates by Hasimoto[3] and by the present author[4] on the basis of Oseen's or Stokes' approximation. In this paper, we shall deal with the problem of the same type as mentioned above for the case of a lattice of elliptic cylinders on the basis of Oseen's approximation.

As for the mathematical procedures use will be made of Imai's general method[5] of solving Oseen's equation, which the author has successfully applied to solve the cases of two circular cylinders[6] and two elliptic cylinders[7].

§2. Application of Imai's Method to the Case of a Lattice of Elliptic Cylinders

We consider a flow past lattice of infinitely many equal and equidistant elliptic cylinders. All the elliptic cylinders are placed parallel to each other and at an angle of attack β to the upstream uniform flow. Their mutual dis-

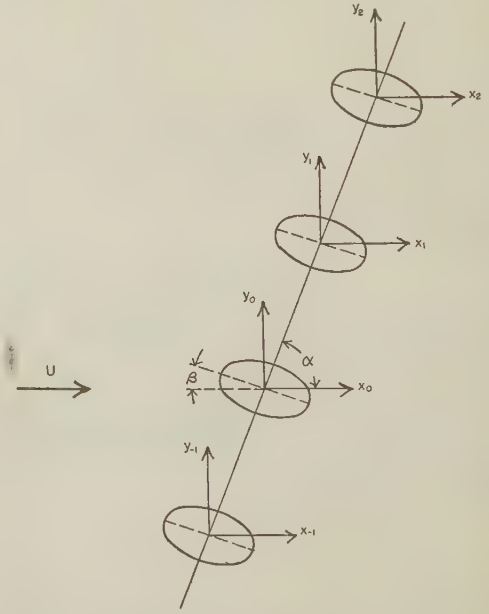

Fig. 1. The general configuration of a lattice of elliptic cylinders.

---

* Sinẓi=Ṣhinji

tance is d and their semi-major and semi-minor axes are $1+\sigma^2$ and $1-\sigma^2$ respectively. We introduce complex variables

$$z_p=x_p+y_p=r_p e^{i\theta_p}\ , \tag{2.1}$$

$$W=u-iv\ , \tag{2.2}$$

where (x_p, y_p) are the cartesian coordinates with the origin at the centre of the pth elliptic cylinder and with the x_p-axis taken parallel to the upstream uniform flow, (u, v) are the velocity components and (r_p, θ_p) the polar coordinates (cf. Fig. 1).

As in the previous paper[6], we can assume the complex velocity W as

$$W=U+\mathcal{E}+\sum_{p=-\infty}^{\infty} W_p\ , \tag{2.3}$$

with

$$W_p(z_p)=e^{kx_p}\sum_{n=0}^{\infty} k^n\{F_{n+1}(z_p)-G_n(z_p, \bar{z}_p)\} \tag{2.4}$$

near the pth elliptic cylinder E_p and

$$W_p(z_p)=\frac{i}{2k}\,e^{kx_p}\left\{A_1K_0(kr_p)+\sum_{n=0}^{\infty}(A_{n+1}\,e^{ni\theta_p}-\bar{A}_n\,e^{-ni\theta_p})K_n(kr_p)\right\}+\frac{df}{dz_p} \tag{2.5}$$

far from E_p. Here U is the velocity of the upstream uniform flow, $\mathcal{E}$, $2k=U/\nu$ (ν being the kinematic viscosity) and A_n are constants and $F_n(z_p)$, $G_n(z_p, \bar{z}_p)$ and $f(z_p)$ are known functions with arbitrary coefficients.

By the transformation function

$$z_p=C(Z_p+\sigma^2/Z_p)\ , \qquad (0\leq\sigma^2\leq 1,\ C=e^{-i\beta}) \tag{2.6}$$

the unit circle $Z_p=e^{i\theta}$ in the Z_p-plane is mapped onto the pth ellipse. In view of the periodicity of the configuration we may employ the boundary conditions:

$$W=U \qquad \text{for} \quad x=-\infty\ , \tag{2.7}$$

$$W=U+\mathcal{E}+\sum_{p=-\infty}^{\infty} W_p(z_p)=0\ , \qquad \text{on the surface of } E_0\,. \tag{2.8}$$

In this paper we shall confine ourselves to the first approximation. Thus we take only the terms of $O(k^0)$ in the complex velocity. Then (2.4) reduces to

$$W_0(z_0)=F_1(z_0)-G_0(z_0, \bar{z}_0)\ , \tag{2.9}$$

where

$$F_1(z_0)=-\tfrac{1}{4}i\bar{a}_0(\ln CZ_0-2S)+P(Z_0^{-1})\ , \tag{2.10}$$

$$G_0(z_0, \bar{z}_0)=\tfrac{1}{4}ia_0(1+\sigma^2\bar{C}^2)-\tfrac{1}{4}i\bar{a}_0\ln CZ_0+2i\{\bar{g}_0'(\bar{z}_0)-\tfrac{1}{8}\bar{a}_0\ln\bar{C}\bar{Z}_0\}+P(Z_0^{-1})\ , \tag{2.11}$$

with

$$\bar{g}_0'(\bar{z}_0)=\tfrac{1}{8}\bar{a}_0\ln\bar{C}\bar{Z}_0+P(Z_0^{-1})\ , \tag{2.12}$$

$$S=\ln(2/k)-\gamma\ , \qquad (\gamma \text{ is Euler's constant}) \tag{2.13}$$

and $P(Z)=\sum_{n=0}^{\infty} C_nZ^n$ where C_n's are arbitrary constants.

We now assume that $kd\geq O(1)$ so that $K_n(kd)\leq O(1)$. Taking the terms of $O(kd)$ in (2.5), we have

$$W_q(z_q)=\pm\frac{i}{2}\left\{K_1(|q|kd)\,e^{-qkd\cos\alpha}-\frac{1}{|q|kd}\right\}e^{-i\alpha}a_0+\tfrac{1}{2}e^{-qkd\cos\alpha}K_0(|q|kd)\bar{a}_0+P(Z_p) \tag{2.14}$$

near E_p. The double sign denotes that the upper sign is to be taken when $q>0$ and the lower sign when $q<0$.

Introducing (2.3) into (2.7) determines $\mathcal{E}$ as follows:

$$\mathcal{E}=-\lim_{z_n\to-\infty}\sum_{n=-\infty}^{\infty}\frac{ia_0}{2k}\frac{1}{z_n}=\lim_{z\to-\infty}\left(\frac{\pi}{de^{i\alpha}}\cot\frac{\pi z}{de^{i\alpha}}-\frac{1}{z}\right)=-\frac{i\pi}{d}e^{-i\alpha}\,. \tag{2.15}$$

Substituting from (2.7). (2.14) and (2.15) into (2.8), we obtain

$$\begin{aligned}&\bar{g}_0'(\bar{z}_0)-\tfrac{1}{8}\bar{a}_0\ln\bar{C}\bar{Z}_0+P(Z_0^{-1})\\&=\frac{1}{4}\left[2iU+\left\{\tfrac{1}{2}(1+\sigma^2\bar{C}^2)-\frac{i\pi}{kd}\cdot e^{-i\alpha}+2T_1e^{-i\alpha}\right\}a_0-(S+2T_0)\bar{a}_0\right]+P(Z_0)\end{aligned}\tag{2.16}$$

on the profile $Z_0=e^{i\theta}$.

For brevity we introduce two constants

$$R=2(1+\sigma^2)U/\nu=4(1+\sigma^2)k\ ,\tag{2.17}$$

and

$$h=d/(1+\sigma^2)\ ,\tag{2.18}$$

in place of k and d. R is the Reynolds number based on the major-axis of the elliptic cylinder. From (2.12) we find that the left-hand side of (2.16) is $P(Z_0^{-1})$ while the right-hand side of (2.16) is $P(Z_0)$. Hence both sides must be separately equal to zero. Thus we have

$$g_0(z_0)=\tfrac{1}{8}a_0\ln CZ_0\ ,\tag{2.19}$$

$$2iU=\left\{-\tfrac{1}{2}(1+\sigma^2\bar{C}^2)+\frac{4\pi i}{Rh}e^{-i\alpha}-2T_1e^{-i\alpha}\right\}a_0+(S+2T_0)\bar{a}_0\ ,\tag{2.20}$$

$$T_0=\sum_{n=1}^{\infty}K_0(nRh/4)\cosh(nRh\cos\alpha/4)\ ,\tag{2.21}$$

$$T_1=\sum_{n=1}^{\infty}K_1(nRh/4)\sinh(nRh\cos\alpha/4)\ ,\tag{2.22}$$

and

$$S=\ln 8(1+\sigma^2)/R-\gamma\ .\tag{2.23}$$

From (2.20) and its complex conjugate, we can determine a_0 as follows:

$$\begin{aligned}a_0=-\frac{2iU}{J}\Big[&S-\tfrac{1}{2}(1+\sigma^2\cos 2\beta)+\frac{4\pi}{Rh}\sin\alpha+2T_0\\&-2T_1\cos\alpha+i\left\{\tfrac{1}{2}\sigma^2\sin 2\beta-\frac{4\pi}{Rh}\cos\alpha-2T_1\sin\alpha\right\}\Big]\ ,\end{aligned}\tag{2.24}$$

where

$$\begin{aligned}J=&\left\{S-\tfrac{1}{2}(1+\sigma^2\cos 2\beta)+\frac{4\pi}{Rh}\sin\alpha+2T_0-2T_1\cos\alpha\right\}\\&\times\left\{S+\tfrac{1}{2}(1+\sigma^2\cos 2\beta)-\frac{4\pi}{Rh}\sin\alpha+2T_0-2T_1\cos\alpha\right\}\\&-\left(\tfrac{1}{2}\sigma^2\sin 2\beta-\frac{4\pi}{Rh}\cos\alpha-2T_1\sin\alpha\right)^2 .\end{aligned}\tag{2.25}$$

Let us define the drag coefficient C_D and the lift coefficient C_L for one of the elliptic cylinders by

$$C_D=\frac{X}{\tfrac{1}{2}\rho U^2\cdot 2(1+\sigma^2)}\ ,\qquad C_L=\frac{Y}{\tfrac{1}{2}\rho U^2\cdot 2(1+\sigma^2)}\ ,\tag{2.26}$$

where X and Y are the drag and lift on the elliptic cylinder. As was shown in the previous paper[8] (cf.Eq. (2.29) there) we have

$$C_D+iC_L=4\pi i a_0/UR\ .\tag{2.27}$$

Hence, substituting from (2.24) into (2.27) and separating real and imaginary parts, we have

$$C_D=\frac{8\pi}{RJ}\left[S-\tfrac{1}{2}(1+\sigma^2\cos 2\beta)+\frac{4\pi}{Rh}\sin\alpha+2T_0-2T_1\cos\alpha\right], \tag{2.28}$$

$$C_L=\frac{8\pi}{RJ}\left[\tfrac{1}{2}\sigma^2\sin 2\beta-\frac{4\pi}{Rh}\cos\alpha-2T_1\sin\alpha\right]. \tag{2.29}$$

§ 3. Special Cases of $\alpha=\pi/2$

These are the cases in which the flow impinges normally upon the surface of the lattice.

(A) *Elliptic cylinders*

i) β=arbitrary (axes of elliptic cylinders included to the lattice surface)

If we put $\alpha=\pi/2$, the expressions (2.28), (2.29), (2.25) and (2.21) reduce respectively to

$$C_D=\frac{8\pi}{RJ}\left\{S-\tfrac{1}{2}(1+\sigma^2\cos 2\beta)+\frac{4\pi}{Rh}+2T_0\right\}, \tag{3.1}$$

$$C_L=\frac{8\pi}{RJ}\tfrac{1}{2}\sigma^2\sin 2\beta\,, \tag{3.2}$$

$$J=\left\{S+\tfrac{1}{2}(1+\sigma^2\cos 2\beta)-\frac{4\pi}{Rh}+2T_0\right\}\left\{S-\tfrac{1}{2}(1+\sigma^2\cos 2\beta)+\frac{4\pi}{Rh}+2T_0\right\}-\tfrac{1}{4}\sigma^4\sin^2 2\beta\,, \tag{3.3}$$

$$T_0=\sum_{n=0}^{\infty}K_0(nRh/4)=\frac{1}{8}\frac{16\pi}{Rh}+\tfrac{1}{2}\ln\frac{Rh}{16\pi}+\frac{\gamma}{2}-\zeta(3)\left(\frac{Rh}{16\pi}\right)^2+\frac{3}{8}\zeta(5)\left(\frac{Rh}{16\pi}\right)^4-\cdots, \tag{3.4}$$

where ζ is Riemann's zeta function.

ii) $\beta=0$ (minor axis parallel to the lattice surface)

$$C_D=\frac{8\pi}{R}\left\{S+\tfrac{1}{2}(1+\sigma^2)-\frac{4\pi}{Rh}+2T_0\right\}^{-1}, \qquad C_L=0\,, \tag{3.5}$$

iii) $\beta=\pi/2$ (major axis parallel to the lattice surface)

$$C_D=\frac{8\pi}{R}\left\{S+\tfrac{1}{2}(1-\sigma^2)-\frac{4\pi}{Rh}+2T_0\right\}^{-1}, \qquad C_L=0\,. \tag{3.6}$$

(B) *Circular cylinders*

$$C_D=\frac{8\pi}{R}\left\{S+\tfrac{1}{2}-\frac{4\pi}{Rh}+2T_0\right\}^{-1}, \qquad C_L=0\,, \tag{3.7}$$

$$S=\ln(8/R)-\gamma\,, \qquad R=2U/\nu\,. \tag{3.8}$$

This expression coincides with the first approximation of Tamada and Fujikawa's corresponding formula for the case of a lattice of circular cylinders.

(C) *Flat plates*

i) β=arbitrary

$$C_D=\frac{8\pi}{RJ}\left\{S-\tfrac{1}{2}(1+\sigma^2\cos 2\beta)+\frac{4\pi}{Rh}+2T_0\right\}, \tag{3.9}$$

$$C_L=\frac{8\pi}{RJ}\tfrac{1}{2}\sin 2\beta\,, \tag{3.10}$$

$$J=\left\{S+\tfrac{1}{2}(1+\cos 2\beta)-\frac{4\pi}{Rh}+2T_0\right\}\left\{S-\tfrac{1}{2}(1+\cos 2\beta)+\frac{4\pi}{Rh}+2T_0\right\}-\tfrac{1}{4}\sin^2 2\beta\,, \tag{3.11}$$

$$S=\ln(16/R)-\gamma\ , \qquad R=4U/\nu\ . \tag{3.12}$$

ii) $\beta=0$ (flat plates perpendicular to the lattice surface)

$$C_D=\frac{8\pi}{R}\left\{S+1-\frac{4\pi}{Rh}+2T_0\right\}^{-1}=\frac{8\pi}{R}\left\{P-2\zeta(3)\left(\frac{Rh}{16\pi}\right)^2+\cdots\right\}^{-1}, \qquad C_L=0\ , \tag{3.13}$$

where

$$P=1-\ln(\pi/h)\ . \tag{3.14}$$

Only the first term of the expression (3.13) coincides with the corresponding formula of the author's previous paper[4] (Eq. (3.14)), which was obtained by Stokes' approximation.

iii) $\beta=\pi/2$ (flat plates lying on the lattice surface)

$$C_D=\frac{8\pi}{R}\left(S-\frac{4\pi}{Rh}+2T_0\right)^{-1}=\frac{8\pi}{R}\left\{\ln(h/\pi)-2\zeta(3)\left(\frac{Rh}{16\pi}\right)^2+\cdots\right\}^{-1}, \qquad C_L=0\ . \tag{3.15}$$

Only the first term of the expression of (3.15) coincides with the corresponding formula of Hasimoto's paper[3] (Eq. (4.36)), which was obtained by Stokes' approximation.

§ 4. Numerical Discussions

We have five parameters to determine the flow, that is, $\alpha, \beta, h, t=(1-\sigma^2)/(1+\sigma^2)$ (the thickness ratio of the elliptic cylinder) and R. Numerical calculations were carried out only for the case when $\alpha=90°$ and $h=10$. The other parameters β, t and R are taken as follows: $\beta=0°$, $18°$, $36°$, $54°$, $72°$, $90°$; $t=0$ (flat plates), 0.1, 0.5, 1.0 (circular cylinders) and $R=0.08$, 0.4, 1.0 (cf. Fig. 2 and Table I).

It is to be noted that by lattice formation the drag of the elliptic cylinder is increased and the lift is reduced in comparison with the

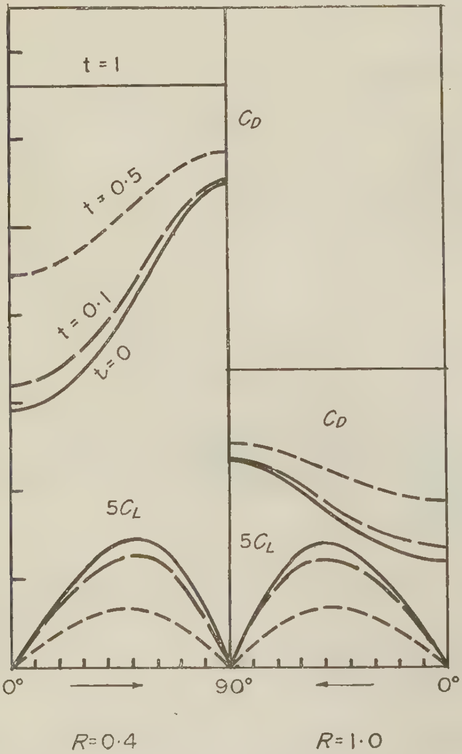

Fig. 2. C_D and C_L vs. β when $h=10$, $\alpha=\frac{\pi}{2}$ and $R=0.4$ and 1.0.

Table I. Calculated values of C_D and C_L for various values of β and R when $\alpha=90°$ and $h=10$.

The Forces experienced by Randomly Distributed Parallel Circular Cylinders or Spheres in a Viscous Flow at Small Reynolds Numbers

By Sinzi* KUWABARA

Department of Physics, Faculty of Science, University of Tokyo

(Received January 8, 1959)

The forces experienced by parallel circular cylinders or spheres which are distributed at random and homogeneously in a viscous flow are investigated on the basis of Stokes' approximation. The results for the case of spheres are applied to the problem of sedimentation and compared with several experimental data.

§ 1. Introduction

Recently a number of investigations have been made on the interference effects submerged in a viscous flow at small Reynolds numbers. However, they have been mostly concerned with the case of two bodies or a regular lattice of infinitely many cylinders. In this parer, we extend such a treatment to the case of infinitely many circular cylinders or spheres which are distributed at random and homogeneously in a viscous flow. These results can be readily applied to the problem of sedimentation of particles of cylindrical or spherical shape. In § 4, we consider the application of our theory to the case of spherical particles, in comparison with other theories and experimental results.

In order to simulate the condition of random and homogeneous distribution of bodies, we take a model such that, in the coordinate system moving with the mean flow velocity U, each one of the bodies is moving with the negative velocity $-U$ in a certain closed surface on which both the normal fluid velocity and the vorticity vanish. The closed surface is taken to be a coaxial circular cylinder or a concentric sphere according as the body is a circular cylinder or a sphere.

---

* Sinzi=Shinji

§ 2. The Case of Parallel Circular Cylinders

In this case, we assume that i) all the circular cylinders have the same radius and the same velocity, ii) they are parallel to each other and perpendicular to the mean flow and iii) they are distributed at random and homogeneously.

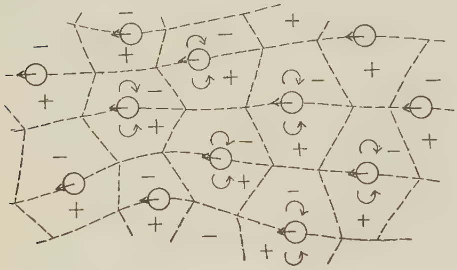

Fig. 1 (a)

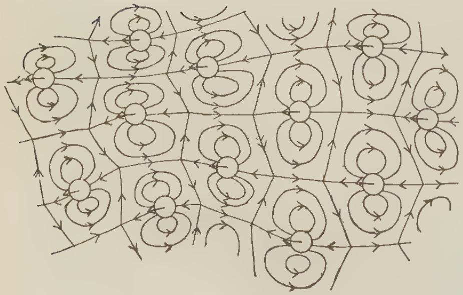

Fig. 1 (b)

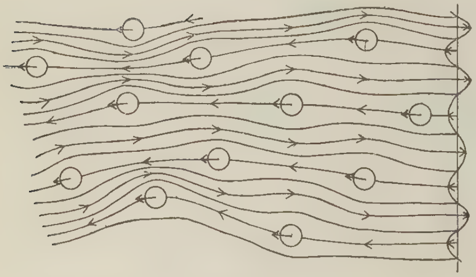

Fig. 1 (c)

Let us assume that the mean flow is directed from left to right. On the upper side of a cylinder the vorticity would be negative and on the lower side positive. Thus, midway between the neighbouring cylinders there will be lines of zero vorticity (the broken lines in Fig. 1 (a)). We may imagine that the streamlines are closed in the neighbourhood of the cylinder in the reference system which is moving at the mean flow velocity (cf. Fig. 1 (b)). In fact, otherwise, we should have a flow pattern consisting of a series of infinitely long strips of fluid with alternating flow direction located side by side (cf. Fig. 1 (c)). It seems however that such a flow would be improbable.

From the above consideration, we take the following mathematical model. We consider an imaginary circular cylinder of radius b enclosing and coaxial with the given circular cylinder of radius a. On the imaginary circular cylinder, the vorticity and the normal component of velocity are assumed to be zero, while on the solid circular cylinder the velocity should be equal to minus the mean flow velocity U (cf. Fig. 2). We take the cross-sectional area πb^2 of the imaginary circular cylinder to be equal to the "free" area corresponding to each solid cylinder, namely

$$\pi b^2 = 1/n \,, \tag{2.1}$$

where n is the number of the solid cylinders per unit area.

To Stokes' approximation the fundamental equation for the two-dimensional steady motion is written as

$$\Delta\Delta\psi = 0 \,, \tag{2.2}$$

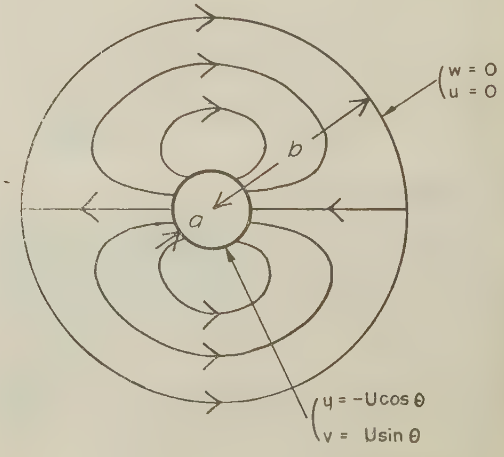

Fig. 2. The model of flow.

where ψ is the stream function such that, using cylindrical coordinates (r, θ), the velocity (u, v) and the vorticity ω are given by

$$u=\frac{1}{r}\frac{\partial\psi}{\partial\theta}\,, \qquad v=-\frac{\partial\psi}{\partial r}\,, \tag{2.3}$$

$$\omega=\frac{\partial v}{\partial r}-\frac{1}{r}\frac{\partial u}{\partial\theta}+\frac{v}{r}=-\varDelta\psi\,, \tag{2.4}$$

where

$$\varDelta=\frac{\partial^2}{\partial r^2}+\frac{1}{r}\frac{\partial}{\partial r}+\frac{1}{r^2}\frac{\partial^2}{\partial\theta^2}\,.$$

The boundary conditions of our model become as follows:

$$u=v=0 \qquad \text{for} \quad r=1\,, \tag{2.5}$$

$$u=U\cos\theta \qquad \text{for} \quad r=l\equiv b/a\,, \tag{2.6}$$

$$\omega=0 \qquad \text{for} \quad r=l\,, \tag{2.7}$$

in the reference system in which the cylinders are at rest*, where U is the velocity of the mean flow parallel to the original line $\theta=0$, and r has been made non-dimensional by taking a as unit.

We have a particular solution of (2.2) in the form

$$\psi=\left(A\frac{1}{r}+Br+Cr\ln r+Dr^2\right)\sin\theta\,, \tag{2.8}$$

where A, B, C and D are arbitrary constants which can be determined so as to satisfy the boundary conditions. Thus, by the boundary conditions (2.5)–(2.7), we have

$$A=\tfrac{1}{2}(U/K)(1-\tfrac{1}{2}l^{-2})\,, \tag{2.9}$$

$$B=-\tfrac{1}{2}(U/K)(1-l^{-2})\,, \tag{2.10}$$

$$C=U/K\,, \tag{2.11}$$

$$D=-\tfrac{1}{4}U/(l^2K)\,, \tag{2.12}$$

where

$$K=P+l^{-2}-\tfrac{1}{4}l^{-4}\,, \tag{2.13}$$

$$P=\ln l-\tfrac{3}{4}\,. \tag{2.14}$$

The drag X experienced by the solid cylinder can be calculated by use of Imai's formula (given as (12.13) in his paper[1]), which is an extension of the Blasius formula to the case of a viscous flow. In our case, the formula can be written simply as

$$X=-2\mu\int_C\frac{\partial\omega}{\partial\bar{z}}\bar{z}\,d\bar{z}\,, \tag{2.15}$$

where $\bar{z}=re^{-i\theta}$ and C signifies the contour of the cross section of the solid cylinder. Thus, we hove

$$X=4\pi\mu C\,. \tag{2.16}$$

The drag coefficient C_D can be obtained as follows:

$$C_D=\frac{X}{\frac{1}{2}\rho U^2\cdot 2}=\frac{8\pi}{RP}\left(1+\frac{1}{l^2P}-\frac{1}{4l^4P}\right)^{-1}$$

$$=\frac{8\pi}{RP}\left\{1-\frac{1}{l^2P}+\frac{1}{l^4P^2}(1+\tfrac{1}{4}P)-\cdots\right\}\,. \tag{2.17}$$

When l tends to infinitely, we have $C_D=0$. This is nothing other than the well-known paradox of Stokes.

§ 3. The Case of Spheres

In this case, we also assume that i) all the spheres have the same radius and the same velocity and ii) they are distributed at random and homogeneously. We use a model similar to the one used in § 2, except that we take, in place of (2.1),

$$\frac{4}{3}\pi b^3=\frac{1}{n}\,, \tag{3.1}$$

where b is the radius of the imaginary spherical surface concentric with the solid sphere.

To Stokes' approximation the fundamental equation for the axisymmetric steady flow is written in terms of Stokes' stream function ψ as

$$\left\{\frac{\partial^2}{\partial r^2}+\frac{\sin\theta}{r^2}\frac{\partial}{\partial\theta}\left(\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\right)\right\}^2\psi=0\,, \tag{3.2}$$

and the velocity and the vorticity are given by

$$u=-\frac{1}{r^2\sin\theta}\frac{\partial\psi}{\partial\theta}\,, \qquad v=\frac{1}{r\sin\theta}\frac{\partial\psi}{\partial r}\,, \tag{3.3}$$

$$\omega=\frac{\partial v}{\partial r}+\frac{v}{r}-\frac{\partial u}{r\partial\theta}\,. \tag{3.4}$$

where (r, θ, ϕ) are the polar coordinates, $(u, v, 0)$ the velocity components and $(0, 0, \omega)$ the vorticity components. Because of symmetry, the ϕ-component of the velocity and the r- and θ-components of the vorticity vanish.

The boundary conditions of our model become

$$u=v=0 \qquad \text{for} \quad r=1\,, \tag{3.5}$$

$$u=U\cos\theta \qquad \text{for} \quad r=l\equiv b/a\,, \tag{3.6}$$

$$\omega=0 \qquad \text{for} \quad r=l\,, \tag{3.7}$$

---

* By the invariance of the Navier-Stokes equations with respect to the Galilei transformation, we can choose any coordinate system suitable for the boundary conditions to be applied.

where U is the velocity of the mean flow parallel to the original line $\theta=0$, and r has been made non-dimensional by taking the radius of the solid sphere a as unit.

We have a particular solution of (3.2)[2] in the form:

$$\psi=\left(A\frac{1}{r}+Br+Cr^2+Dr^4\right)\sin^2\theta\,, \tag{3.8}$$

where A, B, C and D are arbitrary constants. Applying the boundary conditions (3.5)–(3.7) to (3.8), we have

$$A=-\tfrac{1}{4}U\{1-(2/5)l^{-3}\}/K\,, \tag{3.9a}$$

$$B=\tfrac{3}{4}U/K\,, \tag{3.9b}$$

$$C=-\tfrac{1}{2}U(1+\tfrac{1}{2}l^{-2})/K\,, \tag{3.9c}$$

$$D=\tfrac{3}{2}U/(l^3K)\,, \tag{3.9d}$$

where

$$K=\left(1-\frac{1}{l}\right)^3\left(1+\frac{6}{5}\frac{1}{l}+\frac{3}{5}\frac{1}{l^2}+\frac{1}{5}\frac{1}{l^3}\right). \tag{3.10}$$

By (3.3) and (3.4), we have

$$u=-2\left(\frac{A}{r^3}+\frac{B}{r}+C+Dr^2\right)\cos\theta\,, \tag{3.11}$$

$$v=-\left(\frac{A}{r^3}-\frac{B}{r}-2C-4Dr^2\right)\sin\theta\,, \tag{3.12}$$

$$\omega=-2\left(\frac{B}{r^2}-5Dr\right)\sin\theta\,. \tag{3.13}$$

The drag on a sphere may be calculated from the rate of dissipation of energy. The dissipation function Φ has the form

$$\begin{aligned}\Phi=\mu\Bigg\{&2\left(\frac{\partial u}{\partial r}\right)^2+2\left(\frac{\partial v}{r\partial\theta}+\frac{u}{r}\right)^2\\ &+2\left(\frac{u}{r}+\frac{v}{r\tan\theta}\right)^2+\left(\frac{\partial u}{r\partial\theta}+\frac{\partial v}{\partial r}-\frac{v}{r}\right)^2\Bigg\}\\ =12\mu&\left(\frac{3A}{r^4}+\frac{B}{r^2}-2Dr\right)^2\cos^2\theta\\ &+36\mu\left(\frac{A}{r^4}+Dr\right)^2\sin^2\theta\,.\end{aligned} \tag{3.14}$$

Total rate of dissipation of energy in the fluid becomes

$$\begin{aligned}&\int_0^\pi\int_1^l \Phi 2\pi r^2\cdot\sin\theta\,d\theta\cdot dr\\ &=\frac{16\pi\mu}{l^5}\{3A^2(l^2-1)+2ABl^2(l^3-1)\\ &\quad+B^2l^4(l-1)-2BDl^5(l^2-1)+2D^2l^5(l^5-1)\}\,.\end{aligned} \tag{3.15}$$

This is equal to XU where X is the drag experienced by the sphere. Substituting (3.9) into (3.15), we can find the drag and the drag coefficient C_D as

$$X=6\pi\mu U\cdot L(\xi)\,, \tag{3.16}$$

$$C_D=\frac{24}{R}L(\xi) \tag{3.17}$$

where

$$\begin{aligned}L(\xi)=&\left(1+\frac{51}{50}\xi+\frac{3}{50}\xi^2-\frac{7}{25}\xi^3+\frac{2}{5}\xi^4+\right.\\ &\left.+\frac{12}{25}\xi^5+\frac{6}{25}\xi^7+\frac{2}{25}\xi^8\right)(1-\xi)^{-3}\\ &\times\left(1+\frac{6}{5}\xi+\frac{3}{5}\xi^2+\frac{1}{5}\xi^3\right)^{-2}\\ =&1+\frac{81}{50}\xi+\frac{324}{125}\xi^2+\frac{13783}{1250}\xi^3+\cdots\end{aligned} \tag{3.18}$$

and

$$\xi=1/l=a/b\,. \tag{3.19}$$

If we let ξ tend to zero, we have $L=1$. Hence (3.16) reduces to the Stokes formula for the drag of a sphere (of radius 1) in an unlimited viscous flow.

§ 4. Application to the Problem of Sedimentation

This problem has been discussed by a number of authors.[3],[4],[5] Recently Kawaguti dealt with this problem by use of a model such that each one of the particles is represented by a sphere placed in a circular tube with frictionless wall[6]. More recently Hasimoto obtained such solutions of Stokes' equations that are triply periodic and represent the flow past a system of spheres placed at the simple cubic or the body-centred lattice points[7].

We can find the terminal settling velocity of homogeneously distributed sphere by equating the gravitational force to the viscous drag on one of them. The gravitational force is

$$X=(\sigma-\rho)\frac{4}{3}\pi a^3g\,, \tag{4.1}$$

and the drag is, from (3.17),

$$X=6\pi\mu Ua\cdot L(\xi)\,, \tag{4.2}$$

where σ is the density of the particle, ρ that of fluid and a the radius of the particle. Thus, the terminal settling velocity V is given by

$$V/V_0=1/L(\xi)\,, \tag{4.3}$$

where

$$V_0=\frac{2}{9}(\sigma-\rho)ga^2/\mu \tag{4.4}$$

is the terminal velocity of a single particle as given by the Stokes law.

The volume concentration c of particles (the ratio of the volume of particles to the volume of the system) can be related to ξ by

$$c=\frac{4}{3}\pi a^3\bigg/\left(\frac{4}{3}\pi b^3\right)=\left(\frac{a}{b}\right)^3=\xi^3\,. \tag{4.5}$$

Hence we can express (4.3) in terms of c as follows:

$$\begin{aligned}V/V_0&=1/L(c^{1/3})\\&=1-1.62c^{1/3}+0.012c^{2/3}\\&\quad+0.464152c+\cdots\,.\end{aligned} \tag{4.6}$$

For the case of circular cylinders, we can define the volume concentration as follows:

$$c=\pi a^2/(\pi b^2)=(a/b)^2=l^{-2}\,. \tag{4.7}$$

Table I. Calculated values of RC_D for various values of c for the case of circular cylinders by use of (4.8).

c	0.001	0.002	0.003	0.005	0.007	0.01	0.02	0.03	0.05	0.07	0.1
$l=b/a$	31.623	22.361	18.257	14.142	11.952	10.000	7.071	5.774	4.472	3.780	3.162
RC_D	9.292	10.653	11.649	13.199	14.462	16.084	20.501	24.329	31.525	38.761	50.387

Table II. Calculated values of V/V_0 for various values of c for the case of spheres by use of (4.6).

c	0.001	0.002	0.003	0.005	0.007	0.01	0.02	0.03	0.05	0.07	0.1
$l=b/a$	10.000	7.937	6.934	5.848	5.228	4.642	3.684	3.218	2.714	2.426	2.154
V/V_0	0.8388	0.7973	0.7687	0.7263	0.6945	0.6571	0.5719	0.5137	0.4308	0.3703	0.3015

Then (2.17) becomes

$$\begin{aligned}RC_D&=\frac{8\pi}{P}\left(1+\frac{c}{P}-\frac{c^2}{4P}\right)^{-1}\\&=\frac{8\pi}{P}\left\{1-\frac{c}{P}+\frac{c^2}{P^2}(1+\tfrac{1}{4}P)+\cdots\right\},\end{aligned} \tag{4.8}$$

where

$$P=-\frac{1}{2}\ln c-\frac{3}{4}\,. \tag{4.9}$$

§ 5. Numerical Discussions

For the case of circular cylinders, the relation between RC_D and $c=(a/b)^2=1/(\pi n)$ has been numerically calculated and is shown in Fig. 3 and tabulated in Table I. Unfortunately we have no experimental data for this case, so that we cannot compare our theory with experiment.

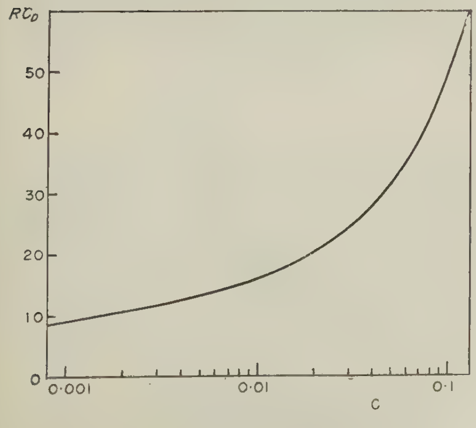

Fig. 3. RC_D vs. volume concentration.

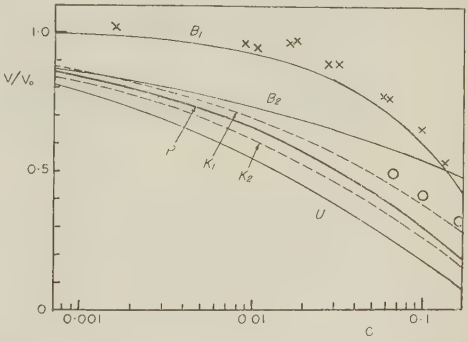

Fig. 4. Sedimentation velocity vs. volume concentration.

For the case of spheres, the relation between V/V_0 and c is obtained as shown in Fig. 4 and tabulated in Table II. In Fig. 4 are also included the theoretical results due to Burgers[5], Uchida[6] and Kawaguti[7], as well as the experimental data of Happel and Epstein[8] and Noda[9]. It is to be noted that the curve V/V_0 against c of our theory lies between Kawaguti's curves for the simple cubic lattice and for the body-centered lattice approximation.

Acknowledgement

The author wishes to express his sincere thanks to Professor Isao Imai for his continual guidance and encouragement throughout this study. He is also indebted to Dr. Mitutosi Kawaguti who kindly furnished him with the data concerning the problem of sedimentation, and to Professor Hidenori Hasimoto and Mr. Hideo Takami for their invaluable discussions.

The Generation of Static Charge on High Polymer

By Shigeyoshi KITTAKA

Department of Physics, Tokyo College of Science, Shinjuku-ku, Tokyo

(Received November 5, 1958)

The generation of static electricity by the contact and seperation between high polymer substances and metals has been studied. The couples of polystyrene-Pt, Acrylite (polymethylmethacrylate)-Pt, and Teflon (polytetrafluoroethylene)-Pt were examined. It was observed that the surrounning conditions have serious effects on the quantity and sign of generated static charge.

The mechanism of generation of electro-static charge has been proposed assuming the energy levels of the localized electrons on the surface of high polymer substances and the change of these energy levels by the absorption of different gases. It was estimated that work functions of polystyrene, Acrylite, and Teflon are 5.74 eV, 5.48 eV and 6.04 eV, respectively.

§ 1. Introduction

The generation of static charge is one of the oldest problems in physics. The electrostatic series of many substances have already been established, and it has been recognized that these may be dependent on some intrinsic properties of insulating materials. However, the exact explanation of these series is not yet established even in recent solid state physics[1-6]. Therefore, we have performed the experiment of generation of static charge by the contact and separation between high polymer substances and metals. The effects of surrounding conditions (oxygen content of air and relative humidity) have been especially carefully studied in the present experiment. The analysis of these experimental results with the idea of surface energy levels[7,8] both on high polymers and metals can give the rough informations of work function of electrons on the high polymer surface, and their change in accompanying with the absorption of various gases in different conditions.

§ 2. Experimental Procedure

The special equipment designed for this experiment is shown in Fig. 1 and 2. The high polymer substances and the metals are brought into contact and then separated gradually. The generated charge on the high polymer test piece is measured in Faraday cylinder (F). The contact potential difference of metal test piece against a standard metal surface (Pt) is also measured. These measurements are repeated several times with successive contact and separation, and whole cycles of experiment are performed in a closed vessel by remote control system. The metal test piece (M) is a small rod of 4 mm in diameter and 2 mm in length, and the high polymer test picece (I) is also a rod of 6 mm in diameter and 100 mm in length. Both test pieces are moved back and forth by servo-motor and brought into contact with same contact force (3.8×10^4 dynes). The bending angle of phosphor bronze plate (P) is measured by reading microscope from the outside of the vessel for the control of contact force.

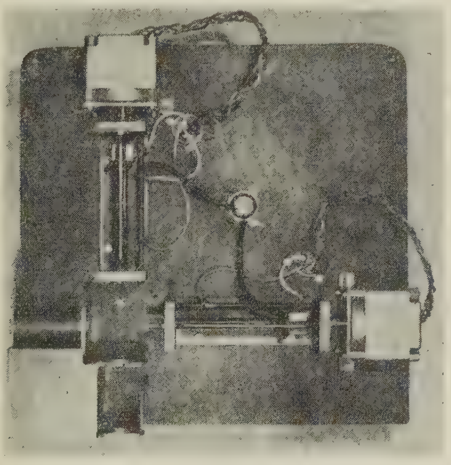

Fig. 1. Contact charging apparatus.

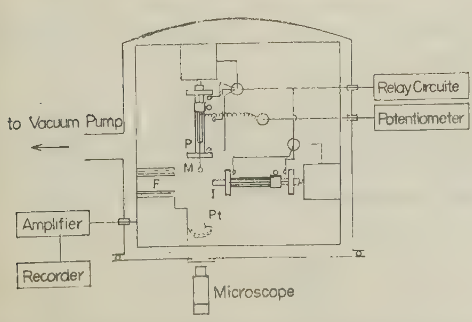

Fig. 2. Schematic diagram of the experimental equipment.

The quantity of electric charge on the high polymer is measured by transporting the high polymer test piece into the Faraday cylinder (F). When the top of the (high polymer) test piece reaches the center of F, the vacuum tube electrometer reading is V_1. In this position almost 95% of the electric lines of force are captured in the cylinder. When the test piece moves back to the original position, the reading of vacuum tube electrometer becomes V_0. Only 1% of the electric lines of force is captured in the cylinder in such a situation.

The absolute quantity of static charge, Q, will be $Q=CV$ $(V=V_1-V_0)$, in which C is electro-static capacity of Faraday cylinder to the earth. The contact potential difference of the metal test piece against the standard metal which is platinum in this experiment, is measured by Kelvin method. The metal test piece is moved to the platinum and the contact potential difference is measured by the potentiometer and vacuum tube electrometer; the latter is the same one as used for the measurement of the charge in Faraday

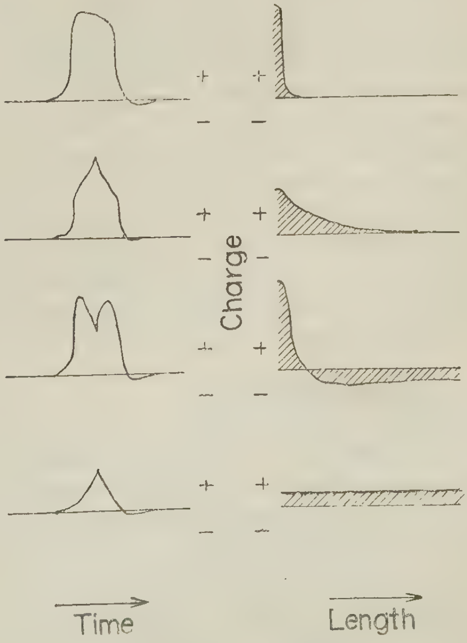

Fig. 3. Relation between the recorded wave form and distribution of charge on sample.

cylinder. The input resistance of vacuum tube electrometer is $10^{12}\Omega$ and connects with the first stage vacuum tube 956. The calibration voltage is applied to the first stage vacuum tube. The total capacity of electrometer is $(50\pm1)\ \mu\mu F$ and the time constant is 50 sec. The measuring period (during which the test piece is moved back and forth) is 12.5 sec. The noise level of the amplifier is 0.2 mV. The accuracy of charge measurement becomes 1×10^{-14}coul. The accuracy of contact potential difference measurement is about 10 mV. This is because the potential difference is divided into the capacity between test piece and standard platinum plate (say $1\ \mu\mu F$) and the input capacity (say $50\ \mu\mu F$).

The charged piece of high polymer is placed in the vessel until all the charges vanish. However, if the dielectric constant of the sample is large enough, the change of input capacitance by inserting the sample affects the voltage of Faraday cylinder. Also the electric conductive sample affects the voltage of electrometer by changing the contact potential. Polystyrene, Teflon and Acrylite have a little effect on input capacity and show regular behaviour in this point. However, the test piece of fused silica shows somewhat different behaviour and the zero point of output signal is hardly obtained.

The form of electrometer reading in the course of experiment gives some informations of distribution of electric charges on the test piece. Square waveform is observed when the charges are concentrated on the top of the test piece. However, in generally, the distribution of charges on the other place of sample gives a more complicated pattern. Typical curves are shown in Fig. 3. These curves also depend on the mechanism of leakage, i.e., leakage through surface conduction or through the surrounding.

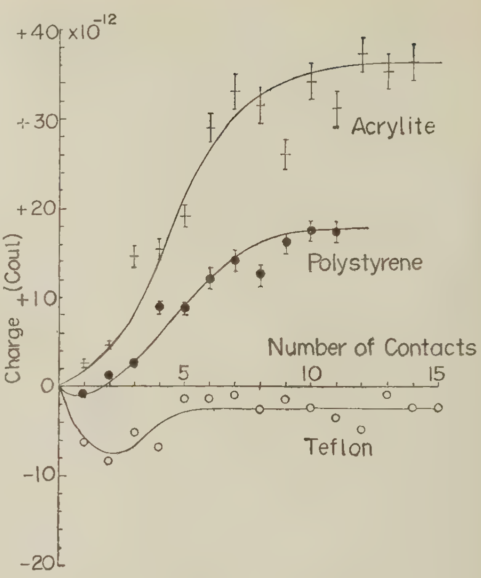

Fig. 4. Static charge on polystyrene, Acrylite and Teflon against Pt vs. contact numbers. at 1 mm Hg.

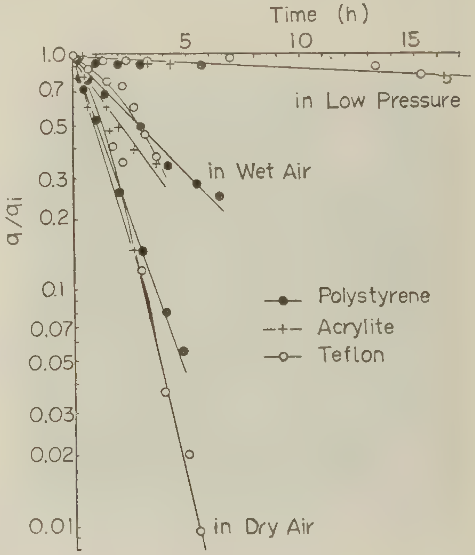

Fig. 5. Leakage curves of charge on high polymer substance. log q/q_i vs. time, q_i is the initial charge.

§ 3. Experimental Results

a) *General*

Fig. 4 shows the results of the experiment performed in vacuum. The generation of static charge showed saturation after 10 times contact and separation. Fig. 5 shows the leakage of electro-static charge in each case. The rate of generation of charge, dq/dt, is

$$\frac{dq}{dt}=\alpha(q_s-q)\ , \qquad (1)$$

were q_s is saturated charge and α is constant. From the results of Fig. 4, α is determined as 0.25 on the high polymer in vacuum.

The leakage of charge by conduction is given by

$$-\frac{dq}{dt}=\beta q\ , \qquad (2)$$

where β is constant which can be determined from the results of Fig. 5, and its value for high polymer is 2×10^{-4} in low pressure air.

From equations (1) and (2) we obtain

$$\frac{dq}{dt}=\alpha(q_s-q)-\beta q\ . \qquad (3)$$

Since the actual value of β is very small compared with α, one can use equation (1) instead of (3) for the analysis of this experiment.

b) *The effect of absorption of water*

Fig. 6 shows the experimental results of polystyrene in dry and wet air.

It is seen that in the dry air the sign of charge on polystyrene is positive, whereas in the 60% R.H. air the sign of charge on polystyrene is negative. This tendency is also confirmed by the experiment in the low pressure 1 mmHg as shown in Fig. 7. In this case the first several contacts and separations produce negative charge, which reaches the maximum. If the experiment is repeatedly performed under this condition, only positive charge is produced from the first contact and separation.

The experimental results of Acrylite are shown in Fig. 8. The sign of charge on Acrylite in the 60% R.H. is positive. But the charging decreases with increasing relative humidity. This we can attribute to decrease in the charge transfered, rather than to increase of surface conductivity.

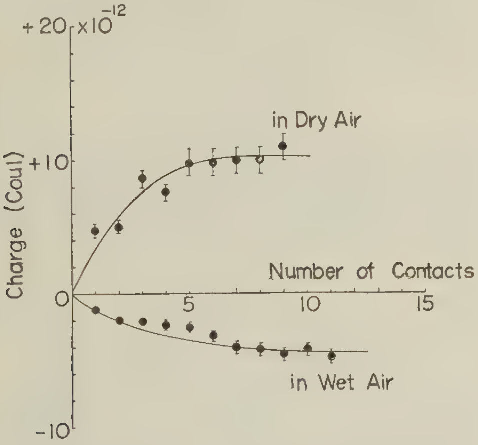

Fig. 6. Effect of absorbed water. Charge on polystyrene against Pt vs. contact numbers in dry air and wet air (60% R.H.)

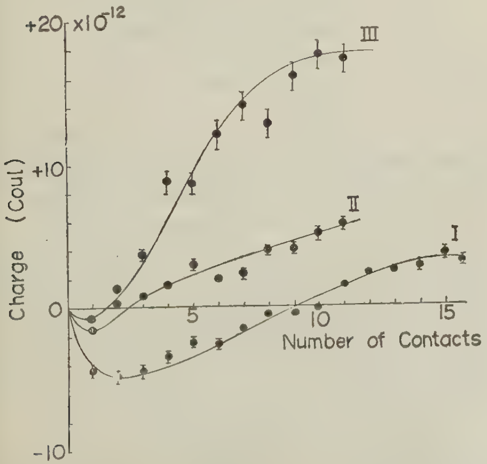

Fig. 7. Effect of absorbed gases. I, II, III, show the order of experiments.

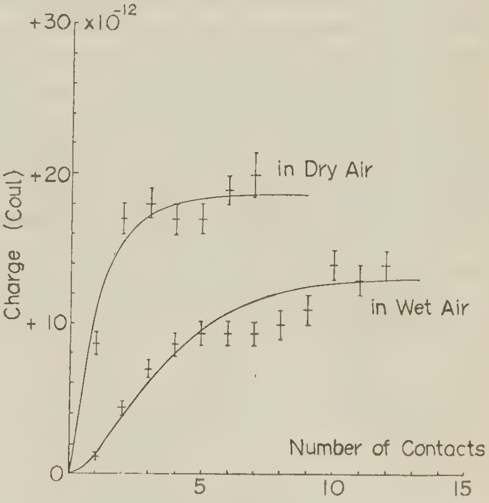

Fig. 8. Effect of absorbed water. Charge on Acrylite against Pt vs. contact numbers in dry air and wet air.

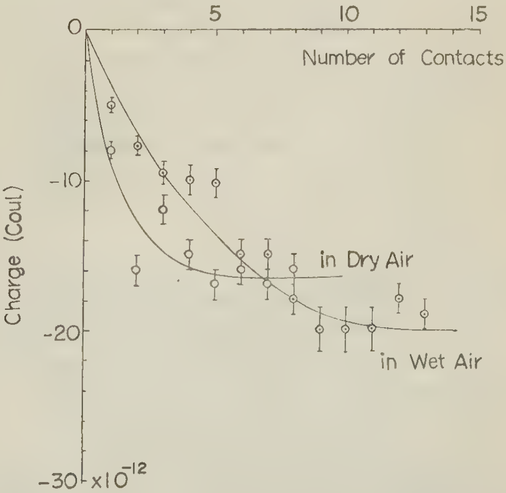

Fig. 9. Effect of absorbed water. Charge on Teflon against Pt vs. contact numbers in dry air and wet air.

The experimental results of Teflon are shown in Fig. 9. In this experiment the sign of charge on Teflon in low pressure is negative. In 60% R.H. air negative charges increase. From these results it seems that the charging on high polymers is shifted to the negative direction with increasing relative humidity.

c) *The effect of the gases*

In the experimental results described in the above sections it is noted that there is a systematic difference between the dry air condition and low pressure condition.

In Teflon-Pt system the negative charge of Teflon is greater in dry air than in low pressure, whereas in case of polystyrene and Acrylite the positive charge of high polymer is greater in low pressure than in dry air.

The experiments in the dry nitrogen gas are carried out and the results are shown in Fig. 10. These results are quite similar to the results in the condition of low pressure. Therefore, the charge difference between the dry air condition and low pressure condition seems to depend on oxygen.

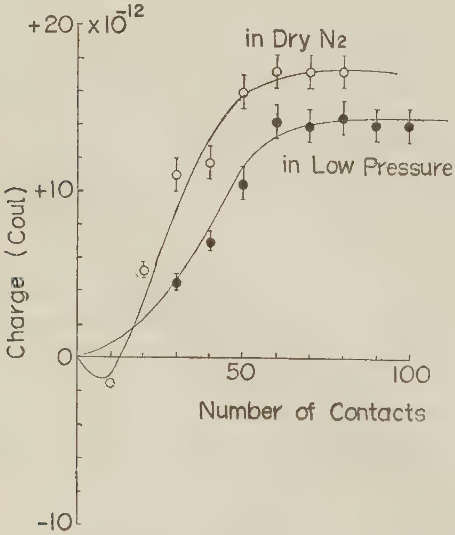

Fig. 10. Charge on polystyrene against Pt vs. contact numbers in dry nitrogen and low pressure.

§ 4. Discussion

a) *The generation of static charges*

Therefore the saturation of static charge in equation (1) will be explained in the following way: We suppose that both metal and high polymer have surface energy levels of electrons which are characterized by work function χ_1 and χ_2 respectively.

The surface energy levels of high polymer are localized and denoted by the dotted line in Fig. 11.

When these two surfaces are brought into contact, the transfer of electrons from one to another occurs and this makes the surface potential barrier which prevents the further transfer of electrons. When the two surfaces are separated, the transfered electrons carry static charge q. In the course of successive contact and separations the contact point of metal and high polymer is moved and the accumulation of static charge is increased.

However, when the potential barrier induced by transfered charges becomes high enough, further contact and separation has no more effect on accumulation of charge.

The saturation charge q_s in this state will be

$$q_s=\frac{A\varepsilon_0}{4\pi d_0}(\chi_1-\chi_2) \qquad (4)$$

were d_0 is average contact distance, A is area of contact and ε_0 is dielectric constant of high polymer. Using this equation we can estimate the relative magnitude of $(\chi_1-\chi_2)$ from the experimental values of saturation charge q_s. The analysis of experimental results in vacuum by equation (4) is tabulated in Table I.

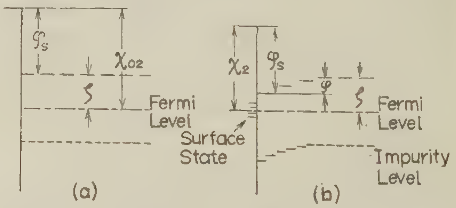

Fig. 11. (a) Energy level diagram of high polymer.
(b) Energy level diagram of polymer surface with absorbed water.

χ_{02} and χ_2 represent the work function, $\chi_2=\chi_{02}-\varphi$. φ is a potential energy change at the surface with absorbed water.

Table I. The charge obtained for high polymer vs. Pt, and estimated work function of high polymer. Assuming that the work function of Pt surface is 6.00 eV and is shifted by about 0.10 eV in wet air.

	q_s($\times10^{-12}$ coulomb)	χ_2 (eV)
Acrylite	36	5.48
polystyrene	18	5.74
Teflon	−2.5	6.04

b) *The effect of absorption of water*

The sign of charge on polystyrene tends to shift toward negative with increasing relative humidity, and the positive charge on Acrylite tends to decrease with increasing relative humidity.

From these experimental results it is concluded that the absorption of water molecule on surfaces of both platinum and polystyrene is the necessary condition for the production of negative charge on the polystyrene. There are several experimental studies[9] in which the absorption of water on the surfaces of metals and semiconductors decreases the surface work function. Hence, one can expect that the surface work function of high polymer will be changed by absorption of water on the surface.

From equation (4)

$q_s \propto \chi_1 - \chi_2$ in 60% R.H. air

$q_{s0} \propto \chi_{01} - \chi_{02}$ in desorbed state,

where

χ_1 is the work function of Pt

χ_2 is the work function of high polymer

The negative sign of q_s means that $\chi_1 < \chi_2$ and further when q_{s0} is positive,

$$\chi_{01} > \chi_{02} .$$

Therefore

$$\chi_{01} - \chi_1 > \chi_{02} - \chi_2 .$$

It follows that the decrease of surface work function of platinum can be greater than the decrease of surface work function of polystyrene, as shown in Fig. 12 schematically.

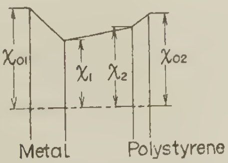

Fig. 12. Schematic diagram of the effect of absorbed water on the work functions of metal and polystyrene.
χ_{01}, χ_{02} are the work function of metal and polystyrene before absorption, χ_1, χ_2 after absorption.

From the experimental results of Acrylite as shown in Fig. 8, positive sign of q_{s0} in dry air means $\chi_{01} > \chi_{02}$. Even in 60% R.H. air q_s is smaller than q_{s0}, but not negative. $\chi_{01} - \chi_{02} > \chi_1 - \chi_2$. These results are explained by the schematic diagram of Fig. 13. The experimental results of Teflon are given in Fig. 9. In this experiment q_{s0} in dry air is negative and it means $\chi_{01} < \chi_{02}$. In 60% R.H. air negative charge is increased; $\chi_{02} - \chi_{01} < \chi_2 - \chi_1$. The results are described by the following schematic energy diagram in Fig. 14.

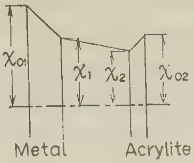

Fig. 13. Schematic diagram of the effect of absorbed water on the work functions of metal and Acrylite.

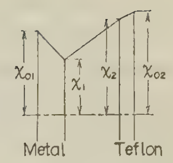

Fig. 14. Schematic diagram of the effect of absorbed water on the work functions of metal and Teflon.

c) *The effects of the absorption of* O_2

In the cases of polystyrene and Acrylite, the positive charge of high polymer is greater in low pressure than in dry air, and the negative charge of Teflon is greater in dry air than in low pressure.

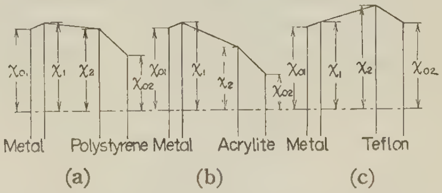

Fig. 15. Schematic diagram of the effect of absorbed O_2 on the work functions of metal and high polymer.
(a) Pt and polystyrene. (b) Pt and Acrylite
(c) Pt and Teflon.

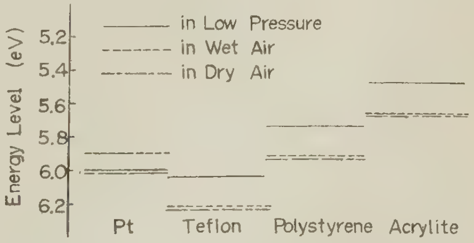

Fig. 16. Schematic energy diagrams of the work function on Acrylite, polystyrene and Teflon. These work functions were calculated from experimental data assuming the work functions of Pt and Pt with absorbed water are 6.00 eV and 5.90 eV respectively.

As shown in Fig. 10 the experimental results in the dry nitrogen gas are quite similar to the results in the condition of low pressure. This suggests that the absorption of oxygen by both surfaces will affect static charges.

There are several studies in which in accompanying with absorption of oxygen on metals and semiconductors surfaces the increase of surface work function was observed⁽¹⁰⁾.

The absorption of oxygen by high polymer can cause the increase of surface work function of high polymer, too.

The difference between q_s in dry air and q_{s0} in low pressure can be explained by the following schematic diagram Fig. 15. It is assumed that there is no appreciable increase of the surface work function by absorption of oxygen on platinum exposed for a long time in room air.

§ Summary

It has been shown in this report that the generation of static charges on high polymers varies with the surrounding conditions. Fig. 16 shows a schematic energy diagram by which the experimental results can be interpreted. From this diagram the work functions of the high polymers are estimated. Moreover, this schematic energy diagram will be applicable to predict the charging of the other high polymer substances.

Acknowledgments

The author wishes to express his cordial thanks to Dr. Jiro Furuichi and Dr. Masatami Takeda for helpful discussions and criticism. He is also grateful to Mr. Akinari Kasai for his assistance in performing the experiment.

On the Low Lying Levels of Mn^{55}, II

By Sadaaki YANAGAWA

Department of Applied Physics, Faculty of Engineering, University of Tokyo, Tokyo

(Received February 24, 1959)

In the previous paper[1], we have discussed the low lying levels of Mn^{55} from the standpoint of the configurational mixings. In that case, the proton configurations for Fe^{56} were assumed to be the mixings of $\{(f_{7/2})^2 J\}$, $\{(f_{7/2} f_{5/2}) J\}$, and $\{(f_{7/2} p_{3/2}) J\}$; and for Mn^{55}, $\{(f_{7/2})^3 J\}$, $\{(f_{7/2})^2 J', f_{5/2} : J\}$ and $\{(f_{7/2})^2 J', p_{3/2} : J\}$. The group of neutrons were frozen to the seniority zero state, though it might be questionable.

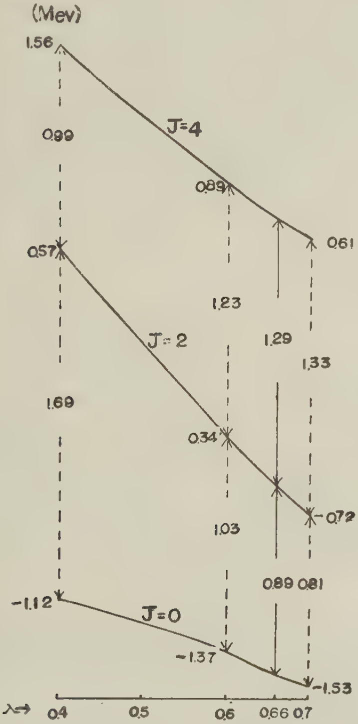

Fig. 1. Fe^{56} $a=0.2$.

We have found it illegitimate however, strictly speaking, to compute them as two and three body problems in the configurational mixings, but we have to calculate them as six and five body problems for Fe^{56} and Mn^{55} respectively. In this paper we assume that the following configurations are mixed with the main configuration $\{(f_{7/2})^{6,5} J\}$.

Fe^{56} $\{(f_{7/2})^4 0, (f_{5/2})^2 0 : 0\}$, $\{(f_{7/2})^4 0, (p_{3/2})^2 0 : 0\}$,
$\{(f_{7/2})^5 J', f_{5/2} : J\}$, $\{(f_{7/2})^5 J', p_{3/2} : J\}$,

where only $J'=3/2$, $5/2$ and $7/2$ are taken into account.

Mn^{55} $\{(f_{7/2})^4 J', f_{5/2} : J\}$, $\{(f_{7/2})^4 J', p_{3/2} : J\}$,

where $J'=0$, 2, 4, 6; and in $J'=2$, 4, the seniority number is assumed to be limited to 2 to simplify the computations.

The method of calculation is completely analogous to the previous one. The two-body interaction is assumed to be of the form $V(r_{12})[1+a(\sigma_1 \cdot \sigma_2)]$, where $V(r)$ is Gaussian potential. For the wave functions, the harmonic oscillator functions are used. The excitation energies of a single nucleon from $f_{7/2}$ to $f_{5/2}$ and $p_{3/2}$ are taken from the new experimental values of the 1st and 2nd excited states of Co^{57}. They are 1.9 Mev and 1.4 Mev respectively[2].

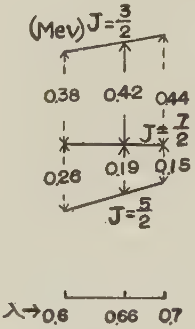

Fig. 2. Mn^{55}.

The results of the calculations for Fe^{56} show that the energy diagrams plotted against the range parameter λ give almost the same features as the previous ones obtained for the same value of the parameter a. (λ is the ratio of the potential range to the constant which determines the extension of the wave function.) It is not surprising that the values of a and λ for both cases, do not differ so much, because the configurations $(f_{7/2})^{\pm 2}$ are reasonably considered to be main for respective case. For $a=0.2$, $\lambda=0.66$, we have solved the secular equations for $J=3/2$, $5/2$ and $7/2$ states of Mn^{55}. The state $J=5/2$ is calculated to be the lowest and the energy splitting between $J=5/2$ and $J=7/2$ is about 0.19 Mev, but the level $J=3/2$ does not agree with the observed value of about 1.5 Mev[3].

Studies on Mercury Fulminate

By Surjit SINGH
TDE(ME) Kirkee, Poona-3 (India)†

(Received December 24, 1958)

Sekiguchi[1] prepared samples of mercuric fulminate at various temperatures by reacting mercury with nitric acid and alcohol in various proportions and observed that at lower temperatures larger proportions of crystals had acute angles of rhomb. Endo and Mashima studied the same reaction and concluded that the reaction product at 45–55°C was mercurous fulminate[2].

This letter describes the extensive study of this reaction in our laboratories and concludes that the end product is a mixture of mercury and mercuric fulminate and not mercurous fulminate as claimed by Endo and Mashima.

The reaction of mercury with nitric acid and alcohol at different temperature ranges (40° to 55°C) was studied and the reaction product was found to consist of crystals of mercuric fulminate with more acute angles of rhomb with occasional pyrimidal crystals (which confirms the observations of Sekiguchi) contaminated with varying quantity of free metallic mercury*. The impure product was crystallised from a 2 : 1 : 1 mixture of ice cold Ammonia (Sp. gr. .88): water: Alcohol and the purified material on analysis gave- Hg=70.40 percent (Hg as HgS): Purity**=99.8 percent.

This clearly shows that the product is mercuric fulminate and not mercurous fulminate.

We have attempted to produce mercurous fulminate by an alternative method. Equimolecular proportions of cold solutions (at −5°C) of sodium or potassium fulminate in methyl alcohol and mercurous nitrate (free from mercuric ion) in dilute nitric acid were mixed together. Immediately an grey amorphous precipitate was obtained. The crude material was dried for one week in an $CaCl_2$ dessicator and on analysis gave, Hg=82.6 percent, purity**=57.6 percent. However, during subsequent purification and crystallisation from Ammonia: Alcohol: water mixture, very large quantities of free metallic mercury were observed as residue. Crystals obtained from the above filtrate on analysis yielded the following results; Hg=70.4 percent; purity**=99.7 percent. This data can only be true for mercuric fulminate. Free mercury in the crude synthetic product was separately estimated and was found to be 41.05 percent. This clearly points out that the crude product was a mixture of equimolecular proportion of free mercury and mercuric fulminate.

Confirmatory evidence as to the above grey compound, even in the solid state being a mixture of free metallic mercury*** and mercuric fulminate is provided by the extreme ease with which a gold wire is amalgamated on passing it a few times through the sample whereas under identical conditions no amalgamation resulted with mercuric fulminate, mercurous nitrate or mercurous chloride.

Some comments on the work of Endo and Mashima will be useful. The presence of mercurous ions in their product was inferred due to the formation of of green mercurous iodide, on addition of potassium iodide to a solution of the substance in dilute nitric acid. It appears that this deduction is not valid, since the free metallic mercury present in the crude product will give rise to mercurous ions with dilute nitric acid and the latter react with potassium iodide to give a green precipitate.

It is well known that some mercurous salts are unstable and decompose into corresponding mercuric state with the liberation of free mercury[3]. Mercurous fulminate also appears to be very unstable and passes spontaneously to mercuric fulminate and free metallic mercury, according to the following reactions.

$$2Na(ON{=}C)_2+Hg_2(NO_3)_2 \longrightarrow 2NaNO_3+Hg_2(ON{=}C)_2$$

$$Hg_2(ON{=}C)_2 \longrightarrow Hg+Hg(ON{=}C)_2$$

Full details will be published elsewhere.

The author is grateful to Prof. D. S. Kothari, Scientific Adviser to the Minister of Defence, for his encouragement and interest throughout the progress of this work. Thanks are also due to Prof. S. Uda for deciphering the paper in Japanese by Endo and Mashima.

Low Temperature Thermoelectric Power of Cu–Mn Alloys

By Seiichi TANUMA

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai

(Received February 20, 1959)

It is known that the dilute alloys of copper with manganese show a minimum in the resistance-temperature curve in the low temperature region followed by a maximum at the lower temperatures[1)-3)]. We have measured the thermoelectric power of these alloys in this range of temperatures. The ingots which were made by melting oxygen-free copper (99.997% purity) and electrolytic manganese in vacuum were forged and cold-drawn to the wires of 0.3 mm in diameter and then annealed at 700°C for 5 hours. The thermoelectric power was measured by constructing a thermocouple with each alloy wire as an arm and a pure annealed copper wire as the reference arm. Thermoelectric voltage (E) of each couple was obtained as a function of the temperature difference between the hot junction immersed in melting ice and the cold junction in the cryostat, temperature (T) of which was varied from 4.2°K to about 200°K. The relation between E and T was plotted in Fig. 1. In all specimens, the sign of thermovoltage was such that the current flows from the copper wire to the alloy wire at the cold junction. Graphical determinations of the gradients of the $E-T$ curves at various temperatures gave the thermoelectric powers relative to copper as shown in Fig. 2. The absolute thermoelectric power (S) of the alloy can be obtained by adding algebraically the absolute thermoelectric power of copper[4),5)] which is denoted by the curve 0_A in Fig. 2. As an example, the curve 1_A is thus obtained for the absolute thermoelectric power of specimen No. 1.

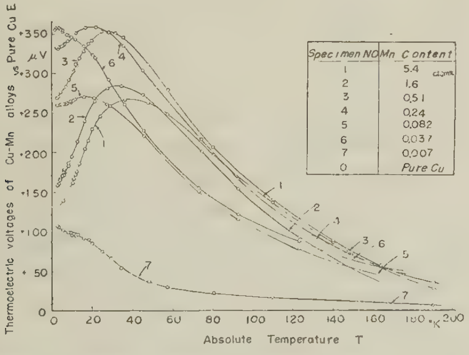

Fig. 1. Thermoelectric voltages of Cu–Mn alloys *versus* pure copper between the abscissa temperatuer and 0°C.

The absolute thermoelectric powers of Cu–Mn alloys, at intermediate temperatures, have negative sign and coincide generally with the values measured by Otter[6)] above the temperature of liquid air. In the $S-T$ curve at low temperatures, however, there appears a minimum followed by a maximum with lowering temperature. This seems to be a characteristic feature of these alloys which display a minimum and a maximum in the resistance (ρ)-temperature curves. The temperature where the maximum or the minimum appears in the $\rho-T$ curve and this point in the $S-T$ curve vary regularly with solute concentration respectively, but the coincidence between them is not necessarily observed. The thermoelectric minimum in these alloys is similar to the anomalous minimum reported in Cu–Sn alloys[4)]. Taking into account of the fact that Cu–Sn alloys show a maximum neither in resistance nor in thermoelectric power, the existence of the maximum in Cu–Mn alloys suggests some complicated factor entering into the nature of the *resistance minimum*. Perhaps this relates to the magnetic properties of solute ions in this alloys[7)].

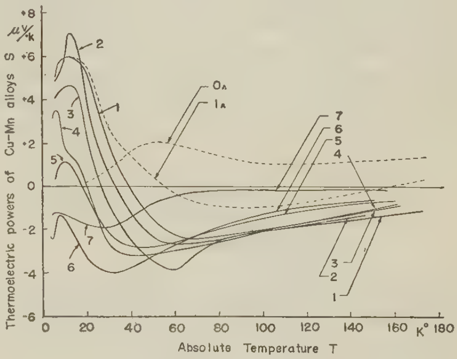

Fig. 2. Thermoelectric powers of Cu–Mn alloys.

The author wishes to express his sincere thanks to Prof. T. Fukuroi and to Assist. Prof. Y. Shibuya for their kindness of giving experimental facilities and stimulating discussions. A part of this work owes to the Scientific Research Fund of the Ministry of Education.

Simplified Representations on the Firing Characteristics of Vibrational-Ignitor Tubes

By Setsuo OKANISHI and Hitoshi KANAMORI
Shimadzu Seisakusho Ltd., Kyoto

(Received February 10, 1959)

We have measured the firing probabilities of vibrational-ignitor tubes, in regard to several variables which are shown in Fig. 1. It was found, however, that such many variables could be reduced to three variables i, L_e and E^n/L $(1<n<2)$, and that general firing characteristics might be simply composed as in Fig. 2, as a conclusion. Where i is the instantaneous value of ignitor current, immediately before an ignitor is pulled up from the surface of a mercury cathode. Those characteristic curves have been explained by considering next two steps as firing process, as same as an ignitron[2)-4)] i.e., production of a cathode spot and stabilization of anode arc. In Fig. 2, abscissa takes i and ordinate takes the firing probability. Curve A shows the probability of cathode spot production, which may be reckoned as a function of i and fixed in such coordinates. Other variables influence it very little. Curve B shows the probability of stabilization of anode arc caused by a cathode spot. It is a function of i, L_e and E^n/L, where $1<n<2$, so that the last two variables are taken as parameters. And, the greater L_e and the greater E^n/L make probability the greater. Finally, curve C shows the probability of production of the arc between an ignitor and a cathode, added to curve B. It is also a function of i, L_e and E^n/L, in the case of greater i and L_e than those of curve B. Actual firing characteristics must be composed as 1–2–3 in Fig. 2, because a tube fires when those two conditions are filled. E_e only influences curve C at small L_e and large i; except that, E_e may be neglected compared with the voltage spike being proportional to L_ei, which produces arc between an ignitor and a cathode. E_e, L_e, R_e and R should not be considered directly.

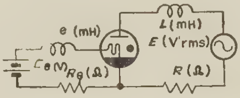

Fig. 1. The circuit and its parameters.

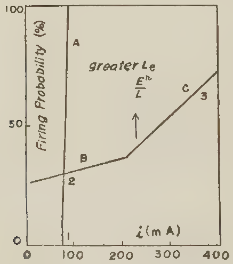

Fig. 2. The typical characteristics composed by 3 curves.

Some actual data are shown in the case of resistive load (Fig. 3). The characteristic curves are occupied by curve A, except upper part near 100%. In that of inductive load, curve B and C appear (Fig. 4). Thus, the possibility to simply represent the characteristics is found, instead of using many parameters in Fig. 1.

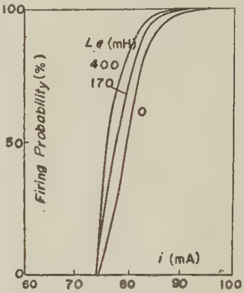

Fig. 3. The firing characteristics in the case of pure resistive load $E=200\sim600$ V, $R=10\sim160\,\Omega$, $E_e=6\sim30$ V.

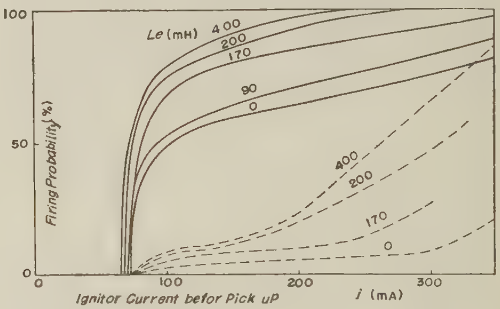

Fig. 4. The firing characteristics in the case of inductive load. Solid lines show the case of $E=600$ V, $L=370$ mH. Broken lines, $E=200$ V, $L=370$ mH.

Cyclotron Resonance in Gas Discharge

By Kuniya FUKUDA, Hiroaki MATUMOTO,
Yoichi UCHIDA and Hisamitsu YOSHIMURA

*Department of Physics, Faculty of Science,
Kyoto University*

(Received February 19, 1959)

The dispersion of cyclotron resonance in gas discharge was measured at microwave frequency of 24,000 MCPS[1)-3)]. Discharge of air was held between a fine kovar wire ($\phi_a=0.5$ mm) inserted coaxially into the cylindrical cavity ($\phi_b=8$ mm) and the cavity wall. Magnetic field was applied perpendicular to the axis of the cylindrical cavity. Pressure of gas was monitored by an oil manometer and a thermister vacuum meter.

The TEM mode of cavity is perturbed only slightly for the exciting wavelength $\lambda<\pi(\phi_a+\phi_b)$[4)]. It may be, however, allowed to use the Langevin equation of motion of electrons in constant homogeneous magnetic field (along z-axis) and oscillating electric field (in xz-plane), which leads to the following equation for the imaginary part of the complex conductivity corresponding to microwave dispersion:

$$\sigma^x_{\mathrm{imag}}=\frac{Ne^2\tau}{m}\,\frac{\omega\tau(\omega_c{}^2\tau^2-\omega^2\tau^2-1)}{(1-\omega^2\tau^2+\omega_c{}^2\tau^2)^2+4\omega^2\tau^2}\,,$$

where ω is microwave frequency, τ mean free time of electron, ω_c cyclotron frequency and N electron density.

Experimental curves of dispersion I, II, and III show in Fig. 1 correspond to those at 1.4 mmHg, 1 mmHg and 0.5 mmHg of gas pressure respectively. They approximately fit the above Lorentzian expression with $\omega\tau\geq 1$. It is possible, therefore, to determine τ-values from the magnitude of magnetic field, giving the dispersion maximum: $\tau=3.9\times10^{-11}$ sec for 1.4 mmHg, 4.6×10^{-11} sec for 1 mmHg and 8.1×10^{-11} sec for 0.5 mmHg respectively. On the other hand, mean free time can also be estimated from the quality factor Q and the resonance frequency shift at zero field $\Delta\omega$ of the cavity under gas discharge, using the relation: $\omega\tau=2Q\Delta\omega/\omega$ $(=\sigma_{\mathrm{real}}/\sigma_{\mathrm{imag}})$. In our case $Q\approx1{,}000$ at each pressure, so that the values of τ are in the range of $3\sim1\times10^{-11}$ sec.

These values of τ derived in two different ways are in good agreement in the order of magnitude with each other, though experimental curves have somewhat complex behaviors in the region near zero field. Electron density in gas discharge is estimated to be of the order of 10^{10}/cc from the dispersion at zero field with $\tau\approx10^{-11}$ sec[6)-8)].

In our experiments the applied electrostatic field, together with the magnetic field, may cause considerable disturbances on the distribution of electron density. It may be preferable for the discharge current to have the same direction as that of the magnetic field. The investigations on other gases over wider pressure range, as well as the refinements of experimental conditions, are now in progress in our laboratory.

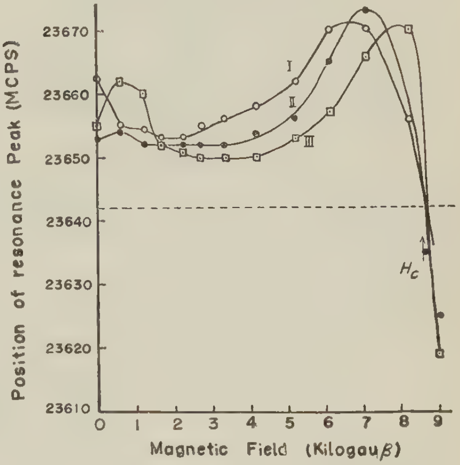

Fig. 1. Curves of the shift of microwave resonance frequency *versus* applied magnetic field. H_c is magnetic field at cyclotron resonance frequency, which is connected with cyclotron frequency ω_c as $\omega_c=eH_c/mc$. Dashed line shows the resonance frequency without discharge.

Effects of γ-Rays on Aqueous Solutions of Synthetic Polymers

By Shintaro SUGAI, Mitsuo ISHIKAWA
and Jiro FURUICHI
Physics Department, Faculty of Science,
Hokkaido University, Sapporo,
Hokkaido, Japan

(Received February 20, 1959)

There has been as yet only a few researches concerning the effects of ionizing radiation on synthetic polymer solutions[1].

In the studies herewith reported, observations were made of the effects of γ-rays from Co^{60} on aqueous solutions of synthetic poly electrolyte Na-CMC, of which the average degrees of polymerization and etherification are respectively 560 and 0.685.

According to ultracentrifugal figures of considerably concentrated solutions, Na-CMC used in the present case seems to be a mixture of two group, one of which has a larger average molecular weight than the other.

Oxygen was not excluded from water and methyl-alcohol used as solvents and the irradiation was carried out under atomospheric pressure.

In Table I, decreases of specific viscosity due to irradiation are tabulated. Changes of molecular weights calculated from the intrinsic viscosity and those of ultracentrifugal coefficients respectively are indicated in Table I and II.

Table I. Decreases of specific viscosity of Na-CMC aqueous solutions under various conditions of irradiation.

〃	850	0.56	0.785

P, P_0: degrees of polymerization of irradiated and original molecules.
N: number of scissons per original molecules.

It seems that the main results in the present studies may be put in order as follows:

1) The molecular degradation only is an essential process in irradiated Na-CMC aqueous solutions.

2) Except in the extremely dilute, cases, typical kinetics of the indirect effect through the activated solvents is clearly observed[2]. The effective protection due to presence of methyl-alcohol and dependency of degradation upon molecular extension seem also to be symptomatic of the indirect effect.

3) From the change of the ratio of two components due to irradiation as shown in Table III.

the random fractures of polymer chains may be reasonably assumed³⁾.

Table III. Changes of ultracentrifugal figures.

c	dose	s_1	s_2	f_1/f_2
gr/cc	r	sved.	sved.	
2.4×10^{-3}	0	2.0	7.9	2.0

6.7×10^{-4}	0	2.5		∞
〃	3800	2.1		∞

s_1, s_2: sedimentation coefficients of two groups.
f_1, f_2: percentage of components of two groups.

Effect of irradiation on the electrical conductivity was also observed⁴⁾. At low temperatures, the conductivity of the irradiated solution is clearly greater than that of non-irradiated one, however that difference is very small at higher temperatures.

The details will soon be published.

Maximum Principles for Vorticity in Viscous Fluid

By Tosio KATO and Hiroshi FUJITA
Department af Physics, University of Tokyo

(Received February 24, 1959)

The object of the present note is to point out that *maximum principles* hold for the vorticity in any two-dimensional flow, stationary as well as non-stationary, of an incompressible viscous fluid. These principles are analogous to the familiar ones for the Laplace and heat equations.

The vorticity is given by $\omega=\partial v/\partial x-\partial u/\partial y$ in terms of the velocity components u, v of the fluid and satisfies the differential equation

$$\frac{\partial\omega}{\partial t}-\nu\Delta\omega+u\frac{\partial\omega}{\partial x}+v\frac{\partial\omega}{\partial y}=0 \tag{1}$$

in the free space, where ν is the kinematic viscosity coefficient. If the flow is stationary, (1) reduces to

$$-\nu\Delta\omega+u\frac{\partial\omega}{\partial x}+v\frac{\partial\omega}{\partial y}=0\,. \tag{2}$$

Note that (1) and (2) can be regarded as *linear* differential equations for ω, whenever a definite flow u, v is being considered.

The maximum principles are given by the following theorems, in which D denotes an arbitrary domain of the x, y plane occupied by the fluid and C is the boundary of D.

Theorem I. *If the flow is stationary, the maximum and the minimum of ω in D are attained on C.*

Theorem II. *If the flow is non-stationary, the maximum and the minimum of ω in the cylindrical domain of the x, y, t space with (x, y) in D and $t_0\leq t\leq t_1$ are attained either on the "bottom" ($t=t_0$) or on the "vertical side" ((x, y) on C).*

If follows from Theorem I, for example, that the vorticity ω of a stationary flow always lies between its maximum ω_+ and minimum ω_- taken on the surface of the obstacle (assuming that $\omega\to0$ at infinity and that $\omega_-\leq0\leq\omega_+$).

The proof of these theorems are rather simple. To prove Theorem I, let ω_+ be the maximum of ω on C. Then $\omega'=\omega-\omega_+$ satisfies the same linear differential equation (2) as ω and its boundary values on C are non-positive. It follows from a standard argument¹⁾ that ω cannot take positive values in D. Thus $\omega\leq\omega_+$ and ω_+ is the maximum of ω in D. The minimum can be dealt with similarly. To prove Theorem II, let ω_+ be the maximum of ω on the bottom and the vertical side of the domain considered. Then $\omega'=\omega-\omega_+$ satisfies the same linear differential equation (1) as ω. Set $\omega''=e^{-ct}\omega'$ with an arbitrary $c>0$. ω'' satisfies the linear differential equation

$$\frac{\partial\omega''}{\partial t}+c\omega''-\nu\Delta\omega''+u\frac{\partial\omega''}{\partial x}+v\frac{\partial\omega''}{\partial y}=0$$

and its values are non-positive on the bottom and the vertical side. From this it follows again²⁾ that ω'' cannot take positive values in the domain of x, y, t space in question. This proves that $\omega'=e^{ct}\omega''\leq0$ and therefore that $\omega\leq\omega_+$. Thus ω_+ is the maximum of ω. The minimum can be treated similarly.

It appears that these maximum principles cannot in general be extended to three-dimensional flows. They are valid, however, in some special cases. In a stationary, axially symmetric flow, for example, analogues of Theorems I and II are seen to hold for the maximum of $|\omega|$ in any domain in which the radial velocity is non-positive.

Interaction of Exciton with *R* Center in KCl Crystal

By Masayasu UETA and Masamitsu HIRAI
Department of Physics, Faculty of Science, University of Tohoku, Sendai

(Received February 27, 1959)

For the investigation of energy transfers which take place between the exciton and electron or hole trapping centers, the interaction with color centers in alkali halide crystals will be one of the most appropriate subjects on account of the fact that the structures of color centers and exciton have been studied so far extensively in these crystals. In the previous report[1] the effects of the exciton upon *F* and *U* centers in KCl and KBr crystals were described and it has been observed the quantum efficiencies for the bleaching of *F* centers and for the conversion of *U* centers to *F* centers by the ultra violet lights, of which wavelengths are in the region of the fundamental absorption tail, are greater than unity and thus the thermal effect of the exciton was discussed.

If the KCl crystal containing only *F* centers are illuminated with *F* absorption light, the complex centers of *R*, *M*, *N* and *K* are enhanced with the consumption of *F* centers. When this crystal is heated in dark, R_1 and R_2 bands are the first to disappear at the temperature slightly below 100°C. Thus, it is clear that *R*-center is most thermally unstable among these centers though it is stable optically. Therefore, assuming that the exciton produce the thermal spike as suggested by Seitz[2] and the thermal effect on *F* and *U* centers discussed in our previous report is correct, *R* center will be destroyed first of all when the crystal containing complex centers are irradiated by the ultra violet light in the exciton absorption band. The following result is considered to provide one possibility of this evidence.

A KCl crystal containing *F* centers with the density of 1.5×10^{17} per cubic centimeters was irradiated at room temperature with a high pressure mercury lamp through a green filter which transmits only the monochromatic light of Hg 5461 A. The irradiation period was so long that, equilibrium state between *F* centers and other complex centers was established and any more irradiation did produce no change in the absorption curve. The absorption curve of the crystal in the equilibrium state is shown in Fig. 1 (a). For the ultra violet light to form excitons a hydrogen discharge tube was used. The window material of the tube was a crystal-quartz plate which is transparent down to 1700 A.

At first, the crystal of which absorption curve is shown in Fig. 1 (a) was irradiated at room temperature for one minute with the hydrogen lamp through a filter of pure KBr crystal-plate of thickness $d=0.9$ mm, but any appreciable change of the absorption curve was not observed. However, against the same period of irradiation through a filter of pure KCl crystal-plate, a large change was detected: namely, *R* bands decreased and *F* band increased. Successive irradiations of ultra violet light with the KCl filter destroyed *R* bands completely and the electrons were transfered to *F* centers as shown in Fig. 1 (b). It is shown from the figure that *K* and *N* bands also decreased, but with a slower rate compared to *R* bands.

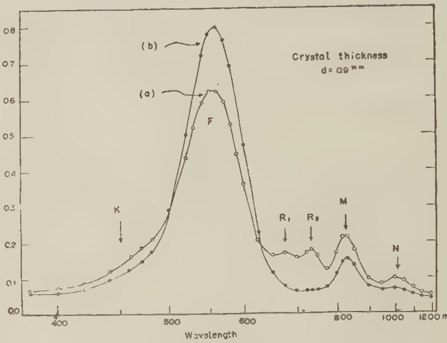

Fig. 1. a) The equilibrium state between *F* and complex centers. b) After the irradiation with exciton light for 20 minutes at 17°C.

From the fact that the ultra violet light filtered with KBr crystal has no appreciable effect, the wavelength of the photon which is effective upon the bleaching of *R* centers is shorter than that of the edge absorption of KBr crystal: i.e. 205 mμ. On the otherhand the KCl crystal ($d=0.7$ mm) is transparent down to 185 mμ and the tail of the fundamental absorption band extends to 210 mμ[1]. The total photon number of the ultra violet lights included in the region between the wavelengths of transmission limits of KCl and KBr crystals: (185 mμ–205 mμ) were measured with a thermopile as 8×10^{14} quanta per cm^2 per sec. at the position of irradiated crystal. From these facts, it is safely concluded that the observed photo chemical reaction can be attributed to the exciton.

To obtain the quantum efficiency for the reaction and the quantitative discussion, investigation on the thermal stability of *R* bands and the detailed absorption spectrum of the exciton absorption tail of the crystal containing the complex centers have being carried out.

ANNOUNCEMENT

REVISED Price List of Back Numbers (for subscribers abroad)

*Vols. 1–4	$ 6.40 each
*Vols. 5 & 6	$13.00 each (single copy: $2.50)
*Vols. 7 and succeeding ones	$ 8.00 each (single copy: $1.50)

Back number prices are effective for volumes other than last four (4) volumes (the current volume inclusive).

Thus, volumes 1 through 16 will be regarded as back numbers while volume 20 is being published.

The revised prices will be effective on and after August 1, 1958.

Elastic and Inelastic Scattering of 22 Mev Alpha Particles by Light Elements

By Chuin HU, Shohei KATO, Yukiyasu ODA
and Minoru TAKEDA

Department of Physics, Faculty of Science,
Osaka University, Osaka, Japan

(Received December 8, 1958)

The scattering of 22 Mev alpha particles from carbon, magnesium and silicon has been studied with scintillation counter technique. The elastic scatterings from carbon and magnesium have shown the characteristic diffraction pattern, which can be obtained from the theory of diffraction by an opaque sphere. The observed inelastic angular distributions could be approximated by the squares spherical Bessel function of second order as predicted by direct interaction theory. The agreement is appreciably good for our elements. However, the cross sections do not tend toward small values in the forward direction for magnesium and silicon.

§ 1. Introduction

Recently many experiments on the elastic and the inelastic scattering of alpha particles by various elements have been reported[1),2)]. The angular distributions of elastically scattered alpha particles by light nuclei in these experiments have been characterized by the appearance of diffraction patterns. It seems that these features can be interpreted well in terms of the optical model analysis, and many calculations were carried out[3)]. These calculations uses generally the depth of real and imaginary potentials, nuclear radius and boundary diffuseness, and they are appreciably complicated. But, in some cases, these diffraction patterns are also interpreted more simply by the classical point of view to give the interaction radius of incident particles and target nucleus. Because of short wave length and spinless properties of incident alpha particles, the elastic scattering of alpha particles has some analogy with the diffraction of light scattered by sphere[4)]. In order to calculate the differential cross sections, it is convenient to assume that the target nucleus can be represented as an opaque sphere, then one may find

$$\frac{d\sigma}{d\Omega}=k^2R^4\left[\frac{J_1(2Rk\sin(\theta/2))}{2Rk\sin(\theta/2)}\right]^2. \qquad (1)$$

The range of validity of this expression is restricted by some conditions on the scattering angle θ. On the other hand, the differential cross sections of inelastically scattered alpha particles were found to vary strongly with scattering angle, suggesting a direct interaction process of nuclear reaction. The form of the angular distribution based on the direct interaction proposed by Austern, Butler and McManus[5)] is found to be

$$\sigma(\theta)=\sum_l a_l[j_l(qa)]^2 \qquad (2)$$

and the interaction radius, which is chosen so as to make the curve of and angular distribution best fit, is determined. It is an interesting problem to compare the magnitudes of interaction radii obtained from both analysis of the elastic and inelastic sacttering data.

An another interesting feature of inelastic scattering of alpha particles is related with the isotopic spin selection rule. According to this prediction, bombardment of alpha particles cannot lead to any state of intermediate nucleus with different isotopic spin from that of the target nucleus, and in the case of inelastic scattering of alpha particles, only states with the same isotopic spin as the ground state can be excited. In fact, it has been shown experimentally[2)] that the probabilities of excitation forbidden by this selection rule are smaller than few percents of those of the allowed levels.

In the present experiment, the target of C^{12}, Mg^{24} and Si^{28} were bombarded by 22 Mev alpha particles accelerated by Osaka University cyclotron and the differentical cross sections of elastically and inelastically scattered alpha particles were measured by the scintillation counter. The appeared levels in our experiment have the same isotopic spin with the ground state.

§ 2. Experimental

The alpha particles were produced in Osaka University 44″ cyclotron by accelerating doubly ionized helium atoms to an energy of 22 Mev. A schematic diagram of the cyclotron, scattering chamber, and NaI scintillation counter was illustrated in our previous paper⁶⁾.

In the present experiment we did not use any particle selection technique, since the yield of protons from (α, p) reaction was very small compared with those of alpha particles scattered elastically or inelastically by light nuclei⁷⁾, and furthermore the (α, d) reaction has very large negative Q-value for the present case.

All targets, used above, were self-supported one and holded in aluminum target frames of $2\,\text{cm} \times 2\,\text{cm}$ in size. The carbon target of about $1\,\text{mg/cm}^2$ thickness was obtained by painting a soot dispersion in alcohol on a thin collodion film of several $\mu\text{g/cm}^2$. For the case determining the absolute cross sections, a 20 μ thick polyethylene foil was used. The magnesium target of $0.78\,\text{mg/cm}^2$ thickness prepared by evaporation method, and fused quartz foil of $1.4\,\text{mg/cm}^2$ thickness was used as silicon target.

The pulse height distributions of scattered alpha particle groups from the 22 Mev alpha particle bombardment on C, Mg and SiO_2 are shown in Figs. 1, 2 and 3, respectively.

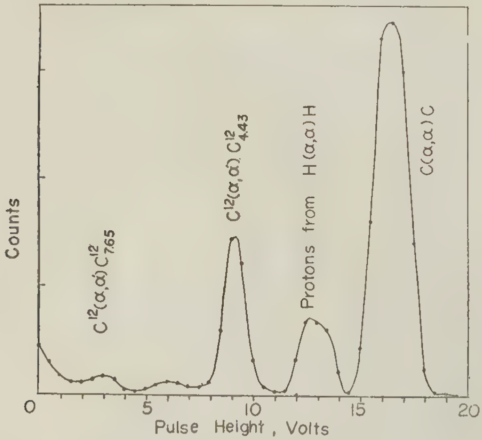

Fig. 1. The pulse height distribution of scattered particles from carbon target at $\theta=30°$. The first excited group is separated from recoil protons, due to hydrogen contamination, by Inserting a alminium foil in front of detector.

In the case of carbon we observed appreciable hydrogen contamination in the target. The group of this hydrogen contamination and the alpha group excited to the first excited level of carbon overlapped unfortunately, at about 25°. However, by inserting an aluminium absorber in front of the counter aperture, we could separate these groups. On the other hand, in the inelastic scattering from silicon we could not measure the differential cross sections at the angular region larger than 50° since the alpha group from the first excited level of silicon was masked by that of elastic scattering by oxygen.

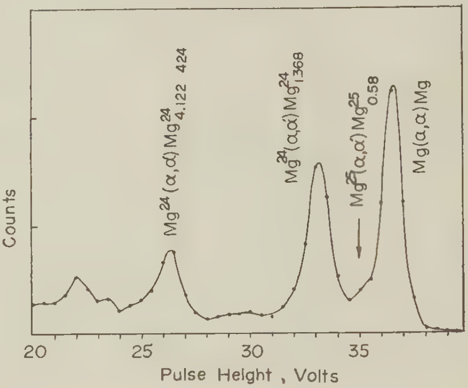

Fig. 2. The pulse height distribution of alpha particles from magnesium target at $\theta_{\text{lab}}=32.5°$.

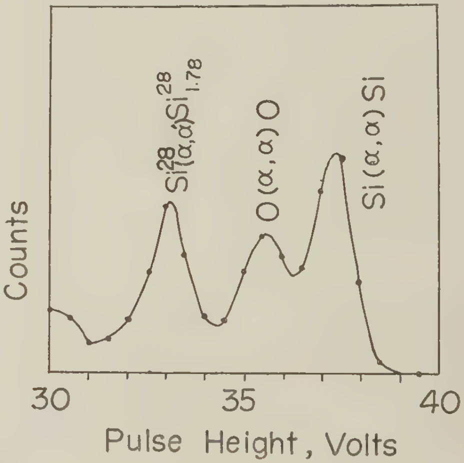

Fig. 3. The pulse height distribution of alpha particles from SiO_2 target at $\theta_{\text{lab}}=30°$.

§ 3. Results

1) *Elastic scattering*

The angular distributions of alpha particles elastically scattered by C^{12} and Mg^{24} are illustrated in Figs. 4 and 5, where the calculated Rutherford cross section are indicated by a dashed curve.

Diffraction patterns appear evidently in the forward direction in both cases. For the case of C^{12}, the smooth variation of the cross section from 60° to 78° which appeared in Watter's 31.5 Mev alpha particle experiments[2], is not observed in our 22 Mev experiments. This phenomena may be considered to be an energy dependent effect such as the dependence of the angular positions of maxima (or minima).

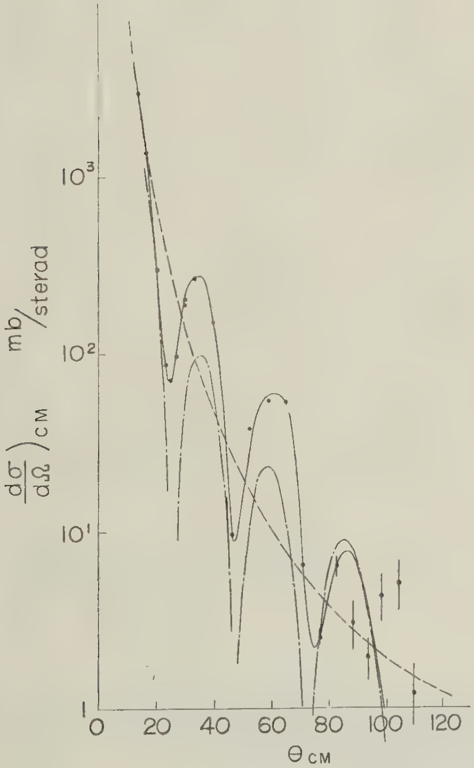

Fig. 4. The angular distribution of elastically scattered alpha particles from carbon.

As is shown in Fig. 4, the calculated curve assuming the scattering from an opaque sphere is in fair agreement with the experimental one, and it is true for the case of Mg^{24} also. In this calculation, we used expression (1) and the interaction radii have been adjusted to 5.5 and 6.0 fermis (1 fermi$=10^{-13}$ cm) for C^{12} and Mg^{24}, respectively, and they will be compared below with those fitted to inelastic scattering data.

The angular dependence of the deviations from the Rutherford scattering are different for the both cases, i.e., the experimental points are distributed around the Rutherford cross sections in the case of C^{12}, while for Mg^{24}, the diffraction pattern appears below the Rutherford curve. This situation is similar to that of 31.5 Mev work[2].

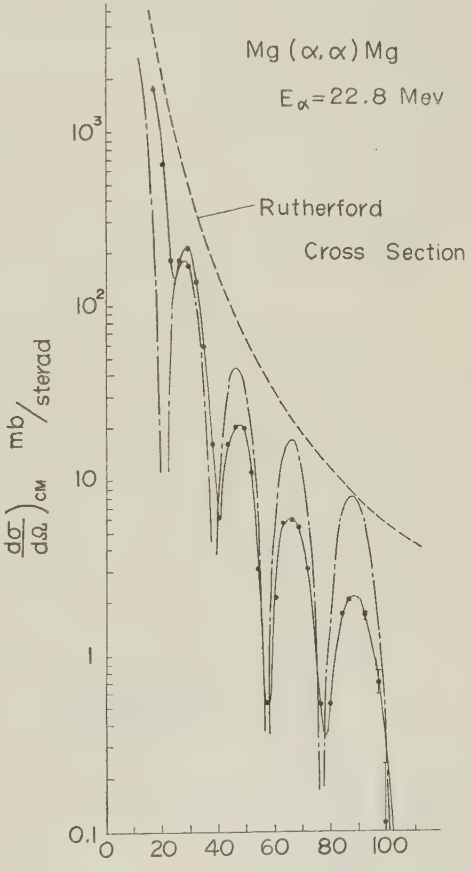

Fig. 5. The angular distribution of elastically scattered alpha particles from magnesium.

2) *Inelastic scattering*

In our case the spins and parities of the ground and excited state are respectively 0(+) and 2(+).

a) $C^{12}(\alpha, \alpha')C^{12*}$, $Q=-4.43$ Mev. The most pronounced feature of the angular distribution for this case is that the first maximum is at about 28°, though in the 31.5 Mev data[2] the cross section increase linearly at small angles. The theory predicts an angular distribution of the form of $[j_2(|\boldsymbol{k}_{\alpha}-\boldsymbol{k}_{\alpha'}|a)]^2$ for this case, and this is illustrated in Figs. 6 with the present experimental result. The interaction radius has been adjusted as 5.08 fermis and the agreement between the theoretical and experimental results is very good.

b) $Mg^{24}(\alpha, \alpha')Mg^{24*}$, $Q=-1.368$ Mev. Since the spins and parities of the ground state and the first excited level are 0(+) and 2(+), respectively, one may expect an angular distribution varying as $[j_2(|\boldsymbol{k}_\alpha-\boldsymbol{k}_{\alpha'}|a)]^2$. As illustrated in Fig. 7, the theoretical curve reproduces the experimental angular distribution fairly well, assuming the interaction radius of 6.3 fermis.

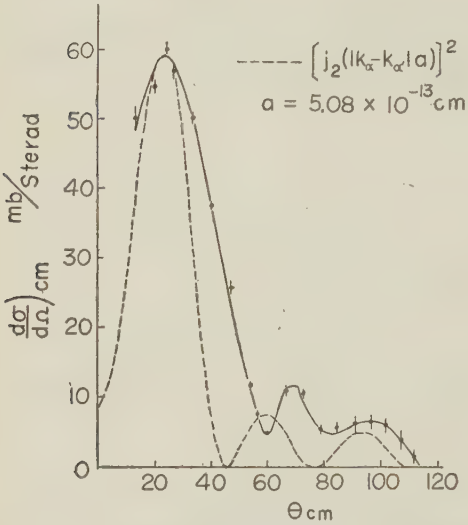

Fig. 6. The angular distribution of inelastically scattered alpha particles from carbon, $Q=-4.43$ Mev.

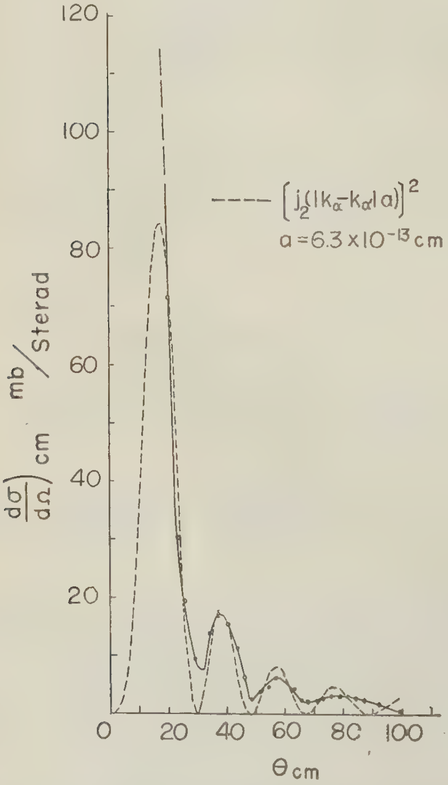

Fig. 7. The angular distribution of inelastically scattered alpha particles from the first excited states of magnesium, $Q=-1.368$ Mev.

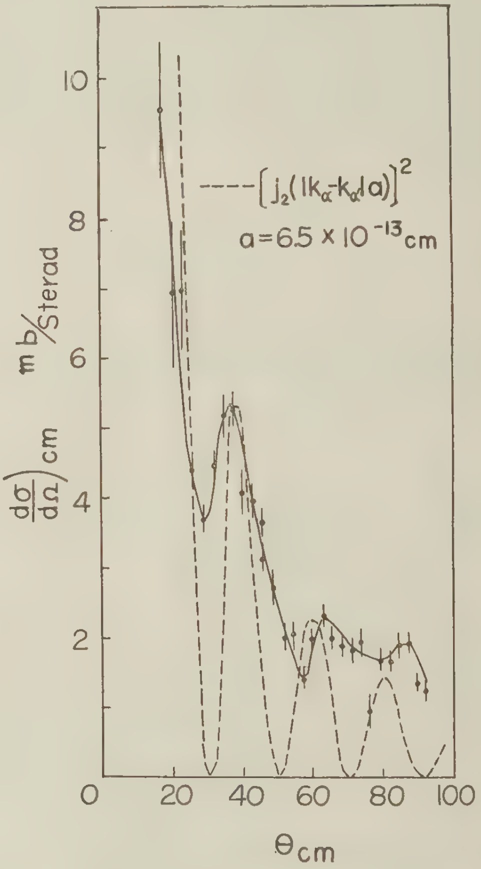

Fig. 8. The angular distribution of inelastically scattered alpha particles from the second and third excited states of magnesium, $Q=-4.12$ and -4.23 Mev together.

c) $Mg^{24}(\alpha, \alpha')Mg^{24*}$, $Q=-4.2$ Mev. The experimental differential cross section for this process is shown in Fig. 8.

Although the second excited levels of Mg^{24} has doublet structure of 2(+) and 4(+), the angular distribution of Fig. 8 seems to be contributed from the 2(+) level only since theoretical $[j_2]^2$ curve can reproduce the experimental results with a reasonable magnitude of interaction radius $a=6.5$ fermis.

d) $Si^{28}(\alpha, \alpha')Si^{28*}$, $Q=-1.78$ Mev. In Fig. 9, the experimental and calculated $[j_2|\boldsymbol{k}_\alpha-\boldsymbol{k}_{\alpha'}|a)]^2$

curves are illustrated together. Chosing the interaction radius as 6.16 fermis, the agreement between experimental and theoretical results is good, though the range of the scattering angles is only from 17° to 46°.

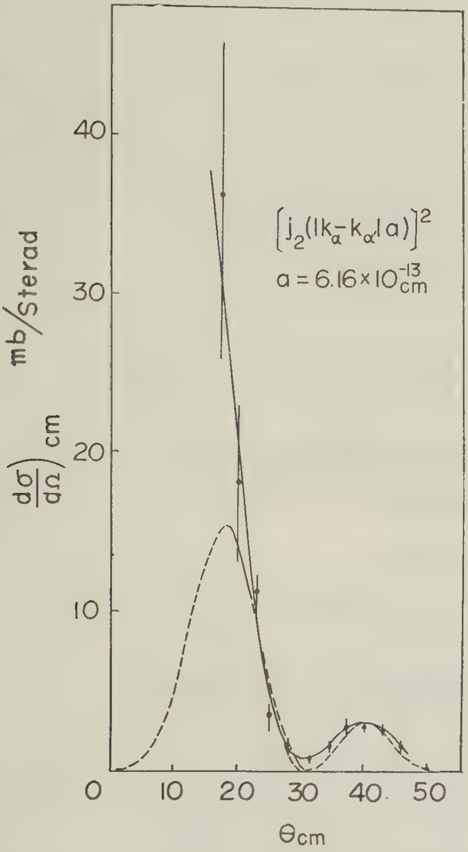

Fig. 9. The angular distribution of inelastically scattered alpha particles from the first excited state of silicon, $Q=-1.78$ Mev.

§ 4. Discussion and Conclusion

It is interesting to compare the nuclear radii determined by the elastic scattering of alpha particles with that deduced from inelastic scattering, although the two mechanisms of scattering of alpha particles are quite different each other. In the case of C^{12}, we have chosen the interaction radius as 5.5 fermis for the elastic scattering from the opaque sphere model and 5.08 fermis for the inelastic scattering from the direct interaction theory. In the case of Mg^{24}, we have taken the interaction radii as 6.0 and 6.3 fermis for elastic and inelastic scattering respectively. These agreements are rather good and they also agree with the radii which were determined by the sharp cut off model analysis⁹⁾. But these radii are larger than that obtained by optical model analysis³⁾.

The recent experiments about the inelastic scattering of nucleons from light nuclei have revealed some complexities in the angular distributions of the scattered particles which can not be explained by either the simple compound or direct theory of nuclear reactions. While the results for inelastic scattering of alpha particles described here are well interpreted by the simple direct theory of Austern, Butler and McManus. The angular distributions for the elastic scattering show that the nucleus would be almost black for the impinging of alpha particles. The existence of sharply defined boundary surface between the inside and outside of nucleus would play a role to exhibit the diffraction phenomena.

Almost all parts of our experimental results of the inelastic scattering are on the first excited states of even-even nuclei. The angular distributions predicted by the collective excitation theory also have the form of $[j_2(qa)]^2$ for these cases quite similarly to that of the former direct theory. Therefore, we can not argue which theory is more preferable as long as we concern only to the experimental results of the angular distributions. Now the above formal expression gives a small cross section at 0°. This feature has been recognized well in our result for C^{12}. Large forward peaks are, however, observed for Mg and Si, although the experimental error are somewhat large. This is explained by neither of the theories mentioned above.

As the yields of the reactions observed in our experiments are appreciable, it will be reasonable to say that the excited states studied have the same isotopic spin with that of the ground state. It is worthwhile to note here that the yield of second excited state of C^{12} is so small as we could not measure the angular distribution. This feature seems not to depend seriously on the incident energy²⁾. Similar results has been also found in the case of the inelastic scattering of protons from C^{12}.⁸⁾ Probably these features suggest that the nature of the second excited state would be greatly different from that of the ground state, and the transition would be highly suppressed.

Acknowledgements

The authors are indebted to Professor T. Wakatsuki for his continued interest in the problem. We also would like to express thanks to members of Osaka University Cyclotron.

$Be^9(n,2n)Be^8$ and $B^{11}(n,\alpha)Li^8(\beta)Be^8$ Reactions by 14 Mev Neutrons

By Masakatsu Sakisaka

Department of Physics, Kōnan University, Kōbe

(Received December 19, 1958)

$Be^9(n, 2n)Be^8$ and $B^{11}(n, \alpha)Li^8(\beta)Be^8$ reactions induced by 14 Mev neutrons were studied by the method of beryllium and boron loaded nuclear emulsions.

In the former reaction, the angular distributions of Be^8 nuclei were strongly peaked backward in the center-of-mass system, suggesting that the direct interaction of the incident neutrons with beryllium—an inelastic scattering process before second neutron emission and a pick-up process probably—had a major contribution to the reaction. The cross sections were measured as 0.18±0.07, 0.03±0.02, 0.11±0.04 and 0.05±0.03 barns for the 3, 5, 7.5 and more than 9 Mev excited states of Be^8 respectively. When 0.17±0.03 barns was cited to the cross section with respect to its ground state, the total $(n, 2n)$ cross section was estimated as 0.54±0.09 barns.

The cross section of the latter reaction was measured as 35±7 millibarns in which the contribution of Be^8 in the ground state was not included. Most Li^8 nuclei were found to be left at the states lower than 2.5 Mev in the reaction. The decaying rates of Li^8 to the Be^8 states of 3, 5 and more than 8 Mev were about 75, 15 and 10% respectively and the mixing of the allowed transitions of such rates was consistent with the known β-spectrum of Li^8.

§ 1. Introduction

The interactions of various nuclei with fast neutrons have been studied and many informations about the reaction processes have been obtained, but there remain much ambiguities even in the phenomena concerning light nuclei.

$Be^9(n, 2n)Be^8$ reaction by 14 Mev neutrons was investigated by some workers$^{1)-4)}$ by observing the emitted neutrons from beryllium. Though these experiments gave important knowledges about the reaction cross section and the energy spectrum of the emitted neutrons, the angular distributions of the neutrons or recoil Be^8 nuclei have not yet been observed. Recently Anderson *et al.*5) have given the angular distribution of inelastically scattered neutrons corresponding to the 2.43 Mev level of Be^9 by a time-of-flight method.

$B^{11}(n, \alpha)Li^8(\beta)Be^8$ reaction at 14 Mev neutron energy has been studied by Heiberg6) and Armstrong and Frye7), but there still remain many uncertainties because of the small cross section of the reaction.

The final product of the above reactions is Be^8 nucleus. This nucleus has been most frequently investigated both theoretically and experimentally owing to its interesting nuclear character, but the existence of the excited states between 3 and 7.5 Mev has not yet been decisive. More precise experiments about these reactions are therefore desirable.

In this paper the two reactions induced by the 14 Mev neutrons were investigated by the method of the beryllium and boron loaded nuclear emulsions.

§ 2. Experimental Procedures

(1) *Neutron irradiations and monitoring*

The deuteron beam was accelerated to 170 Kev by a Cockcroft-Walton type accelerator. The magnetically analysed beam of a few μA bombarded to a thick tritium-titanium target producing 14 Mev neutrons of $T(d, n)\alpha$ reaction. The irradiation of nuclear plates by neutrons was performed as follows. Several Sakura NR-Ml nuclear plates (1″×3″ in size and 90 μ and 170 μ in thickness) were cut in half. The fellows of the halves were loaded with beryllium or boron by the procedures described in Appendixes I and II. The contents of beryllium and boron were determined by means of chemical and activation analysis respectively. The loaded plates and the unloaded ones for the background measurements wrapped by black papers separately were arranged abreast and 10 cm apart from the target on a plane perpendicular to the deuteron beam. The cadmium covers of 0.2 mm in thickness were used for both plates in order to filter the probable thermal neutrons. Their glacing angles were chosen as 5°.

To obtain the number of neutrons impinged on the nuclear plates, the recoil alpha-particles of $T(d, n)\alpha$ reaction emitted in the perpendicular direction with respect to the deuteron beam were counted by a CsI(Tl) crystal of 1/16″ in thickness viewed with a photomultiplier RCA 6810. The surface of the crystal was screened by two sheets of aluminium foils of 0.13 mg/cm^2 in thickness to prevent scattered deuterons and beam glow from reaching the crystal. The counting error was estimated to be less than 2%. The experimental arrangements are shown in Fig. 1.

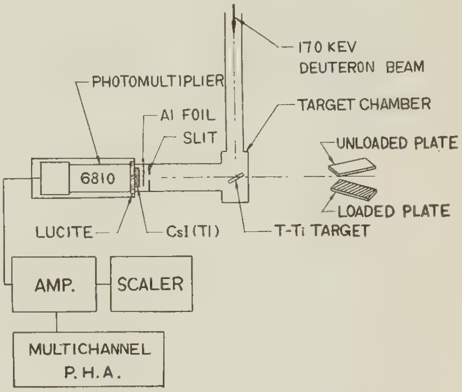

Fig. 1. Experimental arrangements.

The recoil alpha-particles of the neutrons used to irradiate the emulsions were emitted in the direction of 84° to the deuteron beam at the bombarding energy of 170 Kev. Therefore the counts of alpha-particles in this arrangement did not give directly the correct number of the neutrons falling on the emulsions, but the correction could be easily made, because the angular distribution of the neutrons in $T(d, n)\alpha$ reaction was found to be isotropic8) in the center-of-mass system at such a low deuteron energy.

The neutron energy was 14.1±0.2 Mev and the number of the irradiated neutrons at the plates was $(3.77 \pm 0.08) \times 10^7$ neutrons/cm^2 in each experiment.

(2) *Plate analysis*

The exposed plates were processed by the procedures shown in Appendixes I and II. The scannings of the processed emulsions were performed with two Tiyoda binocular microscopes at a magnification of 1350 for the beryllium loaded and the unloaded emulsions, while a magnification of 900 was adopted for the boron loaded ones, since the stars attributed to the boron disintegration reaction could be easily perceptible. Some typical examples are shown in Fig. 2.

The measurements of the following three quantities were made on each prong of an observed track or a star:

(a) horizontally projected length of the prong,
(b) dip of the prong,
(c) angle between the prong and the direction of the incident neutron.

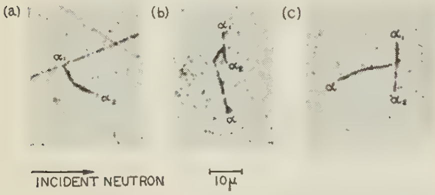

Fig. 2. Typical track and stars in beryllium and boron disintegrations respectively.
(a): Track of $Be^9(n, 2n)Be^8$ reaction:
E_1=2.09 Mev, E_2=2.54 Mev, E^*=4.10 Mev, Θ=147°
(b), (c): Stars of $B^{11}(n, \alpha)Li^8(\beta)Be^8$ reaction:
(b) E_1=1.23 Mev, E_2=1.23 Mev, E^*=2.36 Mev
(c) E_1=2.48 Mev, E_2=2.56 Mev, E^*=4.94 Mev
Both Li^8 are left at the ground state in the (n, α) reaction.

The errors of these quantities were estimated as ±0.5 μ, ±0.3 μ and ±2° respectively.

Since the range-energy relations for alpha-particles have not been given in the NR-Ml emulsion, they were determined experimentally as stated in Appendix III. The energy of each prong was obtained from the measured range-energy relations, from which the energies and the angular distributions in the center-of-mass system could be calculated about the reaction products.

§ 3. Results and Discussions

(1) $Be^9(n, 2n)Be^8$ *reaction*

It was found that even in the unloaded emulsions there were found many tracks similar to those due to Be^8 disintegration. These background tracks would be attributed to the followings:

(a) bent tracks of scattered low energy protons which are difficult to discriminate from those of alpha-particles,
(b) bent tracks of alpha-particles,
(c) 3-alpha stars from carbon whose one prong is too short to be detected or two of them are too close together to be resolved,
(d) tracks of light nuclei accompanied by the emission of a charged particle—the recoil atoms sometimes give the tracks indistinguishable from those of alpha-particles,
(e) tracks attributed to the emission of two charged particles.

At first the same areas of the beryllium loaded and unloaded pair were scanned and all the tracks in question were measured. When the energies of two alpha-particles were denoted as E_1 and E_2, there were the difference of the E_1+E_2 histograms between both plates near the energies of 3.5, 7.5 and more than 9 Mev. Moreover, when the number of tracks per Mev of E_1+E_2 was plotted against the energy ratio γ of the two alpha-particles (defined as $\gamma \geq 1$), it became clear that the differences were found only for the low γ region of $1 \leq \gamma \lesssim 2.5$. Therefore the subsequent scannings were performed so as to choose only the tracks of γ less than 3, that is, the tracks whose range of the longer prong did not exceed about three times of the other were chosen. By such a selection the scanning labour was greatly reduced.

In the track analysis, the length between the end of two alpha-particle prongs (P_1 and P_2 in Fig. 3) was first measured, from which

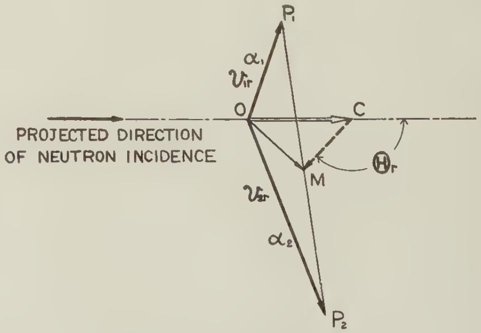

Fig. 3. Velocity vector diagram of the $Be^9(n, 2n)Be^8$ reaction on the projected plane.
Suffix r means the horizontal projection of the respective vector. Solid arrows show the vectors in the laboratory system and broken arrow gives the vector in the center-of-mass system. White arrow is the projected vector of the center of mass.

M: middle point of $\overline{P_1P_2}$,
$\overrightarrow{OM}$: projected velocity vector of Be^8

the excitation energy E^* of Be^8 could be calculated. The tracks in both emulsions were analysed in this way and the net histogram of E^* distribution is shown in Fig. 4. Besides the well-known ground, 3 and 7.5 Mev states, a level near 5 Mev and unresolved levels above 9 Mev are seen to be probable.

The angular distributions of Be^8 were obtained for the 3 and 7.5 Mev states from the direction $\overrightarrow{CM}$, which showed the strongly backward predominance in the center-of-mass system, as shown in Fig. 5. The reliable results were not given to the 5 Mev and above 9 Mev states owing to the small number of the net events.

In the $Be^9(n, 2n)$ reaction by 14 Mev neutrons, Rosen and Stewart[3] have reported the existence of the 2.43 and 7.9 Mev states of Be^9 and also found the emission of many neutrons of low energies. This indicates that the reaction proceeded mainly by an inelastic scattering of the incident neutron with beryllium at first and then the excited Be^9 nucleus disintegrated into a second neutron and Be^8 residual. Such a two-step process of the reaction has been found by Fowler *et al.*[9], Fischer[10], and Wagner and Huber[11] at the lower incident neutron energies.

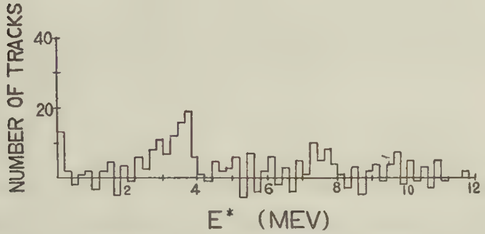

Fig. 4. Histogram of the excitation energy of Be^8 obtained from the $Be^9(n, 2n)Be^8$ reaction.

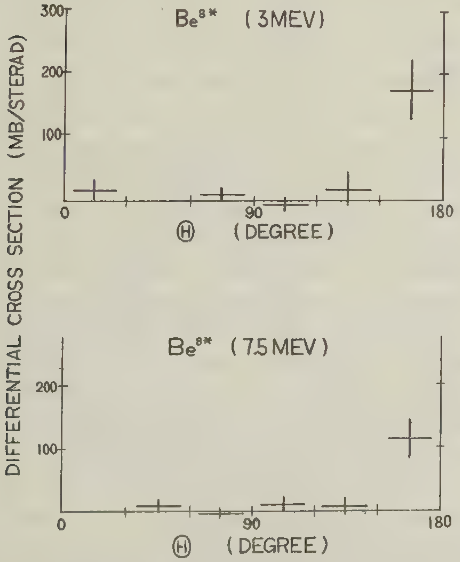

Fig. 5. Angular distributions of Be^8 from the $Be^9(n, 2n)Be^8$ reaction in the center-of-mass system.

The angular distribution of the neutrons inelastically scattered by the 2.43 Mev state Be^9 has recently been observed to be peaked forward[5]. Unfortunately, those for other levels of Be^9 have not yet been given. However the sharp and forward angular distributions of the inelastically scattered neutrons have been shown in the same paper by Rosen, though they were concerned with other nuclei of Ta and Bi.

To explain the present experimental results according to the two-step process alone, the following assumption would be necessary, that is, the inelastically scattered neutrons by Be^9 proceeded sharply and forwardly in the center-of-mass system (the recoil Be^9 are peaked backward) and the energy release† in the second process was small. Then the angular distributions of the residual Be^8 would resemble to those of the recoil Be^9. But it seems to be difficult that this assumption is correct.

Another quite different assumption might be admitted to the reaction mechanism; namely an incident neutron picked up the other neutron of Be^9 just as (n, d) or (p, d) reactions. In this process the residual Be^8 nucleus has an appreciable probability of backward predominance in its angular distribution. Again, the pick-up process alone is not satisfactory for explaining the energy spectrum of the emitted neutrons obtained by Rosen and Stewart. Rather, some mixing of the two-step process and the pick-up process seems adequate for the present investigation. But, since the further details cannot be derived at the present state of knowledge, more experiments are necessary.

Quite recently Remy and Winter[12] have investigated the $Be^9(n, 2n)$ reaction by time-of-flight method and obtained the complex energy distribution of the neutrons, showing that the reaction was not considered to be due to the simple two-step process alone—the various levels of Be^9 and Be^8 were not only concerned in the two-step process but also the pick-up process was expected from the angular correlation of the emitted neutrons. However the mixing ratio of the processes has not been given and, at this time, their investigation is correlated to the present study only qualitatively.

---

† If the excited Be^9 was at rest, one ninth of the energy release of $E_0^* - E^* - 1.67$ is given to Be^8 where E_0^*, E^* and -1.67 are the excitation energies of Be^9, Be^8 and the Q-value of $Be^9(n, 2n)$ reaction respsectively.

To obtain the reaction cross sections some corrections were necessary. First, the correction of the escaping probability of tracks from the emulsions was made by the ordinary method. Next, the effect of the increase of light nuclei in the loaded emulsions was corrected. It amounted to about 10±5%. And finally the contribution of a few tracks of γ greater than the chosen value was taken into account, which was estimated to be less than 5%.

* σ_n means the nonelastic cross section, which is tabulated for the sake of comparison.

** $E_n=14.5$ Mev.

The results are tabulated in Table I for the reactions proceeding *via* various levels of Be^8 nucleus. The value of 0.03±0.01 b for the Be^8 ground state is only a lower limit, because the tracks due to the disintegration of Be^8 in this state are difficult to be detected and liable to be missed. The total $(n, 2n)$ cross section is also shown in the table. It was obtained by summing up the cross sections corresponding to the respective levels of Be^8. But, in the summation, the value for the Be^8 ground state was chosen as 0.17±0.03 b† according to Anderson *et al.*[5]. The present value agrees well with the recent result of Ashby[13]. Comparing with some of the nonelastic cross sections, it may be concluded that the $(n, 2n)$ cross section is the major part of the nonelastic cross section.

The semi-empirical model of this reaction presented by Sachs[14] affords isotropy in the center-of-mass angular distributions of the neutrons and Be^8. This model seems inadequate so far as the reaction mechanism concerns, since the isotropical contributions was small in the present experiment. Bnt the behaviour of the $(n, 2n)$ cross sections measured by many workers up to 14 Mev of neutron energy fits well with Sachs' theory.

(2) $B^{11}(n, \alpha)Li^8(\beta)Be^8$ *reaction*

Of the neutron-induced disintegrations in boron, $B^{11}(n, \alpha)Li^8(\beta)Be^8(2\alpha)$ reaction gives rise to the hammer-shaped star, since the Li^8 does not decay until it has come to rest in the emulsion. This characteristic star could easily be found in the scanning, but that in which Be^8 was left in the ground state was hardly observed. The star is also indistinguishable from the 3-alpha star from carbon having one bent prong and two collinear equilateral ones, because the prongs of alpha-particles and recoil Li^8 atom would be short enough, if Li^8 would be left at the highly excited states. But the latter case was found to be rare as described later.

Fig. 6 gives the spectrum of the excitation energy E^* which was obtained by measuring the break-up of the final Be^8. In addition to the broad 3 Mev state a level of 5 Mev is seen. Armstrong and Frye⁷⁾ showed the slight indications of 2.2 and 4.0 Mev levels as well as the broad 3 Mev state but did not find the 5 Mev, though the number of their observed events was more than those of the present investigation.

---

† This value was obtained for the inelastic scattering of the neutrons proceeding *via* the 2.43 Mev level of Be^9 which was considered to decay to the Be^8 ground state only by neutron emission, since no gamma rays were found in the reaction. Therefore, Anderson's value may be taken to be equal to the disintegration cross section of Be^8 in the ground state.

The relative decaying rates of Li^8 to the 3, 5 and more than 8 Mev levels of Be^8 were about 75, 15 and 10% respectively. From the alpha-particles energy spectrum of the (n, α) reaction most Li^8 nuclei were found to be left in the states less than 2.5 Mev as shown in Fig. 7, but these states were not well resolved.

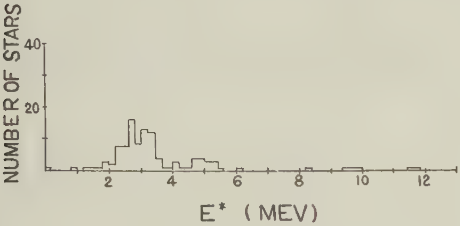

Fig. 6. Excitation energy of Be^8 obtained from the $B^{11}(n, \alpha)Li^8(\beta)Be^8$ reaction.

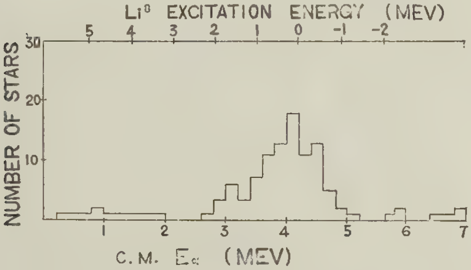

Fig. 7. Alpha-energy spectrum of the $B^{11}(n, \alpha)Li^8$ reaction in the center-of-mass system.

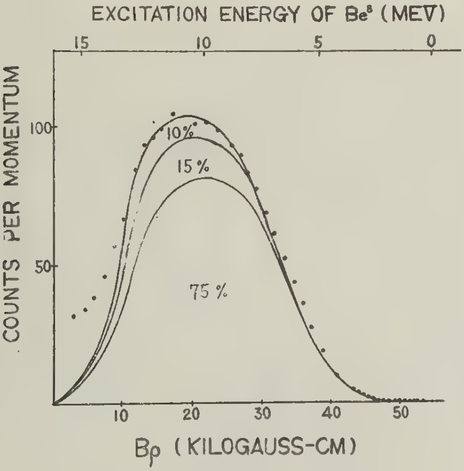

Fig. 8. β-spectrum of Li^8.

The dots show the measurement by Hornyak and Lauritsen¹⁵⁾.

The broadness of the respective levels of Be^8 is taken into account.

The cross section was 35±7 mb but it does not include the events of Be^8 in the ground state. Heiberg⁶⁾ gave about 30 mb to the reaction cross section at 14 Mev neutron energy, while Armstrong and Frye showed the cross section as 38.4±7.4 mb at 13.0 Mev and 30.9±6.3 mb at 14.7 Mev, both of which are in good agreement with the present observation.

The excited levels of Be^8 between 3 and 7.5 Mev have not yet been sufficiently decisive. But the present study has given a more reliable indication that at least one level exsists near 5 Mev.

According to Hornyak and Lauritsen¹⁵⁾, the β-ray spectrum of Li^8 indicated that about 90 per cent of the β-transitions occured to the 3 Mev state of Be^8 and 10 per cent to the states at nearly 10 and 13 Mev. However, the spectrum can be equally well explained, as shown in Fig. 8, by the superposition of the transitions obtained in the present experiment, namely; 75 and 15 per cent of the decays to the 3 and 5 Mev states respectively and 10 per cent to the state above 8 Mev. Here all the transitions are taken to be of the allowed type.

Burchum *et al.*¹⁶⁾ and Inall¹⁷⁾ have shown that in the $Li^7(p, \gamma)Be^8(2\alpha)$ reaction the weakly excited states were found near 4.2 and 5.4 Mev of Be^8 whose spins were assigned as $J=2^+$ by the $\gamma-\alpha$ angular correlation. It is reasonable that their 5.4 Mev is taken to be the same as the present 5 Mev one. Then, since the ground state of Li^8 is 2^+, the β-transition to the 5 Mev state of Be^8 is of the allowed type as assumed above. It is not inconsistent with the observations of Hanna *et al.*¹⁸⁾ and Bunbury¹⁹⁾ that the $\alpha-\beta$ angular correlation was isotropic within a few per cent in the $Li^8(\beta)Be^8(2\alpha)$ decay.

The reaction $B^{10}(n, t)Be^8$ was also observed. The cross section was estimated as 42±16 mb which did not include the contribution from the Be^8 ground state. Further results could not be obtained because of the very small number of the events.

Frye and Gammel²⁰⁾ found the total (n, t) cross section to be 102±17 mb for the 14.1

Mev neutrons. Comparing with the present result, the Be^8 ground state has nearly the same contribution as the excited states. According to Ribe and Seagrave[21], however, the ratio was 1:10. The more precise experiments would be desirable.

Acknowledgements

The author wishes to express his hearty thanks to Profs. B. Arakatsu and S. Kawata for their valuable discussions and continuous encouragements and to Mr. K. Yuasa and Mr. B. Saeki for their cooperative efforts during the experiments. He is indebted to Miss K. Ikeda, Miss A. Sukeno and Mr. K. Hanamoto for their scannings and calculations. He also wishes to thank Mr. Y. Kusaka for the advice in the chemical analysis of beryllium and Mr. S. Morita and others of the Kyūshū University for their cordial cooperation in the preliminary experiments.

This work was partly supported by The Scientific Research Expenditure of the Ministry of Education.

Appendix I. Preparations of the Beryllium Loaded Nuclear Emulsions

Since the supplies of the beryllium loaded nuclear plates have been stopped by the manufacturers owing to the poisoneous character of beryllium, one is obliged to try the loading by himself.

The 22% solution of beryllium acetate whose pH was about 5 was prepared. The Sakura NR-Ml nuclear plates of 90 μ and 170 μ in thickness were soaked in the solution for an hour at 11±1°C and dried in the ordinary atmosphere.

The plates were processed by the temperature method with amidol developer (pH=7.2) the emulsions were imprignated by a 2% glycerine solution after washing. The time of each stage in the course of the processing was the same as that[22] given to the Ilford C2 nuclear plates. However, 2 hours were adopted for the presoaking stage to remove the loaded beryllium in the emulsion which had a bad influence on the processing. The shrinkage factor of the loaded emulsions (~15 mg/cc of Be) was measured as 2.09±0.05 whereas that of the unloaded ones was 2.19±0.04.

Since pH of the loading solution was low, it is feared that the sensitivity decrease and the faster fading of the loaded emulsions may occur. By the grain counting of the tracks both in the loaded and unloaded plates irradiated by fast neutrons and alpha-particles from polonium, it was found that the loaded emulsions processed by the developer (pH=7.2) were as sensitive as the unloaded ones processed by the developer whose pH was adjusted to about 6.3. Therefore in the actual processing, pH of the developer was chosen as 7.2 for the loaded emulsions and 6.3 for the unloaded ones. The fading factors were measured for both plates and plotted in Fig. 9 against the time after irradiation. They were obtained for the alpha-particle tracks on the emulsion surfaces by counting the grain density. Since the irradiation time of the plates was less than an hour and the processing was done immediately after the irradiation in the present experiment, the effects of the fading would be negligible.

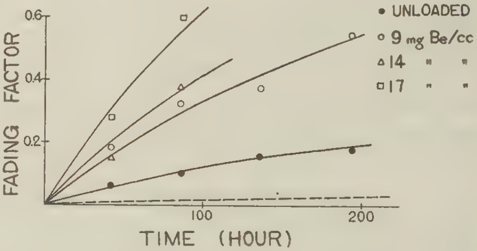

Fig. 9. Surface fading factor of the unloaded and beryllium loaded NR-M1 nuclear emulsions. The broken line shows the internal fading predicted for the unloaded emulsion.

The content of beryllium loaded in the emulsion was determined by the usual gravimetric analysis. The known quantity of the loaded emulsion was put into perchloric acid solution and warmed for an hour on water bath. After adding NH_4OH until pH of the solution came to about 9 the precipitate produced was filtered. Then the precipitate was dissolved in HCl solution and again NH_4OH was poured up to pH$\approx$9. The re-precipitated $Be(OH)_2$ was washed with hot water and changed to BeO by ignition in a porcelain crucible. The weight of BeO thus obtained was measured, from which the beryllium content could be determined within the error of about 5%. The contents of beryllium were 19.8 mg/cc and 13.5 mg/cc for the emulsions of 90 μ and 170 μ in thickness respectively.

Appendix II. Preparations of the Boron Loaded Nuclear Emulsions

The 5% solution of ammonium borate whose pH was 7.5 was used in the loading. The NR-M1 plates were soaked in the solution for two hours at 15±1°C.

The method of ordinary temperature processing was adopted in this case but the fixing was somewhat difficult. No significant difference of the sensitivlty was found between the loaded and unloaded plates. The shrinkage factor was about 1.8.

To obtain the content of boron in the emulsions the activation analysis method was chosen, since the chemical analysis was rather difficult. As shown in Fig. 10, a 50 mg Ra-Be neutron source was sunk in a paraffin block of 20 cm in diameter and 31 cm in height. The silver and indium foils of various thicknesses with and without cadmium covers were placed in a hole of the paraffin block and irradiated by thermal neutrons.

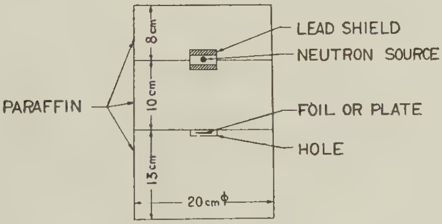

Fig. 10. Irradiation by thermal neutrons.

The induced activities of the foils by the reactions of $Ag^{107}(n, \gamma)Ag^{108}$ and $In^{115}(n, \gamma)In^{116}$ were measured by an end-window G-M counter. From the curve of foil thickness *vs* specific activity the propor thickness of the foil† necessary to obtain the total hot atoms in the sample was known.

If the foil is irradiated in the time interval 0 to t_0 by the constant flux of thermal neutrons and the induced activity is measured from time t_1 to t_2 after the end of the irradiation, the flux ϕ at the hole of the paraffin is derived by the following expression:

$$\phi = \frac{\lambda C \rho G}{N_0 \sigma_0 w_0 (1-e^{-\lambda t_0})(e^{-\lambda t_1}-e^{-\lambda t_2})} ,$$

where

λ : decay constant,
C : net count of the foil of proper thickness,
ρ : density of the foil,
G : factor involving the geometrical conditions and the effects of the absorption and the scattering of β-rays,
N_0: number of Ag^{107} or In^{115} atoms in unit volume of the foil,
σ_0 : activation cross section by thermal neutrons,
w_0 : weight of the foil of proper thickness for absolute β-counting.

The data in the flux measurements are shown in Table II. The neutron flux was estimated to be $\phi=(3.21\pm0.30)\times10^2$ neutrons/cm²·sec as a mean of the results for silver and indium.

Table II. Data of the neutron flux measurements.

Sample	Silver	Indium
t_0 (min)	5	30
t_1 (min)	0.5	2
t_2 (min)	5	30
λ (min^{-1})	0.295	0.01285
σ_0 (b)	44 ± 9[23]	145 ± 15[23]
C	369 ±4%	3650 ±2%
G	4.72 ±3%*	4.70 ±4%*
w_0 (mg)	337**	170**
ϕ (cm^{-2}·sec^{-1})	$(3.44\pm0.72)\times10^2$	$(2.97\pm0.33)\times10^2$

* The G-M counter used is the same as that used in the experiment by Yasumi[24].

** These values were not equal to the exact weights of the foils of proper thickness but were rather approximate ones, since the foils of exact weight were hardly preparable. The corrections were introduced to the results.

Secondly the boron loaded nuclear plates with and without cadmium covers were placed for 30 minutes in the hole and the short tracks attributed to $B^{10}(n, \alpha)Li^7$ reaction were counted. The number of boron atoms in the emulsion was derived by an equation as:

$$0.188 N\sigma\phi t = \nu ,$$

where N and ν are the number of boron atoms and the tracks in unit volume of the emulsion respectively and 0.188 is the abundance ratio of B^{10}. t is the exposure time and σ is the (n, α) cross section of B^{10} which is taken as 4010±22 b[23]. Referring to the obtained value of ϕ the boron content in the 170 μ emulsion was found to be 27.6±3.1 mg/cc.

---

† The proper thickness is meant as the thickness of the foil which has the same specific activity as that of zero thickness.

Appendix III. Range-Energy Relations of the NR-Ml Nuclear Emulsions for Alpha-Particles and Tritons

The range-energy relations of the NR-Ml emulsions for protons up to the energy of 14 Mev were measured by Nonaka *et al.*[25], but the relations for alpha-particles and tritons have not been given. In the present experiment they were determined as follows.

By measuring the range of alpha-particles from a polonium source attached to the surfaces of the unloaded and beryllium loaded NR-Ml plates, the mean ranges of 22.4 μ and 21.6 μ respectively were obtained from their range histograms. Since the range for the Ilford C2 emulsion is given as 22.2 μ[26][†], its standard range-energy relations for alpha-particles up to about 10 Mev were found to be also available for the NR-Ml unloaded emulsion and even for the loaded ones.[††] This is supported by the measurements of the recorded tracks when the source was placed 0.5 cm apart from the surfaces of the emulsions. The observed range-position relations were the same as those expected from the range-energy curve for the C2 emulsion.

As for tritons, the equation[27]:

$$E = \text{const} \cdot M^{1-n} R^{n}$$

was applied, where E, M and R are the energy, the mass and the corresponding range of a charged particle respectively and n is a constant characteristic of the emulsion. The equation holds for protons, deuterons and tritons. Since the NR-Ml emulsion does not differ greatly from other emulsions, n is assumed to be 0.575 in the energy range from 4 to 10 Mev when M is given in terms of the proton mass, R in microns and E in Mev. Then the range-energy relations for tritons could be obtained in the same energy region from the curve for protons measured by Nonaka[25].

Additional data were given by the slightly lithium loaded emulsion[†††] irradiated by thermal neutrons. The tracks due to $Li^6(n, t)\alpha$ reaction were measured and the range of 33.2 μ was obtained for the 2.73 Mev triton. Therefore, the whole range-energy relations for tritons up to 10 Mev could be obtained by extrapolating smoothly the above-mentioned curve so as to pass through the observed point at 2.73 Mev.

The range-energy relations for the three particles in the NR-Ml emulsions are shown in Fig. 11.

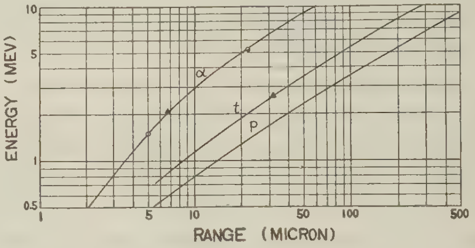

Fig. 11. Range-energy relations for protons, tritons and alpha-particles in the NR-Ml nuclear emulsion.

●: measurement by Po-α,
▲: measurement by $Li^6(n, \alpha)t$,
○: measurement by $B^{10}(n, \alpha)$

[†] The range obtained in the present experiment was 22.1 μ.

[††] It was shown that the same range-energy relations could be applicable to the boron loaded emulsions by observing the range of the alpha-particles from the reaction $B^{10}(n, \alpha)Li^7$.

[†††] A 2% solution of lithium acetate was used in the loading.

Cell Theory of Classical Liquids. Phase Transition between Gas, Liquid and Solid. Part III. Yvon's Method and its Generalization

By Tohru MORITA

Physics Department, Tokyo Institute of Technology

(Received January 26, 1959)

The Method, proposed by Yvon, to start with the cluster expansion formulae and to classify the contributions of the clusters according to the form of the figure showing the coordinates of particles in the summand is fully developed for uniform and non-uniform lattice systems and compared with the cluster variation method. The cell theory of liquids is investigated from the standpoint of this method. It is shown that the cell-pair approximation developed in Parts I and II from the standpoint of the cluster variation method is shown to be identical to the approximation in which the figures that are contained in a cell or a pair of cells are taken into account correctly and the others are neglected, again in our present standpoint.

§ 1. Introduction

As shown in a seperate paper1) by the author and used in Part II2), continuous systems—fluids and solids—may be considered to be equivalent to lattice systems of infinitesimal lattice constant. Therefore, to investigate the phase transition of continuous system, we may take the procedure, first to construct a method for lattice systems and then to apply it to the lattice system of infinitesimal lattice constant. This procedure will be taken in this part. So that, our main interest in this part is to find a method for a lattice system, applicable to a lattice system of infinitesimal lattice constant. The investigation will be made about the cluster expansion method for a lattice system.

Let us consider a lattice system, of L lattice sites of a regular lattice, composed of N identical particles: the density is $\rho=N/L$. The potential energy of the system is assumed to be of the form:

$$\sum_{N\geq i>j\geq 1} V^{(2)}(R_i, R_j)\ , \qquad (R_i, R_j=1, \cdots, L)\ . \tag{1}$$

The cluster expansion formula of the free energy A of this system is:3),1)

$$\frac{A}{kT}=L\rho \ln \frac{\rho}{e}-\sum_{n=2}^{\infty} \frac{\rho^n}{n!} \sum_{R_1=1}^{L} \cdots \sum_{R_n=1}^{L} \sum_{n\geq i>j\geq 1}^{(A)} \Pi F_{ij} \tag{2}$$

with

$$F_{ij}=\exp[-V^{(2)}(R_i, R_j)/kT]-1\,, \qquad (3)$$

where (A) on $\sum^{(A)}$ implies the specification by Mayer[4] that the sum is to be taken over all products which are more than singly connected.

When we start with the continuous counterpart of this expansion formula for the case of continuous system, the following two kinds of approximation are usually adopted. Namely, we take account either of first few terms of small n, entirely neglecting the terms of large n, or of the terms which can be evaluated by means of the Fourier transformation, neglecting the other terms, namely considering the terms of ring[5], of watermelon[6], of netted rings[7] or of hyper-netted chains or rings[8]. It is obvious that the former method will not be available for fluids of not small density. When the latter method is used, it generally leads to a divergence of sum at a density. The theory of radial distribution function by Born, Green and Rodriguez[9] suggests that the results at the densities higher than the density of divergence may be obtained from this expansion by continuing the function analytically to that region. However, if we apply the latter method to the one-dimensional Ising system, for which the rigorous solution is known, there appears a point of divergence and no reasonable results at higher densities than this point can be obtained by the analytical continuation[10]. Therefore, the latter method seems to be valid only for fluids of not too high density. Furthermore, these methods do not give the rigorous result even for a lattice system in which the interaction of particles is such as only to exclude two or more particles to be at the same lattice site[10].

On the contrary, quite a different method of collecting the contributions is presented for a lattice system. That is, Yvon[11] has proposed to group the contributions by the number or the type of the figures of the lattice sites occupied by particles in the summand, and has shown that the consideration only of the pairs of lattice sites leads to the Bethe approximation. Then, for the case of binary mixtures of occupation probabilities ρ near 1/2, he considered the figures of square up to the first order of $\rho-1/2$. Rushbrooke and Scoins[12] starting with the similar standpoint as Yvon, have shown that clusters of lattice sites which contribute to the sum are those of point, bond and closed polygons and presented a systematic method of calculating the sum, for the case of Ising system. In this method, the approximation of point gives the rigorous results for the case of the potential such as only to exclude two or more particles to exist at the same lattice site. The approximation of bond leads to the Bethe approximation, which gives the rigorous results for one-dimensional Ising system, and the calculations in the higher approximations can comparatively easily be performed.

From the results obtained when applied to the one-dimensional Ising system, we expect that the method by Yvon, Rushbrooke and Scoins is superior to the methods developed especially for a continuous system, for fluids of not small density. The reason why the former could give a reasonable results in the region of high densities where the latter could not, will be due to the fact that the correlations of short range could be considered sufficiently in the former method. Therefore, we expect that we can obtain an approximation method applicable to fluids of high densities or solids if we take into account the short range correlations in a similar way. In this paper, we develop the method of Yvon. Rushbrooke and Scoins from the standpoint of the Ursell expansion for both uniform and non-uniform systems and compare it with the cluster variation method developed by Kikuchi et al.[13], in § 2, and then apply it in the "cell and cell pair approximation" to classical liquids in § 3. The results obtained in the cell and cell pair approximation in this formalism are shown to be identical to those developed in Parts I and II from the standpoint of the cluster variation method.

§ 2. Expansion of the Free Energy by Means of "Clusters of Lattice Sites"

We present here the method of Yvon, Rushbrooke and Scoins for a uniform lattice system in a compact form, and then generalize it to the case of non-uniform systems.

2a. *Uniform lattice system*

For the present, we consider a uniform lattice system of L lattice sites composed of $N=L\rho$ particles. The cluster expansion formula of the free energy A of this system is given by (2). The sums over lattice sites in the right hand side of (2) can be decomposed into sums over the clusters of lattice sites occupied by particles as

$$A=\sum_{m=1}^{L}\sum_{L\geq i_m>\cdots>i_2>i_1\geq 1}\sum\sum B(i_1,\cdots,i_m) \tag{4}$$

with

$$\frac{B(i)}{kT}=\rho\ln\frac{\rho}{e}-\sum_{n=2}^{\infty}\frac{\rho^n}{n!}\sum_{n\geq i>j\geq 1}^{(B)}\Pi F_{ij} \tag{5}$$

and

$$\frac{B(i_1,\cdots,i_m)}{kT}=-\sum_{n=m}^{\infty}\frac{\rho^n}{n!}\sum_{R_1=i_1}^{i_m}\cdots\sum_{R_n=i_1}^{i_m}\sum_{n\geq i>j\geq 1}^{(B)}\Pi F_{ij} \tag{6}$$

for $m\geqq 2$, where (B) on $\Sigma^{(B)}$ implies that the sum is to be taken over all products which are more than singly connected and for which every site of $(i_1,\cdots,i_m)$ is occupied by at least one particle.

(5) and (6) with (4) suggest us to define $A(i_1,\cdots,i_m)$ by*

$$A(i)=B(i) \tag{7'}$$

$$A(i,j)=B(i)+B(j)+B(i,j) \tag{7''}$$

$$A(i,j,k)=B(i)+B(j)+B(k)+B(i,j)+B(i,k)+B(j,k)+B(i,j,k) \tag{7'''}$$

. . . .

$$A(1,\cdots,L)=\sum B(i)+\sum_{L\geq i>j\geq 1}^{L}B(i,j)+\sum B(i,j,k)+\cdots+B(1,\cdots,L)\,. \tag{7^L}$$

From the comparison of (4) and (7^L) we see that $A(1,\cdots,L)=A$, and further that $A(i,\cdots,i_m)$ is the free energy per system of the ensemble of M ($M\rightarrow\infty$) replicas of system $(i_1,\cdots,i_m)$;** the potential energy between two particles in different replicas is assumed to be zero.

$A(1,\cdots,m)$ can then be calculated by obtaining the grand partition function per replica by

$$\Xi(1,\cdots,m)=\sum_{N=0}^{\infty}z_{1,\ldots,m}^{N}\sum_{R_1=1}^{m}\cdots\sum_{R_N=1}^{m}\exp\left[-\sum_{N\geq i>j\geq 1}V^{(2)}(R_i,R_j)/kT\right] \tag{8}$$

and determining the value of the fugacity $z_{1,\ldots,m}$ by

$$m\rho=\frac{\partial\ln\Xi(1,\cdots,m)}{\partial\ln z_{1,\ldots,m}}\,, \tag{9}$$

as

$$\frac{A(1,\cdots,m)}{kT}=m\rho\ln z_{1,\ldots,m}-\ln\Xi(1,\cdots,m)\,. \tag{10}$$

When the potential energy has a core: $V^{(2)}(R,R)=\infty$, then the sum in (8) becomes a finite power series of $z_{1,\ldots,m}$: the terms retained are those of $N\leq m$ and (9) may be solved explicitly. For instance, for the case of $V^{(2)}(R,R)=\infty$, for $m=1$

$$\Xi(1)=1+z_1\,,\qquad \rho=\frac{z_1}{1+z_1}\,,\qquad z_1=\frac{\rho}{1-\rho}\,,$$

---

* Note that we could start with the definition of $A(i_1,\cdots,i_m)$ as the free energy per system of M replicas of $(i_1,\cdots,i_m)$ and this Ursell expansion of $A(i_1,\cdots,i_m)$ defining $B(i_1,\cdots,i_m)$ as the correlations. When we have adopted this starting point, we would not need to use the cluster expansion formula (2) which is divergent for condensed phases when seen to be the expansion in powers of ρ.

** For large m, we may say that $A(i_1,\cdots,i_m)$ is the free energy of the system $(i_1,\cdots,i_m)$ when the number of particles in the system is $m\rho$, but for small m we may not say so.

thence

$$\frac{A(1)}{kT}=\rho\ln\rho+(1-\rho)\ln(1-\rho)\,, \tag{11}$$

and for $m=2$,

$$\Xi(1,2)=1+2z_{12}+z_{12}^2\exp[-\phi(a)/kT]\,,$$

$$2\rho=\frac{2z_{12}+2z_{12}^2\exp[-\phi(a)/kT]}{1+2z_{12}+z_{12}\exp[-\phi(a)/kT]}\,,$$

$$z_{12}=\frac{2\rho}{1-2\rho+\beta}\,,\qquad \beta\equiv\sqrt{1+4\rho(1-\rho)\{\exp[-\phi(a)/kT]-1\}}\,,$$

thence

$$\frac{A(1,2)}{kT}=\rho\frac{\phi(a)}{kT}+\rho\ln\frac{(\beta-1+2\rho)\rho}{kT}+(1-\rho)\ln\frac{(\beta+1-2\rho)(1-\rho)}{1+\beta}\,, \tag{12}$$

where $\phi(a)=V^{(2)}(1,2)$.

For the Ising system:

$$V^{(2)}(i,j)=\begin{cases}\infty & |i-j|=0\\ \phi(a) & |i-j|=a\\ 0 & |i-j|>a\,,\end{cases} \tag{13}$$

a denoting the distance of the nearest neighbor lattice sites; if we use the approximation only to consider up to $B(i,j)$ neglecting the higher terms in Eq. (7^L), then we get as an approximation for the free energy

$$\frac{A}{LkT}=\frac{c}{2}\rho\frac{\phi(a)}{kT}+\rho\ln\rho+(1-\rho)\ln(1-\rho)+\frac{c}{2}\left\{\rho\ln\frac{\beta-1+2\rho}{(1+\beta)\rho}+(1-\rho)\ln\frac{\beta+1-2\rho}{(1+\beta)(1-\rho)}\right\} \tag{14}$$

by the help of (7′) and (7″) with (11) and (12). This is just the result of the Bethe approximation$^{14)}$. Here, c is the coordination number of the lattice. In an analogous way, we will be able to proceed to the higher order terms. In that case is useful the theorem of Rushbrook and Scoins that $B(i_1,\cdots,i_m)$ for $m>2$ is zero except when the figure of $i_1,\cdots,i_m$ with bonds drawn between pair i_j and i_k for which $V^{(2)}(i_j,i_k)\neq 0$, is more than singly connected. If we want to estimate the error of the approximation for high temperature region, the theorem teaches that the contribution of the figures neglected in the Bethe approximation is $0(-\phi(a)/kT)^4$ or $0(-\phi(a)/kT)^3$ according as the smallest closed polygon neglected is □ or △; as $F_{ij}\sim-\phi(a)/kT$ for $|i-j|=a$.

2b. *Non-uniform lattice system*

Since we are to consider the system in the solid state where the one particle distribution function is not constant in the system as well as the system in the fluid states, we have to use the expansion formula of the free energy in terms of the one particle distribution function$^{1),15)}$:

$$\frac{A}{kT}=\sum_{R=1}^{L}\rho(R)\ln\frac{\rho(R)}{e}-\sum_{n=1}^{\infty}\frac{1}{n!}\sum_{R_1=1}^{L}\cdots\sum_{R_n=1}^{L}\rho(R_1)\cdots\rho(R_n)\sum^{(A)}\prod_{n\geq i>j\geq 1}F_{ij}\,. \tag{15}$$

This snm can be decomposed as (4) with

$$\frac{B(i)}{kT}=\rho(i)\ln\frac{\rho(i)}{e}-\sum_{n=2}^{\infty}\frac{1}{n!}\rho(i)^n\sum^{(B)}\prod_{n\geq i>j\geq 1}F_{ij} \tag{16}$$

and

$$\frac{B(i_1,\cdots,i_m)}{kT}=-\sum_{n=m}^{\infty}\frac{1}{n!}\sum_{R_1=i_1}^{i_m}\cdots\sum_{R_n=i_1}^{i_m}\rho(R_1)\cdots\rho(R_n)\sum^{(B)}\prod_{n\geq i>j\geq 1}F_{ij} \tag{17}$$

for $m \geqq 2$.

Again, we define $A(i_1, \cdots, i_m)$ by (7')–(7^L) in terms of $B(i_1, \cdots, i_n)$ given by (16) and (17). Then, $A(1, \cdots, L) = A$, and $A(i_1, \cdots, i_m)$ is the free energy per system of the ensemble of M $(M \to \infty)$ replicas of system $(i_1, \cdots, i_m)$ under the restriction that the one particle distribution function is the one prescribed: $\rho(R_i)$; the potential energy between two particles in different replicas is assumed to be zero.

$A(1, \cdots, m)$ can be calculated by using the relations

$$\Xi(1, \cdots, m) = \sum_{N_1=0}^{\infty} \cdots \sum_{N_m=0}^{\infty} z_{1,\ldots,m}(1)^{N_1} \cdots z_{1,\ldots,m}(m)^{N_m} \exp[-\Phi(N_1, \cdots, N_m)/kT] , \tag{18}$$

$$\rho(i) = \frac{\partial \ln \Xi(1, \cdots, m)}{\partial \ln z_{1,\ldots,m}(i)} \tag{19}$$

and

$$\frac{A(1, \cdots, m)}{kT} = \sum_{i=1}^{m} \rho(i) \ln z_{1,\ldots,m}(i) - \ln \Xi(1, \cdots, m) , \tag{20}$$

where $\Phi(N_1, \cdots, N_m)$ denotes the potential energy of the system when $N_1, N_2, \cdots, N_m$ particles are on the lattice site $1, 2, \cdots, m$, respectively, i.e.

$$\Phi(N_1, N_2, \cdots, N_m) = \sum_{m \geq i > j \geq 1} N_i N_j V^{(2)}(i, j) + \sum_{i=1}^{m} \frac{N_i(N_i-1)}{2} V^{(2)}(i, i) . \tag{21}$$

Here we have had to introduce the fugacity $z_{1,\ldots,m}(i)$ for each lattice site i, because the density $\rho(i)$ is prescribed for each lattice site separately.

For instance, we can calculate $B(1, 2)$ for the case when $V^{(2)}(i, i) = \infty$ as follows:

$$\Xi(1, 2) = 1 + z_{12}(1) + z_{12}(2) + z_{12}(1) z_{12}(2) u , \qquad u \equiv \exp[-V^{(2)}(1, 2)/kT] ;$$

$$\rho(1) = \frac{z_{12}(1) + z_{12}(1) z_{12}(2) u}{1 + z_{12}(1) + z_{12}(2) + z_{12}(1) z_{12}(2) u} ,$$

$$\rho(2) = \frac{z_{12}(2) + z_{12}(1) z_{12}(2) u}{1 + z_{12}(1) + z_{12}(2) + z_{12}(1) z_{12}(2) u} ,$$

$$z_{12}(1) = \frac{1}{2(1-\rho(1))u} [-1 + \rho(1) + \rho(2) - (\rho(2) - \rho(1))u + \beta] ,$$

$$z_{12}(2) = \frac{1}{2(1-\rho(2))u} [-1 + \rho(1) + \rho(2) + (\rho(2) - \rho(1))u + \beta] ,$$

$$\beta \equiv \sqrt{(1-\rho(1)-\rho(2))^2 + 2\rho(1)(1-\rho(1))u + 2\rho(2)(1-\rho(2)) + (\rho(2)-\rho(1))^2 u^2} .$$

Thence, we have

$$\begin{aligned} \frac{B(1, 2)}{kT} &= \frac{A(1, 2)}{kT} - \frac{A(1)}{kT} - \frac{A(2)}{kT} \\ &= -(1-\rho(1)-\rho(2)) \ln \frac{1}{2u} [-1 + \rho(1) + \rho(2) + (2-\rho(1)-\rho(2))u + \beta] \\ &\quad - \rho(1) \ln \frac{1}{2} [1 + (\rho(1)-\rho(2))(1-u) + \beta] \\ &\quad - \rho(2) \ln \frac{1}{2} [1 + (\rho(2)-\rho(1))(1-u) + \beta] . \end{aligned} \tag{22}$$

$A(1, \cdots, m)/kT$ can be evaluated also by the variational principle (cf. Ref. 16):

$$A(1, \cdots, m) = \text{Min}\, \mathscr{A}(1, \cdots, m) , \tag{23}$$

$$\frac{\mathscr{A}(1, \cdots, m)}{kT} = \sum_{N_1=0}^{\infty} \cdots \sum_{N_m=0}^{\infty} \rho^{[m]}(N_1, \cdots, N_m) \left\{ \frac{\Phi(N_1, \cdots, N_m)}{kT} + \ln \rho^{[m]}(N_1, \cdots, N_m) \right\} ; \tag{24}$$

the minimum is to be taken by the variation with respect to $\rho^{[m]}(N_1, \cdots, N_m)$ under the restriction that

$$\rho(i) = \sum_{N_1=0}^{\infty} \cdots \sum_{N_m=0}^{\infty} N_i \rho^{[m]}(N_1, \cdots, N_m) \,. \tag{25}$$

The calculation of $A(1, \cdots, m)$ by this variational principle is more powerful for large m than that by the grand partition function, if we are to be satisfied with the approximate evaluation.

The standpoint to cut the series (7^L) at a point and to calculate $A(i_1, \cdots, i_m)$ by the variational methods (23)–(25), can be formulated in the form of the Ursell expansion as we define $\mathscr{B}(i_1, \cdots, i_m)$ by

$$\mathscr{A}(i) = \mathscr{B}(i) \tag{26$'$}$$

$$\mathscr{A}(i, j) = \mathscr{B}(i) + \mathscr{B}(j) + \mathscr{B}(i, j) \tag{26$''$}$$

$$\mathscr{A}(i, j, k) = \mathscr{B}(i) + \mathscr{B}(j) + \mathscr{B}(k) + \mathscr{B}(i, j) + \mathscr{B}(i, k) + \mathscr{B}(i, k) + \mathscr{B}(i, j, k) \tag{26$'''$}$$

$$\cdots\cdots\cdots\cdots$$

$$\mathscr{A}(1, \cdots, L) = \sum_{i=1}^{L} \mathscr{B}(i) + \sum_{L \geq i > j \geq 1} \mathscr{B}(i, j) + \sum \mathscr{B}(i, j, k) + \cdots + \mathscr{B}(1, \cdots, L) \tag{26^L}$$

and consider only $\mathscr{B}(i_1, \cdots, i_m)$ with suitable figure of $(i_1, \cdots, i_m)$ dropping the other $\mathscr{B}(i_1, \cdots, i_m)$ and take the variation with respect to $\rho_{i_1, \ldots, i_m}^{[m]}(N_1, \cdots, N_m)$ under the restriction of (26).

Following the terminology used in the development of the cluster variation method by the author[16)], we call cluster of lattice sites $(i_1, \cdots, i_m)$ a preserved cluster if we retain $\mathscr{B}(i_1, \cdots, i_m)$ and a net-preserved cluster if we neglect $\mathscr{B}(i_1, \cdots, i_m)$. Then the approximation is decided by which clusters of lattice sites are to be preserved.

In this method the variations by $\rho^{[2]}, \cdots, \rho^{[m]}, \cdots$ are independent, while they are dependent on each other in the case of the cluster variation method[13),16),17)]. It is to be noted here that this is the only difference of these two methods. For the case in which the potential energy is such that $\Phi(N_1, \cdots, N_m) = \infty$ if one of N_i's is equal to or larger than two, the approximations to preserve the terms of $\mathscr{B}(i)$ and $\mathscr{B}(i, j)$ are identical for both method; leading to the Bethe approximation. When the terms of larger cluster of lattice sites are preserved, the cluster variation method is expected to give better results. However, the calculations will be far easier for our method developed in this section.

§3. Cell and Cell Pair Approximation

As in Parts I and II, we introduce the cell and cell pair approximation where clusters of lattice sites are preserved if and only if they are conceived in a cell or a pair of neighboring cells.

Let us divide L lattice sites into C cells, each with $s = L/C$ lattice sites, and denote μth lattice site of the ith cell by $i\mu$. Then, in the cell and cell pair approximation (7) is collected into

$$A(\text{cell}: i) = B(\text{cell}: i) \tag{27$'$}$$

$$A(\text{cells}: i, j) = B(\text{cell}: i) + B(\text{cell}: j) + B(\text{cells}: i, j) \tag{27$''$}$$

$$A = A(\text{cells}: 1, \cdots, C) = \sum_{i=1}^{C} B(\text{cell}: i) + \sum_{C \geq i > j \geq 1} B(\text{cells}: i, j) \tag{27^C}$$

where

$$A(\text{cell}: i) = A(i_1, \cdots, i_s) \,, \tag{28$'$}$$

$$A(\text{cells}: i, j) = A(i_1, \cdots, i_s, j_1, \cdots, j_s) \,, \tag{28$''$}$$

etc. Then, $A(\text{cells}: i_1, \cdots, i_m)$ is the free energy per system of the ensemble of M ($M \to \infty$) replicas of the system composed of the set of cells $(i_1, \cdots, i_m)$. With this interpretation, (27) can be taken also as the formulae for the case of a continuous system.

If the calculation of (27) is performed by the variational method analogous to (23) and if the size of a cell is such as not to contain two particles at a time, then the calculation becomes identical to that undertaken in Parts I and II.

As the result, the cell and cell pair approximation developed from the standpoint of the cluster variation method has been found to be an approximation which takes into account those parts of the factors $\Pi_{n\geq i>j\geq 1}F_{ij}$ correctly that the coordinates i and j are all conceived in a cell and a pair of neighboring cells and neglects the other parts. The reason why we could obtained the phase transition between solid and fluids seems to rest on the fact that we could consider the short range correlation for all clusters, may it be however large. From the standpoint in this paper, we can improve the approximation by taking into account also the long range parts of small clusters—2nd virial, rings, etc.—correctly besides short range parts of large clusters: In this way the approximation will be improved at low density region.

We will now conclude this section with a comment on the terms neglected. If the cell is of the size not to allow two of more particles to come in a cell at a time, the theorem by Rushbrooke and Scoins or its generalization teaches us that the clusters of lattice sites or space coordinates neglected are those which are over three or more cells, between which potential energies are not negligible, and on the other hand if we look at these terms from the standpoint of the cluster variation method, the neglect of these terms is allowed when the superposition approximation or its generalization is acceptable between particles in these cells.

§ 4. Conclusion

We have formulated the method of Yvon, Rushbrooke and Scoins to classify the contributions to the free energy according to the clusters of lattice sites schematically, generalized it to non-uniform systems and related with the cluster variation method. The cell and cell pair approximation in our method was shown to be identical to that in the cluster variation method: the practical calculations were performed by the author in Parts I and II. The analysis of this paper allows us to consider the approximation in the calculations in Parts I and II from another somewhat more clear standpoint of the cluster expansion method.

From our analysis in this paper, I believe that the essential parts of the contributions in the cluster expansion formula of the free energy responsible for solid and liquid phases and their phase transitions have been considered in our cell theory. Further improvements in the calculations will be discussed in the following papers in this series.

Acknowledgement

I would like to express my cordial thanks to Prof. J. Yvon for his kind disposal which made me acquainted with his theory in Ref. 11. My thanks are also due to Dr. K. Hiroike for his helpful discussions.

Cell Theory of Classical Liquids. Phase Transition between Gas, Liquid and Solid. Part IV. F. C. C. Lattice Gases

By Tohru MORITA

Physics Department, Tokyo Institute of Technology

(Received January 26, 1959)

The method developed in Part III is applied in the approximation of the "statues of 6 points" to the face-centered cubic lattice gases, of nearest neighbor lattice sites distance $a/2$, composed of particles with hard core of diameter somewhat smaller than a, with and without attractive part. The results obtained are that these lattice gases will exhibit the solid-gas phase transition, while the liquid phase will not appear for systems of particles either with or without attractive interactions. Qualitative discussions are given of the reason why the difference that our lattice gases will not become liquid and the real gas condenses to liquid, arises.

§ 1. Introduction

As models for the theoretical investigation of the phase transition of liquid, some efforts have been made to investigate lattice gases, which can be treated more easily[1)-3)]. Since the later investigations[2),3)] have been made for the two-dimensional lattice gases, their results seem to be not suitable to make comparisons with the data for three-dimensional ordinary liquid. As early as 1939, Lennard-Jones and Devonshire[1)] investigated the simple cubic lattice gas, assuming the potential energy between a pair of particles to be positive infinity and a finite positive value when two particles are on the same lattice site and on the nearest neighbor lattice sites respectively and zero thereafter. The system was shown to exhibit a solid-gas phase transition. In their theory, the solid state is characterized as the state where, when we divide the lattice sites into two sublattices (○ and ●) as in Fig. 1, the lattice sites of one of sublattices (e.g. ○) are more populated by particles than the others (●), and gaseous state corresponds to the state where all the lattice sites are equally populated: The one particle distribution function is periodic in the solid state and constant in the gaseous state, in accordance with our physical intuition discriminating solid and gas. This point of view of discriminating the solid from the fluids is adopted in this series of work, both for lattice and continuous systems. Since the liquid —the continuous system— is equivalent to a lattice system of infinitesimal lattice constant, the lattice system with a smaller lattice constant will behave more similarly to the con-

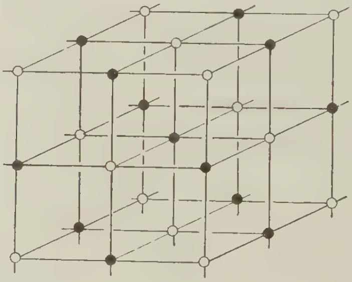

Fig. 1.

tinuous system. In this paper, we will improve the calculation by investigating the three-dimensional lattice gases, of lattice constant smaller than that in Ref. 1, composed of particles with hard core, with and without attractive part, respectively. Then, since these systems can be regarded as the continuous systems, of which the potential energy is determined by the distribution of the lattice sites, the volumes attached to which are occupied, independently of the detailed positions of particles in the volumes⁵⁾, our results can be compared with the phase transitions of ordinary liquids and we will reach some knowledges about what factors cause the phase transitions between gas, liquid and solid.

In § 2, we will apply the formalism of Part III⁴⁾ to our system in the approximation of the "statues of 6 points". In § 3, the detailed calculations will be made for lattice gases of hard spheres. In § 4, the calculations for lattice gases with both hard core and attractive part are given. In § 5, the results obtained will be compared with the phase transitions of ordinary gas, liquid and solid.

§ 2. Approximate Free Energy

The system to be considered in this part is such a lattice system that N identical particles are on $L=8C$ lattice sites, constituting a face-centerted cubic lattice of lattice constant $a/\sqrt{2}$ or nearest neighbor distance $a/2$, and the potential energy is given by

$$\sum_{N\geq i>j\geq 1} V^{(2)}(R_i, R_j) \tag{1}$$

where

$$V^{(2)}(R_i, R_j)=\phi(|R_i-R_j|)$$

$$\phi(r)\begin{cases} =\infty & r=a/2,\ \sqrt{2}\,a/2,\ \sqrt{3}\,a/2 \\ \leq 0 & r\geq a \\ =0 & r\rightarrow\infty; \end{cases} \tag{2}$$

the particle has a hard core of diameter $>\sqrt{3}\,a/2$, $<a$, and moreover we assume that $\phi(r)$ is smallest when $r=a$.* As the consequence, the system at 0°K becomes the crystal in which one of 8 f.c.c. sublattices** of lattice constant $\sqrt{2}\,a$ or nearest neighbor distance a is occupied by particles and others unoccupied. Thence, we may assume that the solid state is the state where one of sublattices is more populated than the others. In fact, we will proceed the discussions in the following taking such standpoint.

We can consider our system to be composed of the cells of Fig. 2 arranged in a f.c.c. lattice of lattice constant $\sqrt{2}$. Then, the lattice sites with $\nu=1, 2, \cdots, 8$ each in Fig. 2 constitutes a f.c.c. sublattice of lattice constant $\sqrt{2}\,a$. A sectional view is shown in Fig. 3.

In Parts I and II, we have considered the correlations of occupations in a cell and pairs of cells and used the generalized superposition approximation for the correlations be-

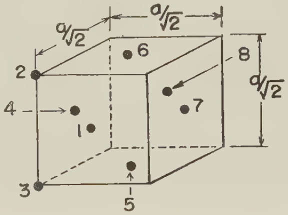

Fig. 2. A cell.

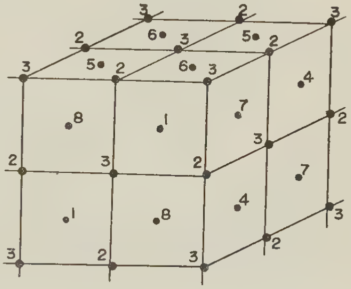

Fig. 3. A sectional view of our lattice. Lattice sites with $\nu=1, 2, \ldots, 8$ each constitutes a f.c.c. sublattice.

---

* In order to understand clearly the distribution of the lattice sites in our lattice, let us consider neighboring lattice sites as seen from a lattice site of $\nu=1$ in Fig. 3. It is as follows:

	distance	number	values of ν in Fig. 3
1st neighbor	$a/2$	12	$2\times(2, 3, 5, 6, 4, 7)$
2nd 〃	$\sqrt{2}\,a/2$	6	$6\times(8)$
3rd 〃	$\sqrt{3}\,a/2$	24	$4\times(2, 3, 5, 6, 4, 7)$
4th 〃	a	12	$12\times(1)$
5th 〃	$\sqrt{5}\,a/2$	24	$4\times(2, 3, 5, 6, 4, 7)$
6th 〃	$\sqrt{6}\,a/2$	8	$8\times(8)$
. . . . . .			

Here, for example, $2\times(2, 3, 5, 6, 4, 7)$ at the last column for the 1st neighbor denotes that 12 lattice sites of the 1st neighbor consist of 2 lattice sites each of $\nu=2$, 3, 5, 6, 4 and 7.

** Note that any regular lattice is composed of $8=2\times2\times2$ sublattices of the same lattice structure but with lattice constant twice of the original one.

tween three cells, even for clusters of lattice sites in a cell displaced, from the stand point of the cluster variation method. The approximation, if we see from the standpoint based on the cluster expansion method developed in Part III, seems to be imperfect in the respect that if a cluster of lattice sites is taken into account, then the clusters of the same form of figures should be taken account of in any stage of approximation. If physically seen, the standpoint of Parts I and II has not so much difficulties while it seems more statisfactory to take into account the clusters of lattice sites which have the same form, at the same time. With this consideration, we may make the calculations either by the formalism of the cluster variation method or by the formalism of the Part III. Here we will use the latter.

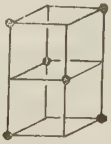

Fig. 4. A statue of 6 points.

Our approximation in the present article is to preserve the clusters of lattice sites inclusive in a "statue of 6 points" as shown in Fig. 4 or its rotated ones and those composed of two lattice sites and to neglect the others. In this approximation, we calculate the free energy and the equation of state of our lattice system, where the solid state will be assumed to be the state where one of the sublattices (e.g. taken to be 1) is the most populated and one (e.g. taken to be 8) is the worst populated and the others are equally populated, that is

$$\rho_1 \geqq \rho_2 = \rho_3 = \cdots = \rho_7 \geqq \rho_8; \tag{3}$$

ρ_ν, $\nu=1, \cdots, 8$, means the number density for each lattice site of the sublattice ν.

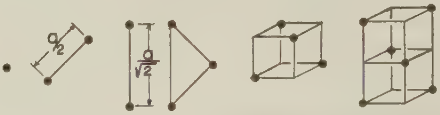

Fig. 5.

Here we are to write Eq. (III. 7^L)* retaining the contributions of the preserved clusters in our approximation. However it can easily be seen that the contributions from the clusters inclusive in the statues of 6 points can be collected to those from the clusters which are the intersections of two statues or the intersections of two intersections just obtained or of a intersection obtained and a statue$\cdots$: the total of which is shown in Fig. 5. Then, we introduce $B(i_1, \cdots, i_m)$ corresponding to these clusters of lattice sites by

$$A(i)=B(i)$$
$$A(i, j)=B(i)+B(j)+B(i, j)$$
$$A(i, j, k)=B(i)+B(j)+B(k)+B(i, j)+B(i, k)+B(j, k)+B(i, j, k)$$
$$A(i, j, k, l; \text{tetrahedron})=B(i)+B(j)+B(k)+B(l)+B(i, j)+B(i, k)+B(i, l)$$
$$+B(j, k)+B(j, l)+B(k, l)+B(i, j, k, l; \text{tetrahedron})$$

$A\Big($  $\Big)$ $=B(i)+B(j)+B(k)+B(l)+B(m)+B(n)+B(i, j)+B(i, k)$

$$+B(i, l)+B(i, m)+B(j, k)+B(j, l)+B(j, n)+B(k, l)+B(k, m)+B(k, n)$$
$$+B(l, m)+B(l, n)+B(m, n)+B(i, k, m)+B(i, l, m)+B(j, k, n)+B(j, l, n)$$

$+B(i, j, k, l; \text{tetrahedron})+B(k, l, m, n; \text{tetrahedron})+B\Big($  $\Big)$. (4)

Then we have for the free energy in our approximation as follows:

$$[A(1, \cdots, L)/kT]_{\text{up to statues of 6 pts.}}=(A/kT)_{\text{h.c.}}+(A/kT)_{\text{a.p.}}\,, \tag{5}$$

$$A_{\text{h.c.}}=\sum_{i=1}^{L} B(i)+\sum B(i, j; R_{ij}=a/2)+\sum B(i, j; R_{ij}=\sqrt{2}a/2)+\sum B(i, j, k; \triangle)$$
$$+\sum B(i, j, k, l; \text{tetrahedron})+\sum B(i, j, k, l, m, n; \text{statue of 6 pts.})\,, \tag{5'}$$

---

* (III-7^L) denotes Eq. (7^L) of Part III[4].

$$A_{\text{a.p.}}=\sum B(i,\ j;\ R_{ij}\geqq a)\ ;$$

where $(A/kT)_{\text{a.p.}}=A_{\text{a.p.}}/kT$ is the part of $A|kT$ which vanishes when the attractive part is absent and $(A/kT)_{\text{h.c.}}=A_{\text{h.c.}}/kT$ is the part which is independent of the attractive part, and hence we have separated into two parts: a. p. (attractive part) and h. c. (hard core part).

For our system, $A(i)$, $A(i,\ j;\ R_{ij}<a)$, $A(i,\ j,\ k;\ \triangle)$, $A(i,\ j,\ k,\ l;$ tetrahedron and $A(i,\ j,\ k,\ l,\ m,\ n;$ statue of 6pts.) are

$$\left.\begin{aligned}
&A(i)/kT=\rho_i\ln\rho_0+(1-\rho_i)\ln(1-\rho_i)\\
&A(i,\ j)/kT=\rho_i\ln\rho_i+\rho_j\ln\rho_j+(1-\rho_i-\rho_j)\ln(1-\rho_i-\rho_j)\qquad\text{for } R_{ij}<a\ ,\\
&A(i,\ j,\ k;\ \triangle)/kT=\rho_i\ln\rho_i+\rho_j\ln\rho_j+\rho_k\ln\rho_k+(1-\rho_i-\rho_j-\rho_k)\ln(1-\rho_i-\rho_j-\rho_k)\\
&A(1,\ 2,\ 3,\ 4;\ \text{tetrahedron})/kT=\sum_{s=1}^{4}\rho_{\nu_s}\ln\rho_{\nu_s}+\left(1-\sum_{s=1}^{4}\rho_{\nu_s}\right)\ln\left(1-\sum_{s=1}^{4}\rho_{\nu_s}\right)\\
&A(1,\ 2,\ \cdots,\ 6;\ \text{statue of 6 pts.})/kT=\sum_{s=1}^{6}\rho_{\nu_s}\ln\rho_{\nu_s}+\left(1-\sum_{s=1}^{6}\rho_{\nu_s}\right)\ln\left(1-\sum_{s=1}^{6}\rho_{\nu_s}\right).
\end{aligned}\right\}\tag{6}$$

These $A(i_1,\ \cdots,\ i_m)$ are determined by the relative positions of the sites of 1 and 8.

A lengthy but straightforward calculation gives

$$\begin{aligned}
(A/CkT)_{\text{h.c.}}=&\rho_1\ln\rho_1+\rho_8\ln\rho_8+6\rho_2\ln\rho_2-13(1-\rho_1)\ln(1-\rho_1)-13(1-\rho_8)\ln(1-\rho_8)\\
&-78(1-\rho_2)\ln(1-\rho_2)+48(1-\rho_1-\rho_2)\ln(1-\rho_1-\rho_2)+48(1-\rho_8-\rho_2)\ln(1-\rho_8-\rho_2)\\
&+114(1-2\rho_2)\ln(1-2\rho_2)+6(1-\rho_1-\rho_8)\ln(1-\rho_1-\rho_8)-12(1-\rho_1-2\rho_2)\ln(1-\rho_1-2\rho_2)\\
&-12(1-\rho_8-2\rho_2)\ln(1-\rho_8-2\rho_2)-48(1-3\rho_2)\ln(1-3\rho_2)-24(1-\rho_1-\rho_8-\rho_2)\ln(1-\rho_1-\rho_8-\rho_2)\\
&-40(1-\rho_1-3\rho_2)\ln(1-\rho_1-3\rho_2)-40(1-\rho_8-3\rho_2)\ln(1-\rho_8-3\rho_2)\\
&+24(1-\rho_1-\rho_8-4\rho_2)\ln(1-\rho_1-\rho_8-4\rho_2)+12(1-\rho_1-5\rho_2)\ln(1-\rho_1-5\rho_2)\\
&+12(1-\rho_8-5\rho_2)\ln(1-\rho_8-5\rho_2)\ .
\end{aligned}\tag{7}$$

As stated in Part III, we should determine the values of ρ_ν's by the condition

$$\frac{\partial A/CkT}{\partial\rho_\nu}=\text{a const. indep. of }\nu\ ,\tag{8}$$

which is the condition of A/CkT minimum under the condition of $\rho=\sum_{\nu=1}^{8}\rho_\nu$ given. We will minimize A/CkT under the restriction that

$$\rho_1=\frac{\rho e^{\alpha}}{2(3+\cosh\alpha)}\ ,\qquad\rho_2=\cdots=\rho_7=\frac{\rho}{2(3+\cosh\alpha)}\ ,\qquad\rho_8=\frac{\rho e^{-\alpha}}{2(3+\cosh\alpha)}\ ,\tag{9}$$

reducing the number of variational variable to one, α. If we substitute these in (7), the condition to determine ρ_ν's is

$$\frac{\partial A/CkT}{\partial\alpha}=0\ .\tag{10}$$

One of the roots is $\alpha=0$. Whether this state corresponds to the stable state or not is determined according as

$$\left[\frac{\partial^2}{\partial\alpha^2}\frac{A}{CkT}\right]_{\alpha=0}=\frac{\rho}{4}\zeta+\frac{1}{C}\left[\frac{\partial^2}{\partial\alpha^2}\sum_{R_{ij}\geqq a}B(i,\ j)\right]_{\alpha=0}\tag{11}$$

with

$$\zeta=1-\frac{13}{8l-1}+\frac{48}{8l-2}-\frac{12}{8l-3}-\frac{40}{8l-4}+\frac{12}{8l-6},\qquad l\equiv1/\rho\ ,\tag{12}$$

is positive or negative. ζ as a function of l is drawn in Fig. 6, which shows that $\alpha=0$ corresponds to a minimum for all values of ρ for a high temperature system where $B(i, j)$ for $R_{ij}\geqq a$ is small or for a system of hard spheres where the second term of the righthand side of (11) is zero. The detailed discussions will be given of the possible roots of (12) in the respective cases in the following sections.

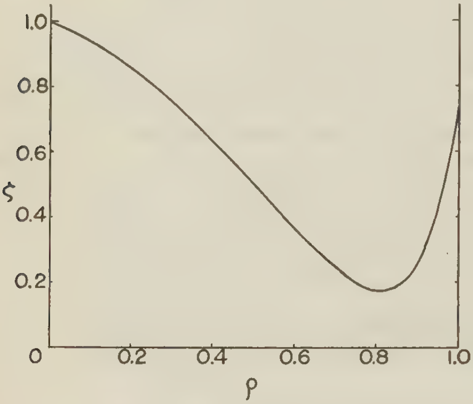

Fig. 6. $\zeta=\frac{4}{\rho}\left(\frac{\partial^2}{\partial\alpha^2}\frac{A}{CkT}\right)_{\text{h.c.},\ \alpha=0}-\rho$ curve.

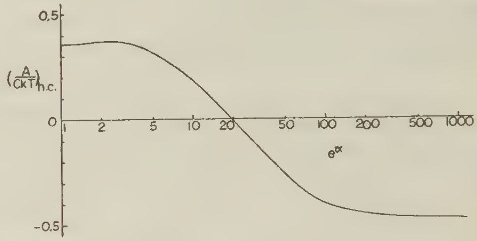

Fig. 7. $(A/CkT)_{\text{h.c.}}-\alpha$ for $\rho=0.8$.

Table I.

ρ	1.0	0.9	0.8	0.7
$\rho_2=\rho_8$	0	0.00001	0.00026	0.00170
$\Delta(A/CkT)_{\text{s.h.c.}}$	0	−0.00006	−0.00179	−0.01191
$(A/CkT)_{\text{s.h.c.}}$	0	−0.3251	−0.5004	−0.6109

§ 3. System of Hard Spheres

Here we will investigate the system of hard spheres, where the potential energy is assumed to be

$$\phi(r)=\begin{cases}\infty & r<a\\ 0 & r\geqq a\,,\end{cases} \tag{13}$$

then the equation for the free energy $(A/CkT)_{\text{h.c.}}$ is given by Eq. (7).

For this case.

$$\left[\frac{\partial^2}{\partial\alpha^2}\left(\frac{A}{CkT}\right)_{\text{h.c.}}\right]_{\alpha=0}=\frac{\rho}{4}\zeta>0 \qquad \text{for } 0\leqq\rho\leqq 1\,, \tag{14}$$

and so the state with $\alpha=0$ corresponds to the stable state for all values of ρ. In order to investigate the possibility of another minimum or another solution of (10), we have drawn $(A/CkT)_{\text{h.c.}}$ as a function of α for $\rho=0.8$ as an instance, which is shown in Fig. 7. It shows that another minimum will exist at $\alpha=\infty$ or $\alpha\sim\infty$; where $(A/CkT)_{\text{h.c.}}$ can be expanded in powers of ρ_2 and ρ_8 as

$$(A/CkT)_{\text{h.c.}}=(A/CkT)_{\text{s.h.c.}}+\Delta(A/CkT)_{\text{s.h.c.}} \tag{15}$$

$$(A/CkT)_{\text{s.h.c.}}=\rho\ln\rho+(1-\rho)\ln(1-\rho) \tag{16}$$

$$\begin{aligned}\Delta(A/CkT)_{\text{s.h.c.}}=&6\rho_2[\ln\rho_2-1-\ln\rho-5\ln(1-\rho)]\\&+\rho_8[\ln\rho_8-1-\ln\rho-5\ln(1-\rho)]+O(\rho_2{}^2,\ \rho_8{}^2,\ \rho_2\rho_8)\ .\end{aligned} \tag{17}$$

A minimum appears at

$$\rho_2=\rho_8=(1-\rho)^5 \tag{18}$$

where

$$\Delta(A/CkT)_{\text{s.h.c.}}=-7\rho(1-\rho)^5\ . \tag{19}$$

For several values of ρ, they are calculated and given in Table I where $(A/CkT)_{\text{s.h.c.}}$ is also given. The correction $\Delta(A/CkT)_{\text{s.h.c.}}$ is seen to be negligible. Then it will be sufficient to calculate $(A/CkT)_{\mathrm{h.c.}}$ for two cases: $\rho_1=\rho_8=\rho_2=\rho/8$ corresponding to the fluids state and $\rho_1=\rho$, $\rho_2=\rho_8=0$ corresponding to the solid state.

For the fluid state, we substitute $\rho_1=\rho_8=\rho_2=\rho/8$ in $(A/CkT)_{\mathrm{h.c.}}$, then we have

$$\begin{aligned}(A/CkT)_{\mathrm{f.h.c.}}=&\rho\ln\frac{\rho}{8}-104\left(1-\frac{\rho}{8}\right)\ln\left(1-\frac{\rho}{8}\right)+216\left(1-\frac{\rho}{4}\right)\ln\left(1-\frac{\rho}{4}\right)\\&-96\left(1-\frac{3}{3}\rho\right)\ln\left(1-\frac{3}{8}\rho\right)-80\left(1-\frac{\rho}{2}\right)\ln\left(1-\frac{\rho}{2}\right)\\&+48\left(1-\frac{3}{4}\rho\right)\ln\left(1-\frac{3}{4}\rho\right).\end{aligned}\tag{20}$$

The pressure and the chemical potential are given by

$$\begin{aligned}\left(\frac{\mu}{kT}\right)_{\mathrm{f.h.c.}}=&\frac{\partial}{\partial\rho}\left(\frac{A}{CkT}\right)_{\mathrm{f.h.c.}}=\ln\frac{\rho}{8}+13\ln\left(1-\frac{\rho}{8}\right)-54\ln\left(1-\frac{\rho}{4}\right)\\&+36\ln\left(1-\frac{3}{8}\rho\right)+40\ln\left(1-\frac{\rho}{2}\right)-36\ln\left(1-\frac{3}{4}\rho\right)\end{aligned}\tag{21}$$

$$\begin{aligned}\left(\frac{p}{kT}\right)_{\mathrm{f.h.c.}}=&\rho\left(\frac{\mu}{kT}\right)_{\mathrm{f.h.c.}}-\left(\frac{A}{CkT}\right)_{\mathrm{f.h.c.}}=104\ln\left(1-\frac{\rho}{8}\right)-216\ln\left(1-\frac{\rho}{4}\right)\\&+96\ln\left(1-\frac{3}{8}\rho\right)+80\ln\left(1-\frac{\rho}{2}\right)-48\ln\left(1-\frac{3}{4}\rho\right).\end{aligned}\tag{22}$$

For the solid state, they are

$$(A/CkT)_{\mathrm{s.h.c.}}=\rho\ln\rho+(1-\rho)\ln(1-\rho)\,,\tag{23}$$

$$(\mu/kT)_{\mathrm{s.h.c.}}=\ln\rho-\ln(1-\rho)\,,\tag{24}$$

$$(p/kT)_{\mathrm{s.h.c.}}=-\ln(1-\rho)\,.\tag{25}$$

They are drawn in Fig. 8 and Fig. 9. They show that our lattice gas of hard spheres exhibits a phase transition of first order between solid and gas. The coexistence densities, pressure and chemical potential are

$1/\rho_{\mathrm{solid}}=1.21$, $1/\rho_{\mathrm{gas}}=2.00$,

$p_{\mathrm{coexistence}}=1.74$, $\mu_{\mathrm{coexistence}}=1.54$,

the heat of sublimation is

$$\Delta S/NkT=\Delta A/NkT=1.35\,.$$

It is of interest to compare this phase transition with that for the continuous system of hard spheres, obtained by Wood, Jacobson, Alder and Wainwright⁶⁾: For the latter system, the metastable regions of gas and solid extend to the volume $v/v_0=1.55$ where their pressures are $pv_0/kT=7.1$ and 5.5 respectively. The corresponding values for our lattice system are calculated as $v=1.65$ and $p/kT=2.75$ and 0.95

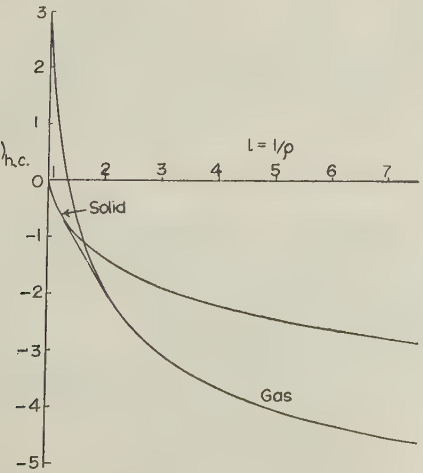

Fig. 8. $(A/C\rho kT)_{\mathrm{h.c.}}-1/\rho$ curve.

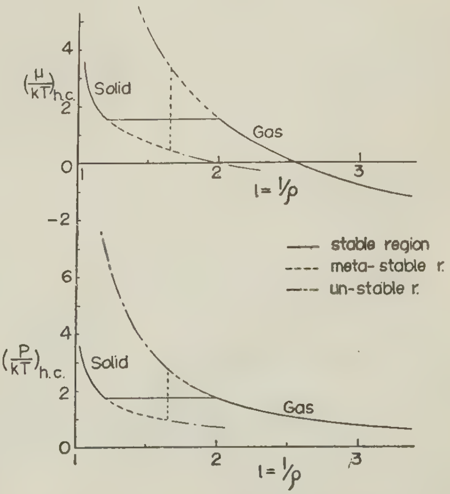

Fig. 9. $(\mu/kT)_{\mathrm{h.c.}}-1/\rho$ and $(p/kT)_{\mathrm{h.c.}}-1/\rho$ curves.

§ 4. System of Particles with Both Hard Core and Attractive Part

In this section we will investigate the system of which the potential energy is given by (1) and (2) with

$$\phi(r)=\begin{cases}\infty & r<a \\ 4\left(\dfrac{1}{r^{12}}-\dfrac{1}{r^{6}}\right) & r\geqq a\end{cases} \tag{26}$$

with $a=2^{1/6}$.

Here we will evaluate $B(i, j)$ for $R_{ij}\geqq a$ as

$$B(i, j)=\rho_i\rho_j\frac{\phi(R_{ij})}{kT}\,. \tag{27}$$

We might calculate it by (III–22), taking fully account of the products of f_{ij}. But, if j and k are neighbors and $B(i, j)$ and $B(i, k)$ are calculated by (III–22 , then the presence of a particle at i tends to make the presence of particles both at j and k favorable while if $B(i, j, k)$ were correctly considered the tendency for the presence of particles at i and j would reduce the tendency for i and k to be occupied at the same time. That is, the use of (III–22) seems to be physically unreasonable. Because of this we have decided to use the coarse approximation of the random mixing, which is not subjected to such an objection.

Then, the attractive part of the free energy becomes

$$\begin{aligned}\left(\frac{A}{CkT}\right)_{\text{a.p.}}&=\frac{1}{C}\sum_{R_{ij}\geqq a}B(i, j)\\ &=6(\rho_1{}^2+\rho_8{}^2+6\rho_2{}^2)\frac{\varphi_a}{kT}\\ &\quad+24(\rho_1\rho_2+\rho_8\rho_2+2\rho_2{}^2)\frac{\varphi_b}{kT}\\ &\quad+8(\rho_1\rho_8+3\rho_2{}^2)\frac{\varphi_c}{kT}\,.\end{aligned} \tag{28}$$

Here,

$$12\varphi_a=\sum_{j=1}^{0}{}^{*}\,V^{(2)}(|R_{i1}-R_{j1}|)\,, \tag{29a}$$

$$24\varphi_b=\sum_{j=1}^{0}{}^{*}\sum_{\nu=2}^{7}V^{(2)}(|R_{i1}-R_{j\nu}|)\,, \tag{29b}$$

$$8\varphi_c=\sum_{j=1}^{0}{}^{*}\,V^{(2)}(|R_{i1}-R_{j8}|)\,, \tag{29c}$$

where * on the summations means that in the summation j for which $V^{(2)}(|r_{i1}-r_{j\nu}|)=\infty$ should be omitted. These values for our potential are calculated as

$$12\varphi_a=-16.7760\,,\qquad 8\varphi_c=-8.7173\,,$$

$$12\varphi_a+24\varphi_b+8\varphi_c=-82.9921\,,$$

by the help of the table of Lennard-Jones and Ingham[7].

The region where $\alpha=0$ can be stable state:

$$\left(\frac{\partial^2}{\partial\alpha^2}\frac{A}{CkT}\right)_{\alpha=0}=\frac{\rho^2}{32}\left\{\frac{8\zeta}{\rho}+\frac{1}{kT}(12\varphi_a-8\varphi_c)\right\}>0\,,$$

is calculated as shown in Fig. 10, under the approximation (27) for $B(i, j)$.

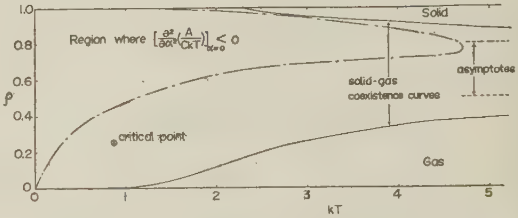

Fig. 10. Phase diagram ($\rho-kT$).

In the following, we calculate A/CkT for $\rho_1=\rho_8=\rho_2=\rho/8$ and $\rho_1=\rho$, $\rho_8=\rho_2=0$ respectively and take the smaller to be our approximate free energy and satisfy ourselves by confirming that the state $\rho_1=\rho_8=\rho_2=\rho/8$ does not come into the region where $\partial^2(A/CkT)/\partial\alpha^2<0$. This is justified so far as there will not appear a new minimum between $\alpha=0$ and $\alpha\sim\infty$. Here, note that the minimum near $\alpha=\infty$ will approach to ∞ where the potential energy is smaller.

For the uniform state, the free energy is

$$(A/CkT)_{\text{f.}}=(A/CkT)_{\text{f.h.c.}}+(A/CkT)_{\text{f.a.p.}} \tag{30}$$

$$\left(\frac{A}{CkT}\right)_{\text{f.a.p.}}=\frac{\rho^2}{16}\frac{12\varphi_a+24\varphi_b+8\varphi_c}{kT}\,. \tag{31}$$

The pressure is given by

$$\left(\frac{p}{kT}\right)_{\text{f.}}=\left(\frac{p}{kT}\right)_{\text{f.h.c.}}+\frac{\rho^2}{16}\frac{12\varphi_a+24\varphi_b+8\varphi_c}{kT}\,. \tag{32}$$

The critical point, then, is easily calculated in this approximation, as the solution of

$$\begin{aligned}-\frac{1}{8kT}&(12\varphi_a+24\varphi_b+8\varphi_c)\\ &=-\frac{104}{(8-\rho)\rho}+\frac{216\times2}{(8-2\sigma)\rho}-\frac{96\times3}{(8-3\rho)\rho}\\ &\quad-\frac{80\times4}{(8-4\rho)\rho}+\frac{48\times6}{(8-6\rho)\rho}\\ &=-\frac{104}{(8-\rho)^2}+\frac{216\times4}{(8-2\rho)^2}-\frac{96\times9}{(8-3\rho)^2}\\ &\quad-\frac{80\times16}{(8-4\rho)^2}+\frac{48\times36}{(8-6\rho)^2}\end{aligned} \tag{33}$$

as

$$\rho_c=0.2557\,,$$
$$kT_c=-\frac{12\varphi_a+24\varphi_b+8\varphi_c}{8\times 12.1970}=0.8505\,.$$

The free energy for the solid state is

$$\left(\frac{A}{CkT}\right)_{\mathrm{s.}}=\rho\ln\rho+(1-\rho)\ln(1-\rho)+6\rho^2\frac{\varphi_a}{kT}\,. \tag{34}$$

$A/C\rho kT$ as a function of $1/\rho$, calculated for $kT=0.8$ and 3.0, are drawn in Fig. 11. It shows that our system will not exhibit the liquid state. The coexistence curves between solid and gas are also drawn in Fig. 10: they have been obtained by drawning $A/C\rho kT-1/\rho$ curves for various values of kT. It is seen that the gaseous region does not come, surely, in the region where $\partial^2(A/CkT)/\partial\alpha^2<0$.

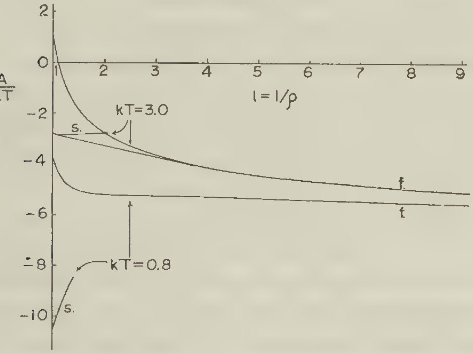

Fig. 11. $A/C\rho kT-1/\rho$ curve for $kT=0.8$ and 3.0.

The result obtained by calculating the hard core part of A/NkT by the approximation of "the statues of 6 points" and the attractive part by the approximation of the random mixing, is such as to exclude the appearance of the liquid state: the free energy for the solid state mixed by gas is lower than that of the liquid state. The phase equilibrium exists between solid of perfect order ($\rho=1$) and gas of comparatively low density, at low temperature region.

§ 5. Discussions

Our lattice gas seems not to exhibit the liquid state, while the ordinary continuous gas condenses to the liquid. Let us investigate the cause by which the difference arises. For this purpose, we consider an equivalent continuous system to our lattice gas. It is a continuous system of which the potential energy is determined only by the distribution of the lattice sites, the cells belonging to which are occupied, independently of the detailed positions of particles in the cells. Then, in such a system, even in the solid state as well as in fluid state, the molecules in a cell exist equally probably in the cell, because of the indifference of the potential energy; while in the ordinary continuous system, in the solid state the probability in a cell will be more restricted to smaller region than in the fluid state. This effect to the free energy is to reduce it for the fluid states and reduces the curve for the fluid state, perhaps until the stable liquid to be possible.

As the result, in order to get the results for the continuous system by using the calculation for a lattice system, we have either to reduce the lattice constant to a value which is small compared with the distance by which the one particle distribution function in the solid state varies or to evaluate the entropy due to the localization of the particles in a cell suitably. Such investigations will be the subject of a future publication.

The author wishes to express his cordial thanks to Dr. K. Hiroike for his helpful discussions.

JOURNAL OF THE PHYSICAL SOCIETY OF JAPAN, Vol. 14, No. 5, MAY, 1959

Study of Reorientational Motion in Solid State of 1, 2, 3-trichlorobenzene and Hexachlorobenzene by Pure Quadrupole Resonance

By Itaru TATSUZAKI

Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received December 26, 1958)

Abrupt increases accompanying the elevation of temperature were observed in the line widths of pure quadrupole resonance spectrum of 1, 2, 3-trichlorobenzene and hexachlorobenzene. The results suggest a possibility of reorientational motion of these molecules in temperature ranges far lower than the melting points. In consideration of hexagonal symmetry of hexachlorobenzene, it was concluded that there was occurring a reorientational motion around the hexagonal axis of this molecule. Its hindering potential barrier was estimated at $12.6 > W \geqslant 9.9$ Kcal/mole by means of pure quadrupole resonance alone. Although 1, 2, 3-trichlorobenzene has no symmetry about the normal axis of the molecular plane, measurements of proton magnetic resonance and dielectric constant, in addition to the pure quadrupole resonance suggested the possibility of the reorientational motion around the normal axis of the molecule, which covers only two neighboring equilibrium positions. From temperature dependence of the line width of pure quadrupole resonance spectrum, the mean height of its hindering potential barrier was estimated at $6.0 > W \geqslant 5.0$ Kcal/mole.

§ 1. Introduction

Molecular rotations in the solid states have been studied by several methods: X-ray analysis, measurement of a specific heat, dielectric measurement and a method of nuclear magnetic resonance. In cases where each molecule rotates almost freely, information about molecular rotations can be obtained either by X-ray analysis or by measurement of the specific heat. In the nuclear magnetic resonance experiment, on the contrary, the line width is affected even though the moleules cannot rotate freely, but can execute so-called reorientational motion. Dielectric measurement can also give information about the reorientational motion, and is however applicable only to polar molecules. In case a nucleus composing a molecule has a large nuclear quadrupole coupling constant, and yet the molecule is non-polar, both methods are not applicable. It is known that a molecule which has a symmetry axis executes a reorientational motion around the axis in temperature ranges far lower than the melting point. The number of molecules with sufficient energy to surmount the potential barrier W is proportional to $\exp(-W/kT)$. Such a motion produces a fluctuating electric field gradient at the nucleus[1)-3)]. This induces the transition between nuclear quadrupole levels, which limits the life time of the levels and accordingly broadens the line width of the pure quadrupole resonance spectrum. Study on this phenomenon was done by Bodin[1)] for the first time, using ethane derivatives. Prior to the present work, the present writer and colleague studied the phenomena for $Cl_3C \cdot CCl_3$[4)] and estimated the height of the hindering potential barrier.

Studies of pure quadrupole resonance spectra of multichlorobenzenes were made by Bray and Barnes[5)]. They reported that 1, 2, 3-trichlorobenzene showed clean signals on oscilloscope with a signal to noise ratio of about 8 to 1 at 77°K but no resonance was detectable at room temperature, even with elaborate recording techniques. Stimulated by this fact, the writer studied the temperature dependence of the line width of 1, 2, 3-trichlorobenzene.

§ 2. Experimental Procedures and Results

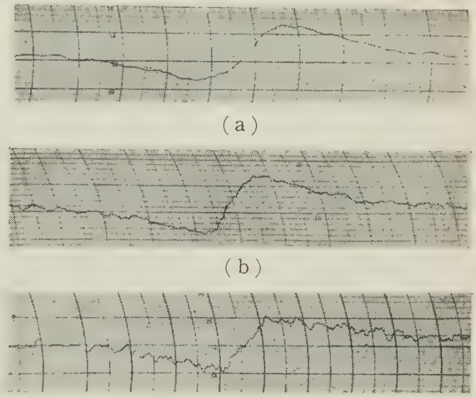
A. *Preparation of materials*

A commercial polycrystalline 1, 2, 3-trichlorobenzene was purified by recrystalization from ethyl alcohol solution and further by vacuum evaporation. The measured melting point of 1, 2. 3-trichlorobenzene was 52.6～52.7°C. Hexachlorobenzene used was commercial reagent grade powdered material with a melting point of 226°C.

B. *Pure quadrupole resonance spectroscopy*

As was done in the previous work[4)], a spectrometer of superregenerative type was used. It gave constantly reproducible absorption curves if both quench frequency and quench voltage were adjusted suitably. Quench frequency of 80～100 Kc/s and quench voltage of 1～2 volts were used throughout the present experiments. The sweep rates of frequency of the spectrometer were calibrated by Kōi's method[6)]. It was 0.02～0.04 Kc/s per second. The time required to sweep over absorption curves was about ten minutes. By integrating the differential curve taken on a recorder, measurement was made of the line width, which is defined as the interval between the two points of the curve where the integrated curve falls to half of the maximum value. The values obtained in repeated measurements agreed within an experimental error of 10%.

To obtain the temperature down to −130°C a cryostat was used. Its main part was a petroleum ether bath. Liquid nitrogen was introduced through a serpentine copper tube immersed in petroleum ether, by means of a water aspirator. The temperature was controlled through varying manually the quantity of liquid nitrogen flowing through the tube. By this method, it was possible to limit the temperature fluctuation in the cryostat within ±0.1°C. Measurements of the temperature were made with a calibrated copper-constantan thermocouple. Only after the desired temperature had been held for at least thirty minutes, were the measurements of quadrupole resonance started. Even though the stirrer had to be stopped to avoid an unfavourable fluctuation of the frequency during the sweeping of the absorption line, no remarkable drift of the temperature was recognized. This was probably associated with a large heat capacity of the cryostat. It is well known that a line width is broadened owing to distribution of resonance frequency caused by a non-uniformity of temperature in the sample. For chlorine nucleus (Cl^{35}, $\nu \simeq 30 \sim 40$ Mc/s), if it be assumed that there is a non-uniformity of 0.1°C in the sample, this broadening should be of the order of 0.3～0.4 Kc/s because the temperature coefficient of resonance frequency $-(d\nu/\nu dT)$ is of the order of magnitude 10^{-4}°K^{-1}. To examine the non-uniformity of temperature in the sample, measurements of the line width were made at several temperatures for para-dichlorobenzene, whose line width is explained by dipole-dipole interactions, which are almost independent of temperature. All values obtained were 1.40±0.05 K/cs, in agreement with those reported by Wang[7)]. This result seems to give assurance that the non-uniformity of temperature in the sample is less than 0.1°C in the course of sweeping of the absorption line. Some of the derivative curves of absorption lines in 1, 2, 3-trichlorobenzene are shown in Fig. 1.



(a)
(b)
(c)

Fig. 1. Examples of the derivative curves obtained for 1, 2, 3-trichlorobenzene. a) 209.5°K, sweep rate of frequency: 0.027 Kc/s per second, half width: 1.75 Kc/s b) 225°K, 0.041 Kc/s per second, 2.3 Kc/s c) 230°K, 0.036 Kc/s per second, 2.6 Kc/s. Paper speed was one division per ten seconds.

1, 2, 3-trichlorobenzene

Six absorption lines were observed by Bray and Barnes[5)]. In the present study measurements were made of the width of the spectrum of the highest absorption frequency assigned to benzene-ring position 2 on the basis of frequency versus sigma value[5)]. Results are plotted in Fig. 2 together with those of hexachlorobenzene.

The broadening of the line width became so remarkable above 225°K that no reliable measurement could be made at temperatures above 240°K. Fig. 2 shows that the line width increases exponentially with the elevation of temperature. This broadening is probably due to the reorientational motion, which is the only possible origin of the increase of the line width accompanying the elevation of temperature. The temperature dependence of the line width is expressed by the formula:

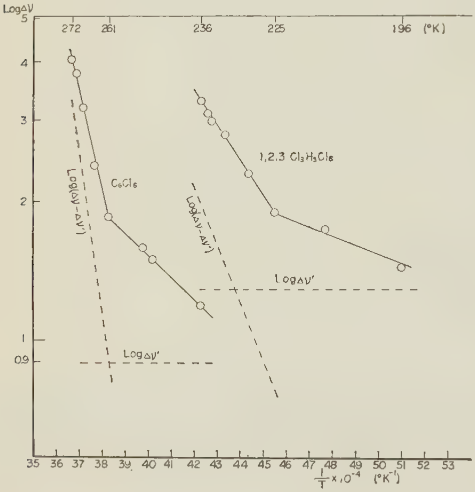


Fig. 2. Behavior of Cl^{35} line width $\varDelta\nu$ as a function of the inverse of the absolute temperature. Solid line: $\log \varDelta\nu$ *vs* $1/T$ Dotted line: $\log(\varDelta\nu - \varDelta\nu')$ *vs* $1/T$ and $\log \varDelta\nu'$ *vs* $1/T$, where $\varDelta\nu'$ is the contribution to the line width from origins other than the reorientational motion.

$$(\varDelta\nu-\varDelta\nu') \propto \exp\left(-\frac{W}{RT}\right) \qquad (1)$$

where $\varDelta\nu'$ is the line width due to the origins other than the reorientational motion. $\varDelta\nu'$ is assumed to be independent of temperature. Though this assumption may not be correct, it would not affect the conclusion seriously. W is the height of hindering potential barrier. The plotted line is now separated into two parts: $\log(\varDelta\nu-\varDelta\nu')$ and $\log(\varDelta\nu')$. From the slope of $\log(\varDelta\nu-\varDelta\nu')$, W is estimated at 6.0±0.1 Kcal/mole. It is reasonable to believe that the reorientational motion is occurring around the normal axis of the molecular plane. As the molecule has no symmetry about this axis, however, one can hardly consider that the reorientational motion becomes a rotation when the temperature is raised further. In order to examine the reorientational motion in this region in detail, the proton magnetic resonance experiment and the measurement of dielectric constant were carried out. Procedures and results will be given below in section 3.

Hexachlorobenzene

The quadrupole resonance frequencies of Cl^{35} were observed as functions of the temperature by Duchesne and Monfils[8]. The hexagonal symmetry of the molecule suggests a possibility of the reorientational motion occurring around the symmetry axis. The line widths of three components coincide with one another within the limits of experimental error. The broadening becomes remarkable above 261°K. From Fig. 2, the value 12.6±0.2 Kcal/mole was obtained for the height of the hindering potential barrier, under the same hypothesis as that adopted for the case of 1, 2, 3-trichlorobenzene.

§ 3 Additional Experiments

A. *Proton magnetic resonance spectroscopy*

The proton magnetic resonance experiment was carried out, in order to examine whether the reorientational motion which causes the broadening of the line width of the quadrupole resonance for 1, 2, 3-trichlorobenzene becomes a rotation at higher temperatures. If a complete rotation should occur at higher temperature, the phenomenon called motional narrowing would be observed, owing to the averaging-out of local magnetic fields at the positions of protons.

The spectrometer used was the same as that used by Odajima et al.[9),10)]. A narrow band amplifier and phase sensitive detector were used to observe the derivative of the absorption line as a function of applied magnetic field. The cryostat employed was one similar to that described by Gutowsky

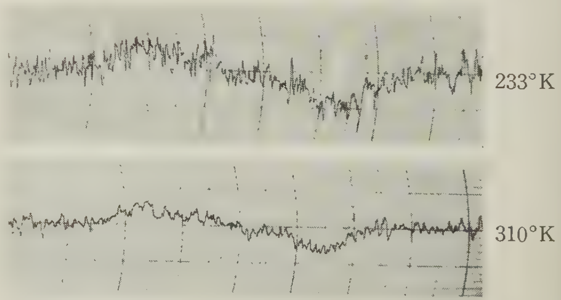

Fig. 3. Typical curves of the proton magnetic resonance for 1, 2, 3-trichlorobenzene. The mean peak-to-peak interval is 6.8±0.5 gauss.

et al.[11]. The constancy of temperature in the course of sweeping of the absorption line was maintained carefully within ±1°C in the vicinity of room temperature and ±3°C in the range 270～220°K. Fig. 3 shows the typical curves recorded for protons. The peak-to-peak intervals of the derivative curves versus temperature are plotted in Fig. 4. No remarkable temperature dependences of the derivative curves of the absorption line are found, up to the melting point. There is however a small reduction in the vicinity of the melting point, which presumably is due to pre-melting of the sample.

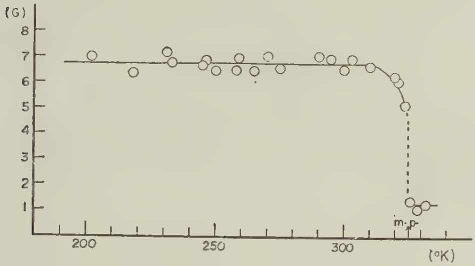

Fig. 4. Peak-to-peak interval of the proton magnetic resonance versus temperature for 1, 2, 3-trichlorobenzene.

It can therefore be concluded that the reorientational motion never becomes such a complete rotation that it can average out the local magnetic fields at the positions of the protons. From the result of the proton magnetic resonance experiment alone, however, another explanation may be possible: neither the rotation nor the reorientational motion does occur below the melting point. This explanation is, however, quite inconsistent with the result of the quadrupole resonance experiment.

B. *Measurement of dielectric constant*

In order to confirm with more certainty the existence of the reorientational motion, the dielectric constant was also measured. 1, 2, 3-trichlorobenzene is polar; the dipole moment lies in the molecular plane. If the reorientational motion occurs around the normal axis of the molecular plane, the dispersion of the dielectric constant ε' has to be observable. The measurement was made at 1 Kc/s with the alternating current bridge. The unbalanced voltage from the detector terminals of the bridge was provided with a sufficient amount of amplification and then led to a cathode ray oscilloscope. The type of the cell by which the dielectric constant ε' was measured was similar to the one described by White and Bishop[12]. The capacity of the cell was 30 pF, whose error was found to be within 3%. Fig. 5 shows the temperature dependence of ε'. From the behavior of ε', it becomes clear that the reorientational motion in fact does occur in the solid state.

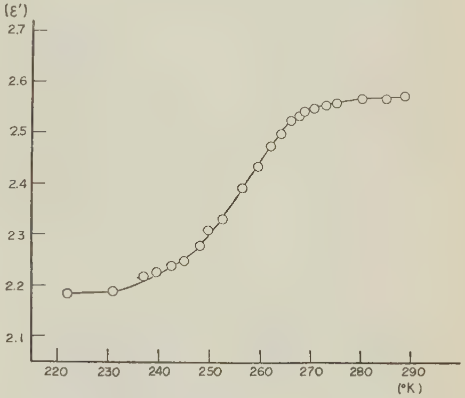

Fig. 5. Dielectric constant ε' of 1, 2, 3-trichlorobenzene *vs.* temperature.

§ 4. Discussions

A. *1, 2, 3-trichlorobenzene*

From the herein described series of experiments, it may be concluded that the reorientational motion occurs around the normal axis of the molecular plane in a temperature range far below the melting point which does not become a complete rotation so long as the substance exists in the solid state. The hindering potential energy of a polar molecule in a solid state depends in general on the magnitude as well as the asymmetry of all the intermolecular forces involved. The effect of various types of crystalline fields on the dipole direction has been considered by Frank[13] and White[14]. In 1940 White et al[15] measured the dielectric properties of hexasubstituted methylchlorobenzenes. They found that these substances possess a more or less restricted rotation freedom for temperatures sufficiently below the melting point. Especially they noticed an abnormal reduction of static polarizability with the decrease of temperature for 1, 2, 3-trimethyl-4, 5, 6-trichlorobenzene. This phenomenon was explained by a model of the hindering potential barrier, which is shown in Fig. 6, in which the reorientational motion occurs from one to another of two equilibrium orientations separated from each other by an angle of 72°C.

Though the methyl radical and proton differ from each other, the symmetry of both molecules is the same. If the analogous model on the hindering potential described above is employed for the analysis of the reorientational motion of 1, 2, 3-trichlorobenzene, the results of the experiments will be explained reasonably—the reorientational motion which occurs from one to another of two equilibrium orientations causes a line broadening of the pure quadrupole resonance spectrum and also causes a dispersion of dielectric constant; this motion can not induce motional narrowing, because the angle between two equilibrium positions is too small to average out the local magnetic fields. From the slope of $\log(\Delta\nu-\Delta\nu')$, W is estimated at 6.0 Kcal/mole under the assumption that $\Delta\nu'$ is independent of the temperature (§ 2). There is, however, also a broadening of the line width due to the molecular oscillation, which was studied by Bayer[16]. This broadening increases with temperature. If this broadening be taken into account, W would become smaller than 6 Kcal/mole. Since the value of 5 Kcal/mole is obtained from the slope of the experimental line in Fig. 2, it can safely be supposed that the height W of the hindering potential barrier lies between 6 Kcal/mole and 5 Kcal/mole. This seems to be reasonable in comparison with the values of 5740 cal/mole and 4610 cal/mole obtained for 1, 2, 3-trimethyl-4, 5, 6-trichlorobenzene.

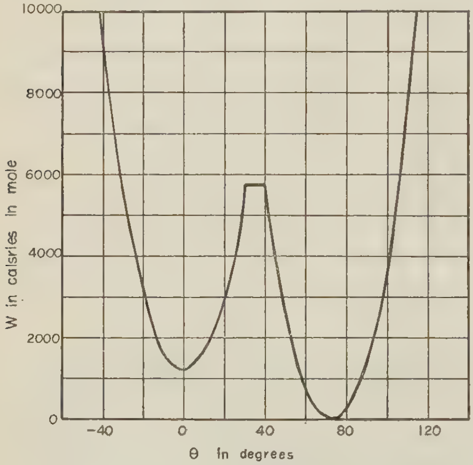

Fig. 6. Potential function assumed for the rotational motion of 1, 2, 3-trimethyl-4, 5, 6-trichlorobenzene. (After White et al[15]).

B. *Hexachlorobenzene*

It is shown through the experiment on the proton magnetic resonance[17] that benzene and hexamethylbenzene reorientate in solid state around a normal axis of the molecular plane. If it is permissible to consider that the hexachlorobenzene is a plane hexagon of carbon atoms, each of which possesses a side-bond chlorine atom in the plane, this molecule can also be considered as a plane hexagon of chlorine. It seems most reasonable, therefore, to associate the broadening of the line width with the six-fold reorientational motion. From the slope of $\log(\Delta\nu-\Delta\nu')$ W is estimated at 12.6 Kcal/mole (§ 2). If the additional broadening of the line width is taken into account, as was done in 1, 2, 3-trichlorobenzene, the reasonable value of W will become $12.6\ \text{Kcal/mole} > W \geqslant 9.9\ \text{Kcal/mole}$. Let it be considered how reliable these values are. Assume that, considering the hexagonal symmetry of the molecule, the hindering potential of the reorientational motion in the solid state has the form

$$V=\frac{1}{2}W(1-\cos 6\theta)\,. \qquad (2)$$

Then the rotational-vibrational frequency is given by

$$\nu_r=\frac{6}{2\pi}\sqrt{\frac{W}{2I}} \qquad (3)$$

where I is the moment of inertia about the axis of hexagonal symmetry. If use is made of the values of $12.6 > W \geqslant 9.9$ Kcal/mole and $I=36.83\times10^{-38}\,\text{gr cm}^2$, ν_r is found to be $1.03\times10^{12} > \nu_r \geqslant 0.91\times10^{12}\,\text{sec}^{-1}$. For polar molecules, the relaxation time τ obtained by the dielectric measurement is given, for any temperature, by

$$\tau=\frac{\varepsilon_\infty+2}{\varepsilon_s+2}\frac{1}{2\pi f_m} \qquad (4)$$

where ε_∞ and ε_s have the usual meanings. f_m is the frequency at which $\varepsilon=(\varepsilon_s+\varepsilon_\infty)/2$. According to the Eyring-Frank theory of an anomalous dispersion, on the other hand, $1/\tau$ is given by

$$\frac{1}{\tau}=\nu_r\exp\left(-\frac{W}{RT}\right) \qquad (5)$$

From the results of dielectric measurements made by White et al.[15] for chlorobenzene derivatives, the temperature at which f_m becomes 1 Kc/s can be estimated as listed in Table I.

Table I. Temperature at which f_m=1 Kc/s, estimated from the experimental results of White et al[15].

Sample	Numbers of Cl	T(°K)
1, 2, 3, 4-tetramethyl-5, 6-trichlorobenzene	2	165
1, 2, 4-trimethyl-3, 5, 6-trichlorobenzene	3	188
tetrachloro-o-xylene	4	203
methylpentachlorobenzene	5	229

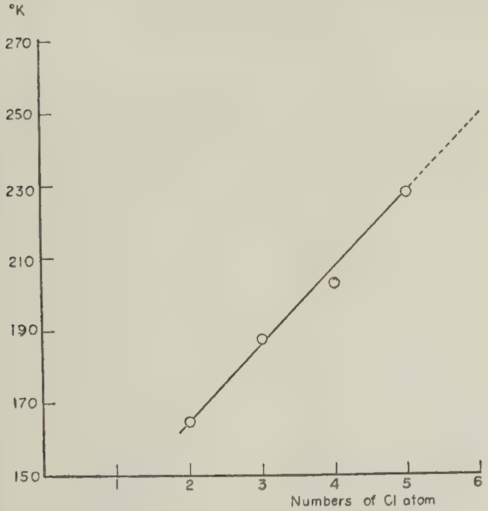

Fig. 7. Temperature T at which f_m=1Kc/s *vs.* number of chlorine atoms.

In Fig. 7 the values of T are plotted versus the number of chlorine atoms in the molecule. There is a remarkable regularity, which was also confirmed for the temperatures at which $\tau=10^{-6}$ sec by White et al.[15].

The temperature for Cl=6 can be determined by extrapolation to be 251°C. From the numerical values given above the value of W can be determined, using Eq. (4), (5) and the relation $(\varepsilon_\infty+2)/(\varepsilon_s+2)=1$ valid for non-polar substances. It becomes $9.41 > W \geqslant 9.33$ Kcal/mole, in good agreement with 9.9 Kcal/mole, the lower limit obtained from the present measurements.

Acknowledgment

The author wishes to express his sincere thanks to Professor Y. Yokozawa for his kind encouragement throughout the course of the present work. He is also grateful to Professor K. Higasi for his useful advices and to Assist. Prof. A. Odajima for his stimulating discussions. Thanks are also due Mr. J. Hori for his valuable criticisms. The present work was supported in part by a Grant of Aid for Developmental Scientific Research in the Ministry of Education.

Electronic Structure of Bismuth Type Crystals, II

By Shoichi Mase

Department of General Education, University of Nagoya

(Received January 8, 1959)

Further study of the electronic structure of bismuth type crystals is made by calculating the energies along some directions in the reduced zone in more detail than in the previous paper, and a discussion is made on the location of electrons and holes in the Brillouin zone. We propose that in the case of bismuth the electrons are located at each centre of upper and lower inclined planes of Jones' zone and the holes are located at a particular point on each cross line of side-planes parallel to the c-axis, while in the case of antimony the electrons are located at the same places as in bismuth and the holes at different places which are defined in the text. On this model some electric and magnetic properties of the metals and alloys are discussed.

§ 1. Introduction

In the previous paper[1] (to be referred to as I), we calculated energy curves along some directions in the wave number space and discussed the relation between the energy bands and the observed values of diamagnetic susceptibility. The calculation was, however, performed only along two directions in the reduced zone. While the electronic properties of bismuth were discussed by Jones[2] basing upon a Brillouin zone which can contain five electron states per atom, Jones' ellipsoids for electrons and holes do not locate at the points equivalent to ours in the reduced zone. Exact knowledge of the energy surfaces is in need in order to see whether existing theories of diamagnetic susceptibility, cyclotron resonance, galvanomagnetic effect and others are appropriate or not to these metals in which considerable anomalies in these properties are observed.

In the present paper, we complement our previous calculation and make clearer on the relation between the energy bands and the electronic properties of the metals and alloys. In section 2, the correspondence between the reduced and Jones' Brillouin zones is discussed. The energy curves in some interesting symmetry directions are also calculated in more detail and it is shown that Jones' location of ellipsoids of electrons and holes is unjustified by our energy band calculation. In section 3, an explanation is given for some experimental results of electronic properties of bismuth, antimony, and bismuth-antimony alloys.

§ 2. Brillouin Zones and Energy Curves

Bismuth crystal has comparatively low symmetry (the space group symmetry D_{3d}^5), but the crystal structure is very similar to that of the simple cubic. It is almost clear that the anomalous properties of bismuth crystal are related to this resemblance, because the first Brillouin zone of the simple cubic lattice contains two electron states per atom while bismuth type metals have five valence electrons per atom. In other words, very small number of conduction electrons with small effective mass should be located somewhere on the zone boundaries which disappear in the case of the simple cubic lattice.

We choose the trigonal axis as z-axis (Fig. 1). The positions of representative atoms of two sublattices are

$$\left.\begin{aligned}
a_0&=(0,0,0)u\,,\\
a_1&=\left(0,\ \frac{\sqrt{6}}{3},\ \frac{2\sqrt{3}}{3}(1+3\omega)\right)u\,,\\
a_2'&=\left(\frac{\sqrt{2}}{2},\ \frac{\sqrt{6}}{6},\ -\frac{2\sqrt{3}}{3}(1+3\omega)\right)u\,,\\
b_2&=\left(\frac{\sqrt{2}}{2},\ \frac{\sqrt{6}}{6},\ \frac{\sqrt{3}}{3}(1+3\omega+3\varepsilon)\right)u\,,\\
b_1'&=\left(0,\ \frac{\sqrt{6}}{3},\ -\frac{\sqrt{3}}{3}(1+3\omega-3\varepsilon)\right)u\,.
\end{aligned}\right\}\tag{1}$$

The primitive translation vectors of the lattice are $\overrightarrow{a_0a_1}$, $\overrightarrow{a_0a_2}$ and $\overrightarrow{a_0a_3}$, then foundamental reciprocal lattice vectors are given by

$$\left.\begin{aligned} \boldsymbol{f}_1&=\left(0,\ \frac{\sqrt{6}}{3},\ \frac{\sqrt{3}}{6}\frac{1}{1+3\omega}\right)u^{-1},\\ \boldsymbol{f}_2&=\left(\frac{\sqrt{2}}{2},\ -\frac{\sqrt{6}}{6},\ \frac{\sqrt{3}}{6}\frac{1}{1+3\omega}\right)u^{-1},\\ \boldsymbol{f}_3&=\left(-\frac{\sqrt{2}}{2},\ -\frac{\sqrt{6}}{6},\ \frac{\sqrt{3}}{6}\frac{1}{1+3\omega}\right)u^{-1}. \end{aligned}\right\} \tag{2}$$

General vector $\boldsymbol{n}$ denoting one of the points of the reciprocal lattice is then given by

$$\boldsymbol{n}=n_1\boldsymbol{f}_1+n_2\boldsymbol{f}_2+n_3\boldsymbol{f}_3\ . \tag{3}$$

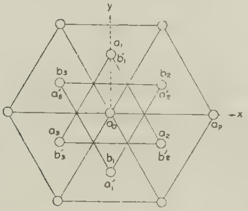

Fig. 1. The lattice structure of bismuth type crystal.

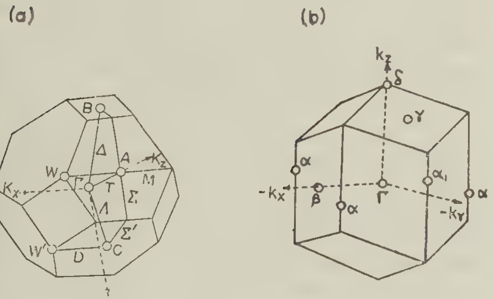

Fig. 2. The reduced zone (a) and the zone which can accommodate five electrons per atom (b).

Fig. 2(a) is the Brillouin zone surrounded by the planes such as (1, 0, 0), (1, 1, 1) and (1, 1, 0). Upper and lower hexagonal faces (the planes (1, 1, 1) and (−1, −1, −1)) and six side hexagonal like faces (the planes such as (1, 0, 0)) disappear in the simple cubic lattice. Fig. 2(b) is the Brillouin zone surrounded by the planes such as (1, −1, 0) (six side planes) and the planes such as (1, 2, 2) (six inclined planes). The latter planes disappear in the simple cubic lattice but the former do not. The points α_1, β and γ in Fig. 2(b) are transformed from the points A, B and C in Fig. 2(a) by the translation vectors given by $\boldsymbol{n}(-2, 0, 0)$, $\boldsymbol{n}(0, -2, 0)$ and $\boldsymbol{n}(0, 2, 2)$ respectively, i.e. these points are given by

$$\left.\begin{aligned} \alpha_1&=\left(0,\ -\frac{2\sqrt{6}}{3},\ \frac{\sqrt{3}}{6}\frac{1}{1+3\omega}\right)\frac{1}{2u},\\ \beta&=(-\sqrt{2},\ 0,\ 0)\frac{1}{2u},\\ \gamma&=\left(0,\ -\frac{\sqrt{6}}{3},\ \frac{5\sqrt{3}}{6}\frac{1}{1+3\omega}\right)\frac{1}{2u}. \end{aligned}\right\} \tag{4}$$

We proposed in I that the electrons occupying the states near the points A and C are responsible for the conduction phenomena of bismuth. While Jones proposed that in bismuth there are energy surface pockets of electrons at β and those of holes at δ. As was expressed already, the structure factor of the planes through β is not zero but two, irrespective of the crystal lattice being simple cubic or rhombohedral. Energy discontinuity should usually be large at such planes and the curvature of the energy curve along the perpendicular direction usually be small.

In Fig. 3 we give the energy curves along some symmetry directions. Fig. 3(a) was obtained with use of the secular equation in I (but by evaluating only few points). Fig. 3(b) and (c) were obtained by solving the secular equations in the case without spin, which were set up with use of the basis functions listed in Appendix. The notation used in the present paper is the same as in

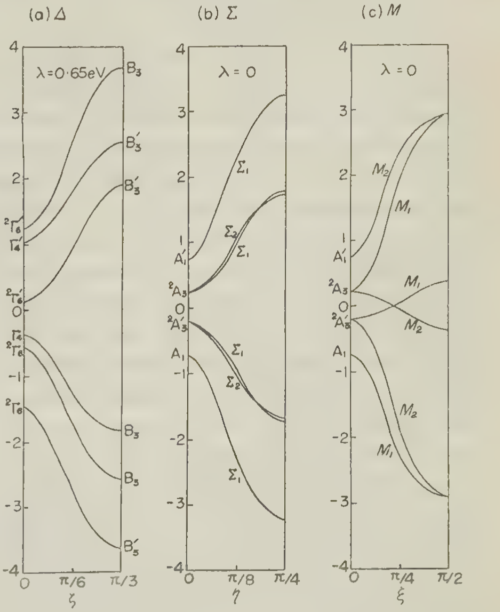

Fig. 3. Energy *versus* $\boldsymbol{k}$ curves along Δ, Σ and and M. The origin of the energy is arbitrary but the same in three cases. (Units ev).

I. The lattice parameters, energy integrals and others are taken the same as in I, i.e.

$$\left.\begin{array}{ll} \omega=0.0173\ , & \mathcal{E}=0.0548\ , \\ (pp\sigma)=1.1\,\mathrm{ev}\ , & (pp\pi)=-0.35\,\mathrm{ev}\ , \\ r_1=3\ , & r_2=6\ . \end{array}\right\} \quad (5)$$

The magnitude of the spin-orbit interaction parameter λ is shown in each figure. As was expected, the energy at β is far from the Fermi surface. In the case of $\lambda=0$, the energy curves along Σ are also far from the Fermi surface except in the immediate neighbourhood of the point A. This result may be unchanged even in the case of $\lambda \doteqdot 0$. Then we would have no interest in the present study, but it is not so along the line M. Without spin the bands M_1 and M_2 cross, but this crossing is got rid of by the spin-orbit interaction and the two bands are separated (see Table II (e) in I). This separation is small if λ is small. The energy curves along Σ' and D should be very similar to those along Σ and M respectively. If the electrons or holes are located somewhere on the lines M or D, we must consider six ellipsoids. If the maxima exist slightly in the zone, we have twelve ellipsoids.

We see the shift of the energy curves due to the change of the magnitude of λ. Since the lattice constants of bismuth and antimony are nearly equal (see Wilson: *The Theory of Metals* (1953) p. 63), the crystal field in the intermediate region of lattice points may not be modified so largely by alloying antimony in bismuth. The largest change in the crystal field should be the decrease in the average of the spin-orbit interaction energy. Although bismuth-antimony alloy is a disordered alloy, we will substitute the crystal potential of a disordered alloy by an average periodic potential, i.e. we neglect the dimness of the energy band due to the random distribution of atoms. Then we can to some extent express the effect of the alloying by the decreasing of the magnitude of λ, so far as we are interested in only the band shape. We show the result in Fig. 4. By decreasing the value of λ, the level $A_4'+A_5'$ goes down drastically but the level ${}^2A_6$ is almost constant, while the levels C_3+C_4 and $C_3'+C_4'$ go down more slowly than the level $A_4'+A_5'$. The energy gaps at A and C increase gradually.

§ 3. Discussion

On the present calculation together with the previous one we suppose that the electrons in bismuth may be located near the point γ (i.e. the point C), while the holes may be near the point α (i.e. A). This supposition is not in accord with Jones' speculation. In order to confirm our supposition, we will examine further whether our theory can explain various electronic properties relating to the energy surfaces.

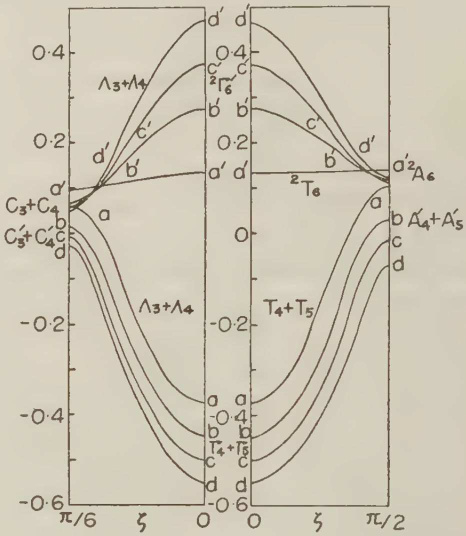

Fig. 4. Energy *versus* **k** curves. a, a′: $\lambda=0.65$ ev, b, b′: $\lambda=0.5$ ev, c, c′: $\lambda=0.4$ ev and d, d′: $\lambda=0.3$ ev. The origin of the energy is the same as that of Fig. 3. (Units ev).

As is known from early, the electrical conductivity, Hall coefficient, thermal conductivity, and thermoelectric power of bismuth-antimony alloy at room temperatures have respective extremum at the composition of about 16 atomic % antimony[3]. The diamagnetic susceptibility of this alloy changes monotonically with the concentration of antimony in the experiment up to 6 atomic %[3]. Recently Tanuma[4] studied these properties from the liquid helium to room temperatures and found similar behavior as in usual semiconductors in a certain range of the concentration of antimony. This behavior can be explained as follows. In the case of bismuth, the location of the electrons and holes was specified above. By alloying antimony having small value of the spin-orbit coupling parameter, the energy level $A_4'+A_5'$ at A gradually goes down relatively to the energy level C_3+C_4 at C. At some small percentage of antimony, the electrons at C and also the holes at A will be completely depleted and then various properties should become semiconductor like* (see the case of $\lambda=0.5$ ev in Fig. 4). By further alloying of antimony, the alloy will again become metallic, since pure antimony is a metal. For the alloy there are two possibilities of recovering metallic nature. One is that somewhere on the line M or D an unoccupied level M_3+M_4 or D_3+D_4 goes down under the level $C_3'+C_4'$ at C. Then the electrons at $C_3'+C_4'$ transfer into the level M_3+M_4 or D_3+D_4, i.e. the holes are produced at C. The other is that on the contrary to the above an occupied energy level on the line M or D is raised up relatively to the unoccupied level C_3+C_4 at C. Then the electrons at M or D transfer into the level C_3+C_4, i.e. the electrons are produced at C. As was already expressed, the levels C_3 and C_3' go down with the decrease of the value of λ. Then the former level becomes more favourable to be occupied by electrons and the latter becomes, on the contrary, more unfavourable to be occupied by holes. This result makes us prefer the second possibility. A natural deduction for the way of the moving of the energy levels in the alloying process is then that the extremum at or in the immediate neighbourhood of the point A moves away along the line M. The height of six or twelve maxima may be comparatively unmoving during this process (because of the crossing of two levels in the case of $\lambda=0$) and at a certain concentration (not so far from 16 atomic %) of antimony, the height of the extrema may again be raised up relatively to the level C_3. Thus, purely semiconductive region with a energy gap between the level C_3 and the maxima on the line M, even if possible, will be restricted in certain narrow range of the concentration of antimony and its energy gap should also be very small. We cannot rule out the possibility that the maxima do not go down under the level C_3, i.e. that there is no energy gap in any concentration, according to the following: If we assume the values of λ in bismuth and antimony to be 0.6 ev and 0.3～0.4 ev respectively and λ of this alloy to be that given by the ratio of the concentration, necessary quantity of antimony to deplete the electrons and holes at C and A is estimated to be more than 12～18 atomic %. This number is approximate, of course, but this result together with the experimental data of the electrical conductivity of the alloy at low temperatures⁴⁾ are rather favourable for this view.

The absence of the de Haas-van Alphen effect due to holes in bismuth remains unexplained. Our theory predicts that the energy surface near the point A has well defined effective mass and the magnitude of the effective mass is favourable order to observe the de Haas-van Alphen effect, if this part is the only energy surface of holes. This prediction is, however, not supported by experiments. Recent experiment of cyclotron resonance in bismuth⁵⁾ reports that there are majority carrier to be corresponded to the de Haas-van Alphen electrons and minority carrier with isotropic energy in the trigonal plane, and other broad lines in higher magnetic field region and comparatively narrow lines in lower field region which may be attributed to subharmonics of the minority carrier peak. Then we would modify a little the band structure near the point A as follows: The point A or slightly lower point is occupied by the minority carrier and along the line M six warped majority carrier surfaces are distributed in the immediate neighbourhood about the minority carrier surface. The former is minority holes with very small definite mass in the trigonal plane and the latter is majority holes which may have vaguely defined larger mass. This supposition of warped surfaces is not based upon the calculation, but is plausible according to Fig. 3(c). In high temperatures (for example above the liquid air temperature) or in samples having large excess of holes, this separation into seven hights is immaterial and the holes will behave like single surface with isotropic mass in the trigonal plane. This view is well suited to fair successes of Abeles-Meiboom's analysis⁶⁾ for galvanomagnetic effect and Lax *et al*'s analysis⁷⁾ for the cyclotron resonance data by Galt *et al*⁸⁾ and also to the experimental results of the de Haas-van Alphen effect and the cyclotron resonance mentioned above.

---

* Some interesting results on the deviation from typical semiconductor due to the random distribution of atoms or due to very slight overlapping of energy bands are reported by Tanuma (reference 4).

In the case of antimony, only one type of the de Haas-van Alphen period due to the energy pocket at C is observed. In order to fit this observation we consider that the hole energy surfaces on or near the line M will be warped surfaces or those with small curvature. Since, however, the energy separation between occupied and unoccupied bands should be fairly small on this line and the Hall coefficient of pure sample is positive, we must rule out the second possibility. In arsenic the situation may be very similar to that of antimony as deduced from Figs. 3 and 4. In this case, however, the overlapping is more pronounced and the Fermi level may pass just on the level ${}^2A_6$. Then we suppose that the long period in arsenic is due to the minority electrons.
